Alteration of basalt glasses: implications for modelling the long-term stability of nuclear waste glasses

The long-term stability of nuclear waste form borosilicate glasses must be predicted from extrapolations of short-term laboratory data and then verified, which is only possible by comparing the glasses with their natural analogues of geological age. Here, we suggest that basalt glasses are useful analogues for predicting the long-term behaviour of nuclear waste form borosilicate glasses. Previous workers[1–11] have considered the possibility of using natural glasses as analogues, but our study is a direct comparison of the experimentally studied corrosion products of basalt glasses, their natural long-term corrosion products and those of borosilicate glasses. Observations on the alteration processes for natural basalt glasses are combined with the experimental data on the alteration of basalt glasses and borosilicate glasses and are used to generate radioactivity release curves for nuclear waste form borosilicate glasses using the QTERM computer code[12–15]. Our data on natural glasses place significant constraints on the anticipated fraction of activity released; major differences between our two release curves do not occur until after 1,000 years.

Hydrothermal leaching experiments were completed on three glasses: two basalt glasses (KL 9 and 11) from Kilauea, Hawaii ($SiO_2 = 50$ wt%, 24 kyr old) and a simulated borosilicate nuclear waste glass, C-31-3EC-SPF-Na ($SiO_2 = 35$ wt%). We report here the results of experiments at 200 °C in saturated synthetic NaCl solution for 30 days. The basalt glasses were remelted before leaching and their chemical composition determined by electron probe analysis (EPA) (Table 1). The compositions of the surface layers and solutions were determined by optical emission spectroscopy (ICP) and the surfaces examined by scanning electron microscopy. The compositions of a basalt glass and its palagonite surface layer (deep-sea dredge sample, USNM 113715, from

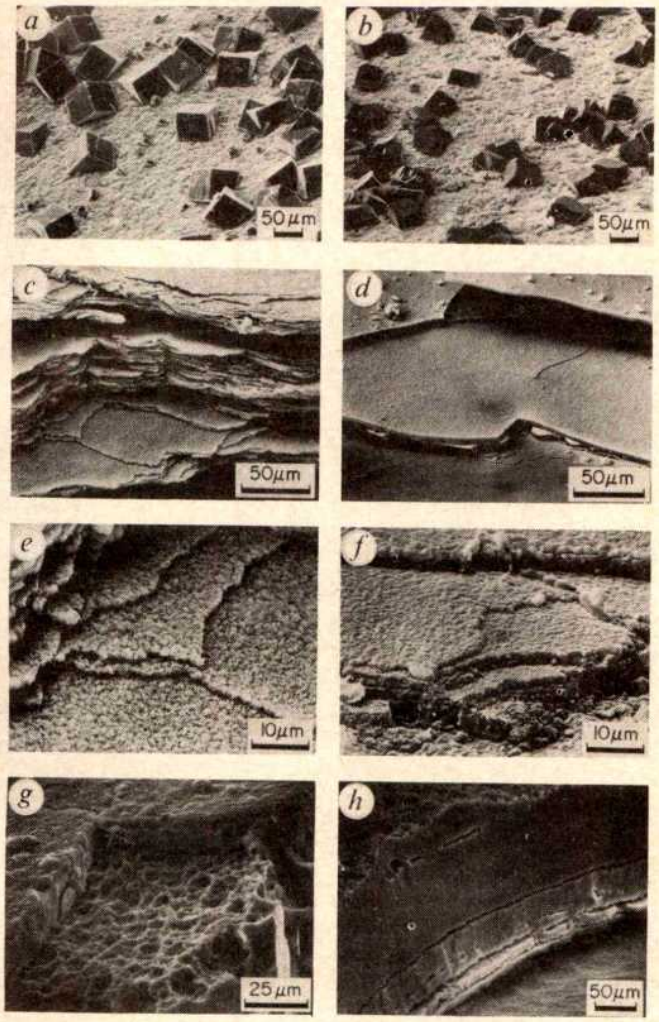

Fig. 1 Scanning electron micrographs of surface of basalt glass, KL 11, (*a*, *c*, *e*) and borosilicate nuclear waste glass (*b*, *d*, *f*) leached in saturated synthetic NaCl solution at 200 °C for 30 days. Dredge sample of basalt glass, USNM 113715, (*g*, *h*), altered in sea water at ~3 °C.

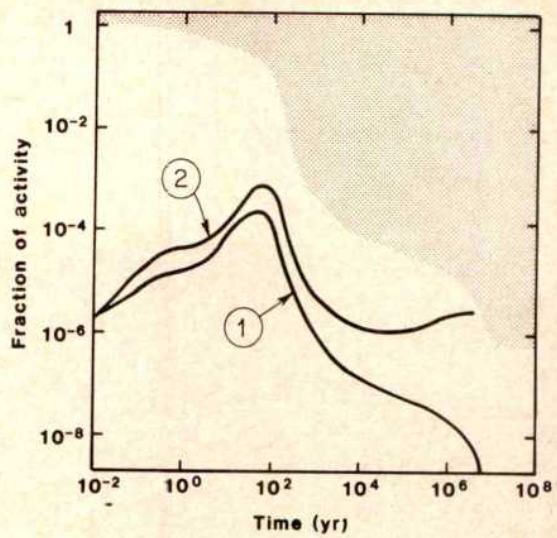

Fig. 2 Fraction of activity inventory released from the glass at any time (radioactive decay and thermal history of the waste form, with maximum temperature of 90 °C, included in the calculation of the curves). Case 1 is for parabolic time dependence; case 2 is for linear time dependence.

the Mid-Atlantic Ridge near the Kane Fracture zone, 2889–2475-m depth) are listed in Table 1 for comparison with our experimental results. This basalt glass is almost identical in composition to the normal Mid-Ocean Ridge Basalt (MORB) and the surface layer is similar to the 'average' palagonite cited by Staudigel and Hart (Table 2 of ref. 16). The dredge sample was altered by natural processes at low temperatures (~3 °C) in contact with sea water.

The most striking evidence for the similarity in the corrosion behaviour of basalt glass (KL 11) and waste form borosilicate glass (C-31-3-EC) is shown in the series of scanning electron micrographs (Fig. 1). In both cases, isometric analcime crystals were formed as surface precipitates (Fig. 1*a*, *b*). At higher magnifications, the repetitive sheet-like structures are apparent for both (Fig. 1*c*, *d*) and, at the highest magnification (Fig. 1*e*, *f*), each sheet is covered by a mat of crystal rosettes (probably clay). More importantly, a similar multiple surface layer structure (Fig. 1*e*, *f*) is common in naturally altered (~3 °C, sea water) basalt glasses (Fig. 1*g*, *h*). The same type of surface morphology on naturally altered basalt glasses has been well illustrated in previous studies[8,17,18].

The chemical similarities in the corrosion process are summarized in Tables 1 and 2. Table 1 compares the concentrations of major constituents of surface layers with the corresponding unaltered glass for basalt glasses, a borosilicate glass and a basaltic glass dredge sample. Note that in Table 1 we report only major constituents for comparative purposes (additional constituents are indicated in the footnotes). For this reason the totals of the analyses are not given, but we assume that the most important component that would bring the analyses to almost 100% is structural water. For example minerals such as vermiculite (an identified phase in surface layers) have water contents as high as 20 wt%. Although it is not possible to give totals for the analyses (because of the undetermined water content), their veracity is confirmed by mass-balance calculations (Table 2). All surface layers show depletion in SiO_2 and CaO, alumina (Al_2O_3) concentrations are approximately constant and there are increases in the concentrations of TiO_2, FeO, MnO and Na_2O in the surface layers. For the experimentally corroded glasses, the basalt glass and borosilicate glass behave similarly in terms of the amount of altered glass (as determined by weight loss and solution chemistry) and calculated depth of reaction (Table 2). For all glasses, surface layer formation is related to glass composition. The higher the ratios of Mg, Al, Fe and Ti to Si in the glass, the higher is the fraction of the surface layer relative to the total reacted glass (Table 2). The mass balance of the solution analyses and the surface analyses can be evaluated by comparing the total amount of altered glass (weight loss measurement with surface layer removed) with the sum of the altered material in the surface layer (weight measurement of surface layer) and the principal elements found in solution (SiO_2, Al_2O_3 and CaO). The data (Table 1) on the naturally altered basalt glass are used to illustrate the degree to which the experimental results of rather short-term experiments (30 days) match those for alteration processes and products of natural basalt glasses of much greater age. Our results for a naturally altered basalt glass are similar to those reported elsewhere[19–23]. There are, however, variations in the observations made among natural basalt glasses that are due to the variety of conditions, time periods and processes of alteration (see particularly Table 1 of ref. 23).

Finally, if the alteration processes and products of natural basalt glasses are satisfactory analogues of what one expects for the long-term alteration of borosilicate glasses, can this information be used to generate (or verify) models used to predict the behaviour of borosilicate glasses? Figure 2 illustrates this application by using the QTERM code (described in refs 12–15) to generate the fraction of radioactivity released for two test cases. The boundary of the shaded area in the upper portion of the figure represents the decay of the radionuclides in the canister and marks the maximum fraction of released activity if there were no borosilicate glass waste form and all activity

were released immediately on contact with water. The experimental data for both cases are taken from data published by the joint research project of Japan, Switzerland and Sweden[24] where a radioactive glass with an SiO_2 content of 45 wt% was used. Experiments were performed in water at 90 °C following the MCC-1P test procedure[25]. The complete composition and experimental conditions are summarized elsewhere[24]. Data are available for up to 182 days. The essential questions are what model of corrosion is applicable, and how widely will results vary as a function of the model selected? In case 1, the time dependence is assumed to be parabolic, $t^{1/2}$ (refs 26, 27), where the most important consideration in the corrosion of the waste glass is the formation of a 'protective' layer that then becomes a diffusion barrier to further release. Beyond the 182-day database, we have continued the parabolic time dependence which has been used to describe the hydration of rhyolitic glasses[28]. In case 2, the time dependence is linear, t^1, based on the analysis of Si and B data[24], assuming an initial first-order dissolution reaction for the glass with silica approaching saturation. Between 28 and 182 days, glass corrosion proceeded at a low but constant rate as indicated by boron release. Beyond the 182-day database, we have continued the linear time dependence, as required in describing the formation of palagonite rinds on basalt glasses[29]. The latter case is the most conservative (maximum) estimate of the released activity. The curves for cases 1 and 2 are only illustrative (as the temperature dependence of palagonitization of natural basalt glass and the alteration of waste glasses is still under investigation), but they do provide us with important examples of time-limited experimental data combined with information derived from the alteration of natural glasses over long periods of time.

Three important points may be made. (1) Depending on the model used to extrapolate the long-term release of radionuclides, there are wide variations in the fraction of released activity (for example, at 10 kyr, an order of magnitude). (2) There is little difference between the two cases in the fraction of activity released during the first 100 yr, but afterwards there is an increasing difference. At 1 Myr, for case 2, there is little difference between the fraction of activity released and the total fraction of remaining activity due to radioactive decay (the intersection of the release curve with the shaded area), whereas at 1 Myr, for case 1, the waste form is still able to reduce the fraction of activity released by two orders of magnitude. (3) Data on naturally altered basalt glasses (that is, time dependence of corrosion, role of layer formation in release of elements and identification of stable phases in the precipitates) can be used in presently available release codes (QTERM). The use of the appropriate natural analogue is of immense value in designing and verifying release codes over long periods of time.

Flow law for ice in polar ice sheets

C. S. M. Doake & E. W. Wolff

British Antarctic Survey, Natural Environment Research Council, High Cross, Madingley Road, Cambridge CB3 0ET, UK

Theories of glacier flow are based commonly on the assumption that ice is not a newtonian fluid, but has a non-linear stress-dependent viscosity[1-5]. Here we re-examine the spreading of Antarctic ice shelves and suggest that the data cannot define a unique flow law. Tilt measurements in four boreholes in both the Arctic and Antarctic seem to show that a linear flow law $\dot{\varepsilon} = A_1\tau$ (where $A_1 \sim 10^{-15}\,s^{-1}\,Pa^{-1}$ at $-28\,^{\circ}C$), where $\dot{\varepsilon}$ is the effective strain rate and τ the effective shear stress, may be just as appropriate for describing the flow of polar ice sheets.

Conventional flow laws for ice are written as[3] $\dot{\varepsilon} = A_n\tau^n$. A_n is often assumed to be modelled adequately by an Arrhenius temperature dependence, $A_n = A_0 \exp(-Q/RT)$, where Q is the activation energy, R the gas constant and T the absolute temperature. To allow for a possible pressure dependence, T is referred to the *in situ* melting point. A_0 is assumed to include the effects of parameters that describe variations in flow, such as grain size, ice fabric and impurity content. According to laboratory experiments, the exponent n can range from 1 at low stresses (below $\sim 10^4$ Pa) to 4 or even higher at stresses $> 10^5$ Pa (ref. 6), in agreement with field data for borehole closure[7], where $n = 3$ was found for $\tau = 2 \times 10^5$-10^6 Pa, although these latter data may include a large component of transient creep.

The stresses that are important for ice-sheet flow, however, lie in the range 10^4-10^5 Pa. Data from spreading of ice shelves have been interpreted[8] as showing that, in this stress range, n is ~3, which is now the generally accepted value, although Whillans[9], using an empirical formulation of the flow law derived from tilting of boreholes, found the stress exponent varied between 1 and 2. Low values of n at low stresses have been explained as the effects of transient creep. Paterson[3,10], reviewing laboratory and field data, has shown that there is a large spread in experimental results, such that under similar conditions strain rates may vary by more than an order of magnitude; but by selecting measurements thought to be most reliable, he could recommend[3] values of $n = 3$, $Q = 60$ kJ mol^{-1} and $A_3 = 5.2 \times 10^{-25}\,s^{-1}\,Pa^{-3}$ at $-10\,^{\circ}C$. Further analysis of borehole data has revealed that Holocene ice in both Greenland and Antarctica was ≤ 20 times softer than expected from ice-shelf spreading data[10]. We have attempted to reduce this discrepancy by re-examining ice shelf and borehole data from several sites, without assuming *a priori* that $n = 3$. We have not attempted to determine a flow law in the rheological sense, but only to find those values for the above parameters that give the best agreement with the field results.

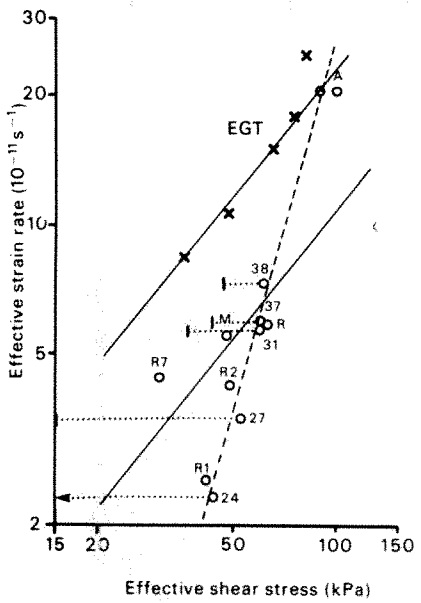

Fig. 1 Plot of effective strain rate against effective stress for ice-shelf sites[8] (A = Amery; M = Maudheim; R = Ross; R1, R2, R7, 24, 27, 31, 37, 38 = Brunt), with an $n = 3$ line (dashed). Error bars show the possible influence of the restraining force from MacDonald Ice Rumples. Solid line is an $n = 1$ line that falls within the error bars. The uppermost line and crosses are for Erebus Glacier Tongue[11].

Ice-shelf data (strain rates and ice thickness) were used by Thomas[8] for sites selected to conform as closely as possible to the ideal of an unbounded ice shelf. Being unable to measure the stress field directly, he calculated the effective shear stress averaged over depth by assuming that there was no restraint by lateral shear at side walls and ice rises and that the only longitudinal restraint was by sea water pressure acting along the direction of the maximum principal strain rate. Figure 1 shows the effective strain rates plotted against effective shear stresses. Thomas[8] stated that a flow law with $n = 3$ fitted the data. Not only were all the sites constrained laterally to a greater or lesser extent, thus giving lateral shear restraint, but also the Brunt Ice Shelf sites, which are the main constraint on the $n = 3$ line, were influenced by MacDonald Ice Rumples. Using his derived flow law, Thomas[8] calculated a significant restraining force exerted by MacDonald Ice Rumples on Brunt Ice Shelf. Although for more distant sites the direction of the force is almost perpendicular to the direction of the maximum principal strain rate and may therefore be considered to have been accounted for by the lateral strain rate, there could still be a lateral shear restraint. Because of this uncertainty in describing the stress field, we show in Fig. 1, for the relevant Brunt Ice Shelf site, error bars on the effective shear stress whose magnitudes are derived from Thomas's plot of restraining force against distance from MacDonald Ice Rumples[8]. The linear flow law line $\dot{\varepsilon} = A_1\tau$, which passes through the data from Maudheim and Ross Ice Shelf, lies well within these error bars.

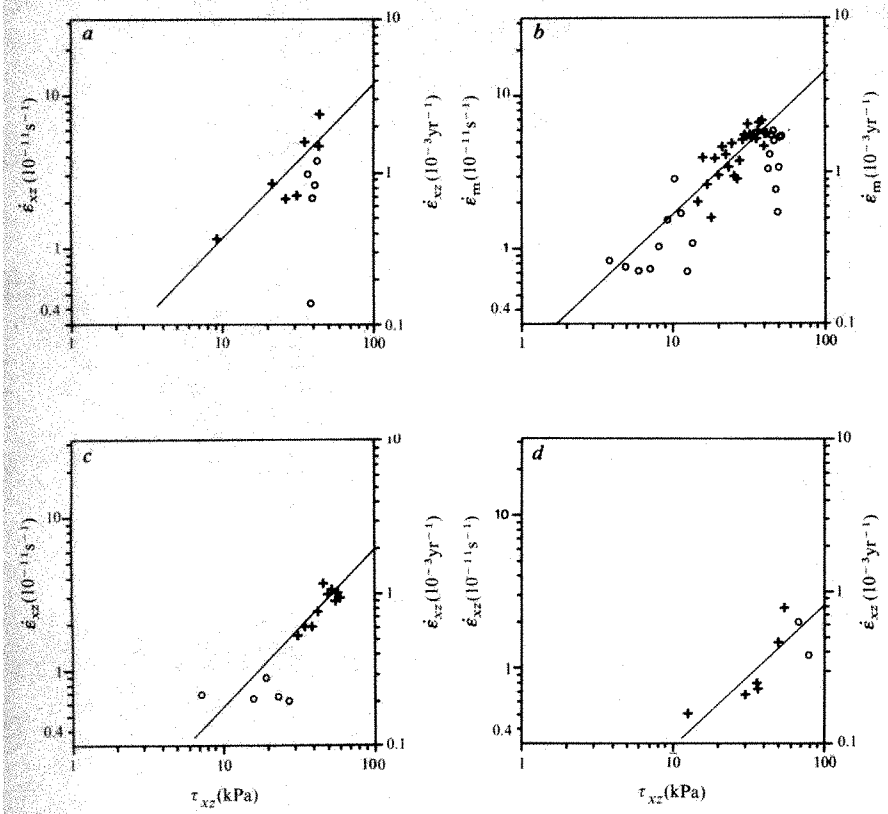

Fig. 2 Logarithmic plots of $\dot{\varepsilon}_{xz}$ against τ_{xz} from the tilting rate of boreholes. *a*, Camp Century; *b*, Byrd Station; *c*, Devon Island; *d*, Law Dome. The Byrd Station and Law Dome data are corrected as described in the text. Data used in the regression are marked as crosses, the rest as circles and the line of best fit is shown.

Erebus Glacier Tongue (EGT) is perhaps a closer approximation to an unbounded ice shelf. Holdsworth[11] interpreted its spreading by assuming that $n = 3$, and he was forced to postulate large variations in the value of A_3. We have plotted these data on Fig. 1. With the exception of the point of highest stress, which is only 2 km from the hinge line and where the velocity field (and therefore strain rate) is uncertain, the points fall closely on a line with $n = 1$. At the mean estimated temperature of −13 °C, the value of A_1 is 2.6×10^{-15} s^{-1} Pa^{-1}. In summary, it seems that, because of the uncertainty in the stress fields, the ice-shelf data cannot be used to determine a unique flow law, although the ice shelf that is closest to being unbounded is that which most strongly suggests a linear law.

Tilt measurements have been made over several years to near bedrock at Camp Century[10,12] in Greenland and Devon Island[13] in Arctic Canada, and for about the top 70% of the ice thickness at Byrd Station[10,12] and Law Dome[14] in Antarctica. Paterson[10] has plotted a restricted data set for Camp Century and Byrd Station on a logarithmic plot of $\dot{\varepsilon}_{xz}$ against τ_{xz} where the axes x, y, z define a rectangular coordinate system, x is the direction of flow and z is vertically downwards. He obtained a reasonable fit to curves computed using $n = 3$, but only when using a value of A_3 15–20 times that previously recommended. But for these few scattered data an equally good or better fit is obtained if curves are computed using $n = 1$. In Fig. 2*a*–*d* we have plotted for the four sites all the data, referred to a temperature of −28 °C, using an activation energy of 60 kJ mol^{-1}.

For Camp Century and Devon Island, we have simply plotted the temperature-compensated $\dot{\varepsilon}_{xz}$ against τ_{xz}, but for Byrd Station, flow in the upper part of the hole can be perpendicular to the surface gradient and in Fig. 2*b* we used, following Paterson[10], a resolved strain rate $\dot{\varepsilon}_m = (\dot{\varepsilon}_{xz}^2 + \dot{\varepsilon}_{yz}^2)^{1/2}$. The reason for the spiralling flow at Byrd is unknown, but it seems reasonable to follow earlier investigators in assuming that the flow, in whatever direction, is driven ultimately by shear stresses related to the surface slope. For Law Dome, laboratory measurements have been made[14] of the relative softness of ice from different depths. Because the relevant experiment used strain rates determined at a given stress and temperature, it does not rely on the assumption of any flow law. The variations in softness were related to ice fabric and were reported as enhancement factors (f) between 1 and 4. In Fig. 2*d*, we have plotted $\dot{\varepsilon}_{xz}/f$ compensated to −28 °C, to remove, where possible, variations in flow resulting from factors other than stress dependence; the two highest stress points were obtained from an extrapolation of strain rates to bedrock, assuming zero basal velocity[14].

As we have allowed for temperature change, we might expect the data in Fig. 2 to fall on a straight line with gradient n, the flow law exponent. Quasi-linearity (that is, gradient = 1 on this plot), however, would be observed for a power law in regions where longitudinal stresses dominate. Therefore, in our regression analysis to find the best value of n, we have discarded all data above the greatest depth (for each site) at which the resolved longitudinal strain rate (taken as the measured surface value, Table 1) is greater than $\dot{\varepsilon}_{xz}$ (or $\dot{\varepsilon}_m$). Following Paterson[10], we have included neither the data for Wisconsin ice, as its flow could be affected by other factors, nor the two extrapolated points at Law Dome. Regressions on the remaining data (shown by crosses in Fig. 2) gave n values of: 1.04 for Camp Century, 0.93 for Byrd Station, 1.03 for Devon Island and 0.8 for Law

Table 1 Measured surface longitudinal strain rates

		Camp Century[10]	Byrd Station[10]	Devon Island[16]	Law Dome[17]
Strain rates (10^{-4} yr^{-1})	$\dot{\varepsilon}_{xx}$	2.6	4.4	6.7	2.3
	$\dot{\varepsilon}_{yy}$	0	1.4	0.2	5.7

Table 2 Values and ratios of A_1 for ice shelves and boreholes (at −28 °C)

	Erebus Glacier Tongue	Camp Century	Byrd Station	Devon Island	Law Dome
A_1 (s^{-1} Pa^{-1})	4.8×10^{-16}	1.5×10^{-15}	1.4×10^{-15}	5.4×10^{-16}	2.1×10^{-16}
Ratio:	1	3	3	1	0.4

Law Dome has been corrected for laboratory measured enhancement factors; the value and ratio should be doubled to be compared with other sites.

Dome. Equivalent analyses using an activation energy of 40 kJ mol^{-1} give similar results, with n between 0.95 and 1.2 for the four sites.

Our results must be qualified because the difficulty in making accurate inclination measurements means that, generally, tilt data are of fairly poor quality, especially in the upper part of the borehole. Regressions through even the deeper data, however, would still give $n \ll 3$. This, together with the fact that all four boreholes suggest the same result, indicates that random errors in the poor quality data have not influenced the result unduly. In the upper layers of an ice sheet there may also be a component of transient creep resulting from the steadily increasing shear stress as the ice moves downwards, but this will also be a feature of the flow of the ice sheet as a whole, and is therefore a factor which a realistic analysis should not exclude.

Our second method of analysis allows explicitly for the effect of longitudinal stresses. For each datapoint we have calculated the value of the flow-law constant A_n normalized to a given temperature (−28 °C) by

$$A_n = \left(\frac{\dot{\epsilon}_{xz}}{\rho g \alpha z}\right)^n \exp\left[\frac{Q_n}{R}\left(\frac{1}{T}-\frac{1}{T_0}\right)\right] \Big/ E^{n-1} \qquad (1)$$

where n is the stress exponent (either 1 or 3), $\dot{\epsilon}_{xz}$ the vertical-shear strain rate, ρ the density, g the acceleration due to gravity, z the depth, α the surface slope, Q_n the activation energy, $T_0 = -28$ °C and E^2 the second invariant of the strain-rate tensor. Local variability in the values of A results from unmodelled factors such as grain size, fabric or impurities. The general trend for all sites, however, is of a constant value of A_1 for a linear law, with the average A_1 in the top half of each hole very close to that found in the bottom half. Alternatively, for a power law ($n = 3$), A_3 shows a consistent decrease with depth over several orders of magnitude. If a power law had been most appropriate at all depths, the trend should have been for a constant value of A_3 and an increasing value of A_1 with depth.

If we assume a linear law applies, then values of A_1 averaged over depth are given by the gradient of plots of $\dot{\epsilon}_{xz}$ against τ_{xz} on linear axes. Using the same data as before gives the values in Table 2; a value for Erebus Glacier Tongue is also given, corrected to a temperature of −28 °C using an activation energy of 60 kJ mol^{-1}. The values agree to within a factor of four, compared with the factor of 15–20 needed by Paterson[10] to reconcile borehole and ice-shelf data using a power law with $n = 3$.

Another way of comparing flow laws is to consider horizontal velocity profiles with depth. These are obtained by integrating the measured borehole shear rates downwards from the surface to the lowest point at which they were measured. If the surface velocity is known, then an upper bound can be placed on the resulting deformation in the lowest unmeasured layers. At Byrd Station, extrapolating the average value of A_1 to the bed and using a linear law suggests a sliding velocity of 1.4 m yr^{-1}, which is reasonable because of the water at the bottom of the borehole[15]. Using $n = 3$ and the average value of A_3 calculated for the last 250 m of measured tilting gives a negative velocity at the bed. There must be another reduction in A_3 (by an order of magnitude) for the basal velocity to be zero. At Law Dome, to avoid negative basal velocities calculated using $n = 3$, Russell-Head and Budd[14] suggested that shear stresses reached a maximum at two-thirds depth and then decreased towards the bed. This postulate is unnecessary with $n = 1$, where values of A_1 can be extrapolated to the bed to give zero velocity there.

For all four boreholes, a linear law gives overall a more coherent explanation of the data and one which agrees better with ice-shelf data. If $n = 3$ were the correct rheological exponent, then such large variations in A_3 would be required (with depth and site) that the flow law would cease to have any predictive value. We conclude that on evidence available at present it is not necessary to use a non-linear flow law to describe the flow and deformation of polar ice sheets.

We thank all those who have criticized and commented on earlier versions of this paper.

Sulphate sequestered in the sulphate-binding protein of *Salmonella typhimurium* is bound solely by hydrogen bonds

J. W. Pflugrath & F. A. Quiocho

Department of Biochemistry, Rice University, Houston, Texas 77251, USA

An important question in understanding substrate binding by proteins is how charged groups are stabilized in the absence of their solvation shell. We have addressed this question here by solving the structure of the sulphate-binding protein of *Salmonella typhimurium* with bound substrate at 2.0 Å resolution. The results are remarkable in that the charged oxygen atoms of the sulphate molecule, which is buried and completely inaccessible to the solvent, are not stabilized by the formation of salt-bridges but by hydrogen bonds donated by specific residues of the protein. These hydrogen bonds are in turn coupled via peptide units to several resonating hydrogen bonding systems. These findings may be of general significance for the role of electrostatic interactions in protein structure and function.

In addition to the sulphate-binding protein, we have recently refined the molecular structures of three other binding proteins specific for L-arabinose[1], D-galactose and Leu, Ile or Val (N. K. Vyas, M. N. Vyas, J. S. Sack and F.A.Q., unpublished data; see also refs 2, 3). These periplasmic proteins, with dissociation constants of ~10^{-6} M, belong to the family of proteins which act as initial receptors for active transport systems and chemotaxis in bacteria[4]. All four structures are ellipsoidal and composed of two similar globular domains connected by a flexible hinge.

The tertiary structure of the sulphate-binding protein at *p*H 4.3, which consists of 2,570 non-hydrogen atoms from 308 residues, 1 sulphate and 143 ordered water molecules, was refined by the method of Hendrickson and Konnert[5] to an *R*-factor of 0.14 for the 16,959 reflections from 8 to 2.0 Å. The refined structure differs from ideal bond lengths and angle distances by overall r.m.s. deviations of 0.015 Å and 0.038 Å, respectively. A more detailed description of the structure determination and protein conformation will be presented elsewhere.

Figure 1 shows the location of the binding site and Fig. 2 and Table 1 illustrate the precise details of sulphate binding. The sulphate is buried in the cleft ~7 Å below the protein surface and becomes completely inaccessible to the solvent; none of the 73-Å^2 accessible surface area[6] of the free sulphate is exposed. There are no positively charged residues, cations or water molecules within van der Waals' distance of the sulphate, thus precluding the formation of salt-bridges to neutralize the charged sulphate. Instead, all of the sulphate oxygens are the recipients of hydrogen bonds from seven residues distributed

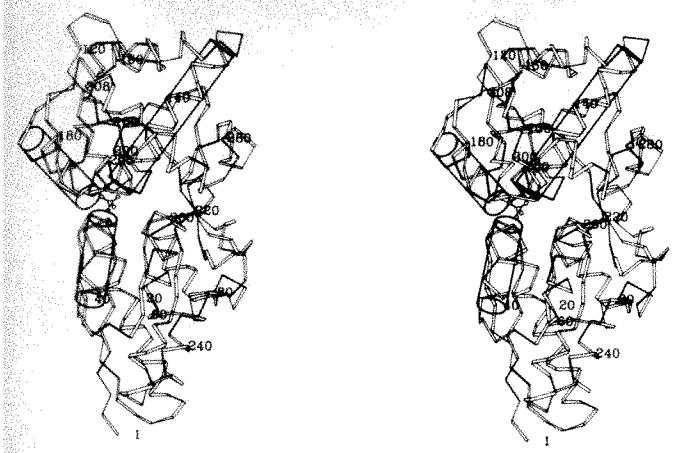

Fig. 1 Stereo view of the Cα backbone trace of the sulphate-binding protein, with the sulphate bound in the cleft between the two domains. The sulphate is shown in a ball-and-stick model and the three helices (44–54, 131–146, 172–181) close to the sulphate are further enclosed in cylinders. The residues hydrogen-bonded to the sulphate originate from both domains: the N-terminal domain supplies Asp 11 and Ser 45 and the C-terminal domain provides Ser 130–Gly 131–Gly 132–Ala 133, Ala 173 and Trp 192. Because of four likely changes to the published sequence of 310 residues[15] as a result of the present refinement, the sequence numbering scheme used in this study is based on the refined structure. However, as these changes (none in the binding site) consisted of one insertion, one deletion and two amino-acid substitutions, the total number of amino acids is unaltered. The last two residues are highly disordered. (Drawing produced by ARPLOT[16].)

Table 1 Hydrogen bonds between sulphate and binding protein

Protein atoms, donor (X)	Sulphate atoms, acceptor (Y)	Distance (Å) X···Y	Angle (°) X–H···Y
Ser 130 OG	O-1	2.76	167
Ala 173 N	O-1	2.70	151
Ser 45 N	O-2	2.84	169
Gly 131 N	O-2	2.83	170
Gly 132 N	O-3	2.77	149
Trp 192 NE1	O-3	2.82	157
Asp 11 N	O-4	2.67	152
	Overall mean:	2.76 (0.07)	159 (9)

Hydrogen bonds were determined on the basis of angle and distance criteria and hydrogen atoms were located on the basis of standard geometry (see ref. 1).

in both domains. These H-bonding residues are also buried. The sequence Ser 130-Gly 131-Gly 132-Ala 133, which forms part of a loop and the first turn of a helix, has a key role in binding, as the first three residues provide a complementary three-point docking site for O-1, O-2 and O-3 of the sulphate, respectively, and the Ala 133 peptide NH donates a hydrogen bond to the Ser 130 hydroxyl (see Fig. 2). The peptide bonds with CO groups from residues 44, 131 and 172 initiate three α-helices (Figs 1, 2*b*).

What neutralizes or stabilizes the sequestered dianion charges? Stabilization could be provided by the inducible hydrogen-bond dipoles, by the three helix macrodipoles (44–54, 131–146, 172–181) close to the sulphate (with opposite polarity) (Figs 1, 2*b*) or by a combination of the two. We propose that fixed hydrogen bond dipoles radially oriented around the sulphate, induced through polarization by the strong electric field of the dianion and further coupled (via peptide units) to several resonating or relay H-bond systems (see Fig. 2*b*), could effectively neutralize the charges. One of these systems, which is composed of two H-bonds (between O-2 of the sulphate and Gly 131 peptide NH and between Ser 130 peptide CO and Arg 134 NE), could dissipate the buried charges. Arg 134, which is 5.7 Å to the sulphate, is further involved in an inter-domain bidentate salt-link with Asp 68. Another relay system is formed by hydrogen bonding between O-4 of the sulphate and NH of Asp 11 and between CO of Tyr 10 and His 42 ND1, which is in contact with the solvent. A similar mechanism for dissipating charges could be achieved by three separate peptide bonds, each providing an NH H-bond to a sulphate oxygen and initiating via the CO group a 'zig zag' continuous sequence of alternating peptide units and H-bonds within the α-helix. The left-handed helical H-bond array has the form $O_i \cdots NH_{i+4}$, where $i = m+3(n-1)$; m is the residue bearing the first O and $n = 1, 2, 3 \cdots$. An α-helix has three such arrays; ones of interest in SBP have m values of 44, 131 and 172.

As the Ser 130 hydroxyl is polarized by the dianion and is the recipient of a hydrogen bond from 133 NH located at the N-terminus of helix 131–146, the hydroxyl proton could be shared with the O-1 of the sulphate, yielding transient HSO_4^- species (the pK_1 and pK_2 of the sulphuric acid are ~ -3 and 1.9, respectively[7]). Proton sharing could be further facilitated by the coupling of 133 NH with another resonating H-bond array ($m = 132$).

Helix macrodipoles have been implicated in anion binding at the positive N-terminus of macrodipoles[8]. It has been calculated that binding of a single negative charge 5 Å from the helix macrodipole N-terminus involves a substantial attractive energy contribution of 12 kcal mol^{-1}, which is minimally diminished by desolvation energy[8] (this value may be overestimated significantly)[9]. The three helices in the sulphate-binding protein close to the dianion could provide charge stabilization. The effect of the macrodipoles may be diminished as the sulphate is not centred on any helix axis. These helices and several others with their N-termini converging towards the binding site cleft could also promote long-range attraction of anions preparatory to actual tight binding[8]. This would seem to be generally applicable to binding proteins except that several of the substrates are uncharged sugars and amino acid zwitterions.

The mechanism we have described above confines the function of an α-helix primarily to a specific H-bonded peptide array and takes into account resonances and polarizability of the array in dissipating buried charges. The mechanism would be more effective when the array is exposed to the solvent. This is what we observed in the amphipathic[10] helices with m values of 44 and 172; the third helix is partially buried. Further, we have made similar observations from other proteins (for example, flavodoxin) known to bind anions at N-termini of amphipathic helices (unpublished findings). In this connection, it has been shown that carbonyl oxygens within the hydrophilic side of helices are often H-bonded to solvents[11].

The proposed function of a specific H-bond helical array could, in much the same way as it might enhance the sharing of a serine hydroxyl proton with the sulphate, increase the reactivity of enzyme active-site residues or of coenzymes hydrogen-bonded to the first turn of helices.

The structure of flavodoxin resembles one of the domains of the periplasmic binding proteins (G.L.G., M.A.S. and F.A.Q., unpublished data). Although the substrate site of flavodoxin is located in a crevice at the surface[12] (coordinates obtained from Protein Data Bank[13]), we observed some similarities in the binding of the phosphate moiety of the buried flavin mononucleotide with the sulphate binding described above. (1) Of the 10 H-bond donors to the phosphate oxygens, 5 are from peptide NH groups of loops and the N-terminus of the one helix (10–26) near the phosphate dianion; (2) a Ser OH simultaneously donates a H-bond to the phosphate and accepts a H-bond from a peptide NH; (3) the one line of peptide H-bonds ($m = 10$) is exposed to the solvent. As the phosphate is not deeply buried within the flavodoxin, several relay systems as found in SBP may not be required. Nonetheless, the carbonyl oxygens of peptides bearing the NH groups H-bonded to the phosphate

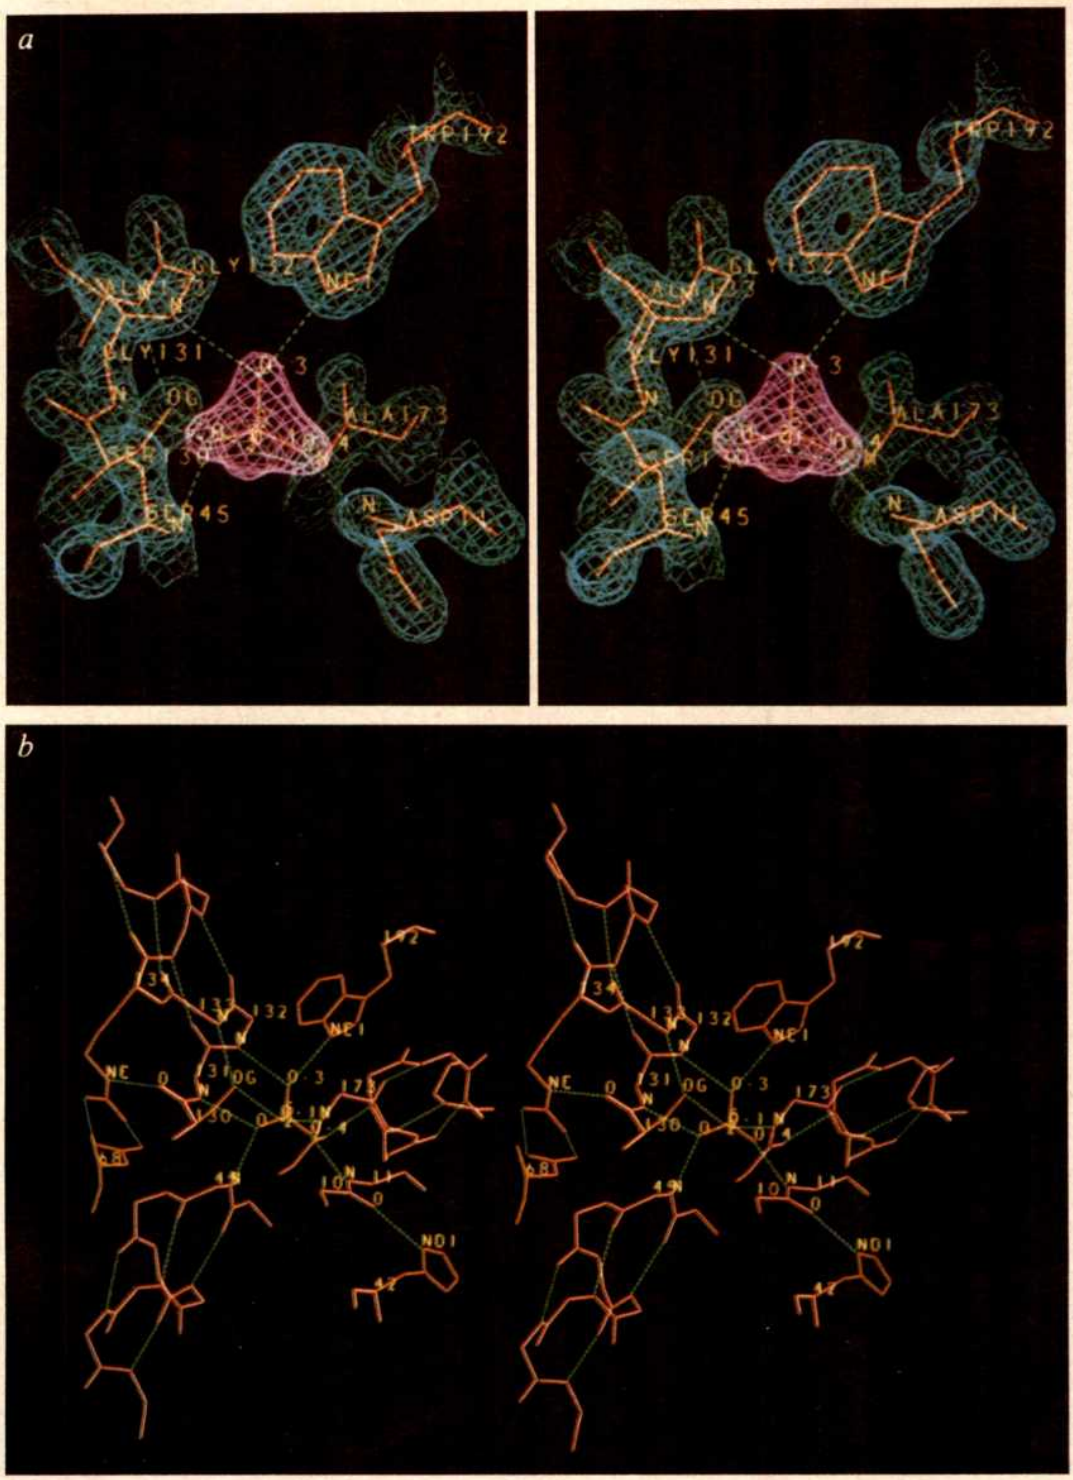

Fig. 2 *a*, Stereo view of the electron density of the tetrahedral sulphate and essential residues of the sulphate-binding protein superimposed on the refined model. The density map was calculated with coefficients $(2|F_o|-|F_c|)$ and final 2 Å refined α_c. The density surface (sulphate in purple and amino acids in blue) was contoured at 1.5 times the estimated standard deviation of the electron density and at grid-spacing of 0.4 Å. The green dotted lines represent hydrogen bonds. The H-bonds formed between the sulphate and the sulphate-binding protein are listed in Table 1. The α-carbons are identified with the amino-acid name and number. The plane formed by Ser 130 OG, Gly 131 N and Gly 132 N is parallel to and maximally superimposed on the plane of O-1, O-2 and O-3 of the sulphate. *b*, The same as *a* except that the electron density surface and residue names have been removed for clarity. Furthermore, other hydrogen-bonding systems (described in the text) and at least the first turn of three helices close to the sulphate have been added. The molecular graphics program FRODO[17] extensively modified for the E & S PS300 system[18] was used in the refinement and in generating these figures.

are in contact with the solvent.

Despite completely different substrate specificities, there are similarities in the binding sites of the L-arabinose-binding protein[1] and the sulphate-binding protein. The L-arabinose is also bound in the cleft via several H-bonds from six buried residues in both domains and is inaccessible to the bulk solvent. It is notable, especially in view of the importance of peptide bonds in anion binding, that while only side chains are involved in hydrogen-bonding the sugar in the arabinose receptor, five of the seven H-bonds to the sulphate are from the peptide backbone. (We have also observed that the charge of the solvent-inaccessible Arg 151, one of three essential charged residues in

the arabinose-binding protein, is stabilized entirely by protein and sugar dipoles[1].) As H-bonds are highly directional, they confer geometrical specificity on the site and ensure correctness of fit for the substrate. It may also be important that these bonds are stable enough to provide significant binding but are of sufficiently low strength to allow rapid ligand dissociation. The estimated turnover rates of binding proteins *in vitro* are comparable to the V_{max} values for *in vivo* transport[14]. Transport could be impeded if the sulphate were bound with salt-links.

The novel finding of general significance presented here is that charges from as strong an acid as sulphate can be stabilized in an enclosed, solvent-inaccessible site within a protein by bonds other than salt-links. This particular result and other observations reported here have far-reaching importance in understanding not only other ion-binding and transport systems, but protein stability, enzyme catalysis and other biochemical processes that require charged intermediates.

Significance of enamel thickness in hominoid evolution

Lawrence Martin

Hard Tissue Unit, Department of Anatomy and Embryology, University College London, Gower Street, London WC1E 6BT, UK

Enamel thickness has assumed unique importance in the debate about the hominid status of *Ramapithecus*, despite the fact that there is little agreement about the meaning of 'thick enamel' or the significance of enamel thickness for hominoid taxonomy[1-19]. My aim here is to evaluate the usefulness of enamel thickness and microstructure as characteristics for determining the relationships of the later Miocene hominoids, based both on a quantitative study of enamel thickness in extant hominoids and four species of later Miocene *Sivapithecus* (including '*Ramapithecus*') and on scanning electron microscope analysis of enamel microstructure[20]. Four categories of enamel thickness are defined metrically here and have been related to enamel microstructure and developmental rates. Thin fast-formed (pattern 3) enamel represents the ancestral condition in hominoids; it increased developmentally to thick pattern 3 enamel in the great ape and human clade and that condition is primitively retained in *Homo* and in the fossil hominoid *Sivapithecus* (including '*Ramapithecus*'). Enamel thickness has been secondarily reduced in the African apes and also, although at a different rate and extent, in the orang-utan. Thick enamel, previously the most important characteristic in arguments about the earliest hominid, does not therefore identify a hominid.

The most useful measurement of the amount of enamel on a tooth would be the volume of the tissue. This could be expressed as a thickness by dividing the volume of enamel by the surface area of the enamel/dentine junction over which the enamel formed; this area is proportional to the number of ameloblasts which formed the enamel. Such a measurement can be approximated by dividing the area of the enamel cap exposed by a single saw cut through the tooth by the length of the enamel/dentine junction over which it formed (average enamel thickness, Fig. 1). Single linear measurements of enamel thickness were found to be poorly correlated with this value, and such studies[15], especially those based on estimates from worn teeth[4] or naturally fractured teeth[21,22], are of limited value[20].

Enamel thickness increases allometrically (with increasing body and tooth size) in anthropoid primates[4,15]. Gorillas have absolutely thicker enamel than do chimpanzees (Fig. 1) in direct relation to body size[20], whereas orang-utans and humans have relatively thicker enamel when scaled for body and tooth size (Fig. 1)[20]. As body weight data are not available for fossil species, a dental estimate of body size must be used to scale average enamel thickness. Tooth crown measurements are of little use[4] as they include two measurements of enamel thickness in their magnitude and are not independent variables. The best estimator of body size was the combined area of dentine and pulp in the same section on which enamel thickness was measured (see Fig. 1)[20]. When combined with average enamel thickness (c/e), this produces a dimensionless index: relative enamel thickness $= (c/e \times 100)/\sqrt{b}$, where c is the area of the

Table 1 Relative enamel thickness of fossil and recent great apes

	Pan	*Gorilla*	*Homo*	*Pongo*	*Sivapithecus*
No. of specimens	14	17	13	17	9
Mean	10.10	10.04	22.35	15.93	19.71
Minimum	7.02	6.75	13.76	11.32	16.07
Maximum	13.31	13.39	32.26	20.45	22.68
Standard deviation	2.09	1.74	6.23	2.51	2.58
Mean low 95%	8.90	9.15	18.58	14.65	17.73
Mean high 95%	11.30	10.93	26.12	17.21	21.69
$\frac{c/e}{\sqrt[3]{\text{b.wt}}} \times 100$ (mean)	1.68	1.80	3.00	2.84	—

The sample studied included 24 unworn, or very lightly worn, molar teeth for each of *Pan troglodytes* (the chimpanzee), *Gorilla gorilla*, *Pongo pygmaeus* (the orang-utan) and *Homo sapiens*, and a smaller number of molars of *Hylobates*, *Sivapithecus sivalensis* (formerly called *Sivapithecus indicus*[20,28]), *Sivapithecus punjabicus* (formerly '*Ramapithecus*' *punjabicus*[14,20]), *Sivapithecus darwini* and *Sivapithecus alpani* (formerly referred to '*Ramapithecus*' *wickeri*[20,22]). These were mainly cut longitudinally in the coronal plane through the mesial cusps to provide two surfaces for measuring enamel thickness. Examples of each species were sectioned in the sagittal plane to determine the correspondence of the tips of the dentine horns with the cusp tips. The teeth were cut using a diamond wafering machine (Isomet, Buehler Ltd) producing a cut 350 μm wide. It has been shown that obliquity of section can exaggerate apparent enamel thickness[20], but the method used here ensures that measurements of enamel thickness were taken at or within a few micrometres of the ideal plane of section through the enamel cap, and even at worst no more than 175 μm mesial or distal to the ideal (see Fig. 1 legend). Mean low 95% and mean high 95% refer to the 95% confidence limits for the mean values for these samples. The final row gives values, for the living species, of a relative enamel thickness index based on body weight (b.wt, data from Dr Ben Rudder), which provides the same ranking of enamel thickness.

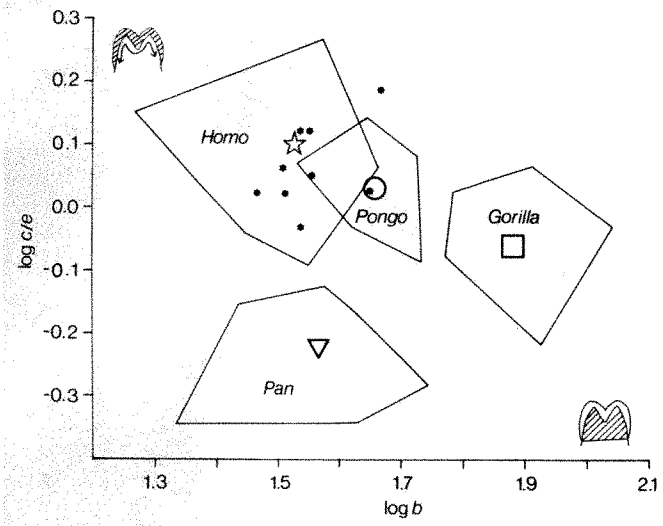

Fig. 1 Enamel thickness in relation to size. The vertical axis shows the average enamel thickness (c/e) and the horizontal axis the combined dentine/pulp area (b); both axes are logarithms to base 10. The shaded area of the tooth section shown on the y-axis is the enamel cap area (designated c) and the length of the interface between the shaded area and the unshaded area on the y-axis is the enamel/dentine junction length (e): average enamel thickness = c/e. The shaded area of the tooth section on the x-axis is the combined area of dentine and pulp (b), which was found to be the best dental approximator for body size that excluded any contribution from the enamel[20]. The species ranges observed are shown as minimum area polygons, with the species means indicated. Fossil specimens attributed to four species of *Sivapithecus* are shown by site, ☆ representing specimens from the Siwaliks, Indo-Pakistan, and * representing specimens from Pasalar, Turkey.

Sample details are given in Table 1 and individual data points are given in ref. 20. Measurements for all upper and lower molars are combined, which could only increase the species ranges, as no significant differences in enamel thickness between different molars were found[20]. Measurements were taken on photographs of the cut surface taken at constant magnification, with the cut face parallel with the film plane, and prints were also made at constant magnification[20]. Area and perimeter measurements were made using a pen transducer attachment for the graphics pad of an Apple computer, and tracing errors were small[20]. Linear measurements were taken to determine a good simple approximator of average enamel thickness. Correlations between average enamel thickness (c/e) and linear enamel thicknesses were $r = 0.27$–0.75 for nine single linear dimensions in *Gorilla*[20]; when two or three of these measurements were averaged before calculating the correlation, it increased to $r = 0.74$–0.76 (ref. 20); and the correlation for the mean of all nine measurements on c/e was 0.85 (ref. 20). These results indicate the unreliability of single linear dimensions (*contra* Gantt[15]), and raise questions about the reliability of studies based on these[15,19], and even more so about studies based on estimates of linear dimensions of enamel thickness[4,21].

enamel cap, e is the length of the enamel/dentine junction over which the enamel formed and b is the combined area of dentine and pulp in the same section (Fig. 1). Table 1 gives values for this index together with values for a second index expressing enamel thickness relative to the cube root of body weight; the two dimensionless indices produce the same ranking of relative enamel thickness, although their actual values differ[20]. The dentally based index has therefore been used as a measure of relative enamel thickness which is applicable to fossil species.

Four categories of relative enamel thickness are defined, based on the 95% confidence limits of the species means of relative enamel thickness (Table 1): thin enamel (species mean values of relative enamel thickness 8.90–11.30), intermediate/thin enamel (mean values 11.31–14.64), intermediate/thick enamel (mean values 14.65–17.49), and thick enamel (mean values 17.50–26.20). Thin enamel is found in *Pan*, *Gorilla* and *Hylobates*, intermediate/thick enamel in *Pongo* and thick enamel in *Homo*, and also in *Sivapithecus* (17.73–21.69).

These variations in enamel thickness can be explained in terms of the microstructure of hominoid enamel. Pattern 1 enamel[23] has previously been reported to occur in great ape enamel, while pattern 3 enamel is found in hominines[24]. In contrast, Vrba and Grine[25] found pattern 3 enamel to be common in all hominoids, and Boyde and Martin[26] found that pattern 3 enamel predominates in the deep layers of hominoid enamel, sampled in developing surface preparations, although some pattern 1 enamel is always present superficially. The prevalence of pattern 3 enamel in hominoids has subsequently been recognized by Gantt[19].

In the present work, sequential cuts made into the enamel provided information about enamel prism cross-sections, at a series of known depths, in the course of sectioning teeth for enamel thickness measurements[20,26]. The cut surfaces (Fig. 2*C*) were examined by back-scattered scanning electron microscopy to give additional information about packing patterns in the deeper enamel, prism cross-striation repeat intervals, and the distribution of Hunter-Schreger bands (Fig. 2)[20,26,27].

The distributions of these features were correlated in hominoid enamel. In all cases, pattern 3 enamel was associated with a cross-striation repeat interval of 5–7 μm (Fig. 2*B*), corresponding to the daily rate of ameloblast secretion (values are averages for large numbers of repeat intervals)[20]. Hunter-Schreger bands occurred only in areas of pattern 3 enamel (Fig. 2*A*). Where pattern 1 enamel was found, it was associated with cross-striation repeat intervals of <2.5 μm, a much lower accretionary rate, and an absence of Hunter-Schreger bands. This indicates that, in hominoids, pattern 3 enamel with prism decussation is formed about three times faster than is non-decussating pattern 1 enamel.

All of the hominoid species examined had two very thin (20–30 μm) layers of slowly formed (pattern 1) enamel, one at the tooth surface and the other immediately adjacent to the enamel/dentine junction, corresponding to the start and finish of enamel production by the ameloblasts. In *Homo*, *Hylobates* and *Sivapithecus*, the rest of the enamel was fast-formed (pattern 3) decussating enamel (Fig. 2) accounting for 90–95% of the enamel thickness.

Gibbons have thin enamel because it forms for a relatively shorter period (in relation to size) than does enamel in species of the great ape and human clade, which have extended developmental periods for tooth enamel relative to size. If all of their enamel was fast-formed it would be thick, as indeed it is for man. In the great apes, the thin enamel and intermediate/thick enamel form over the same relative time period as in the thick-enamelled species, but their enamel is thinner because the superficial layer of slow-formed pattern 1 enamel is much thicker and the average daily incremental rate is reduced. In *Pongo*, the slowly formed layer represents ~20% of maximum enamel thickness (~200 μm laid down at 2.5 μm per day and a further 50 μm laid down at 1.8 μm per day). In *Pan* and *Gorilla*, the slowly formed layer represents ~40% of maximum enamel thickness (~400 μm in *Gorilla* and ~300 μm in *Pan*), and was formed throughout at <1.5 μm per day. Thin enamel is structurally different in gibbons and African apes, and therefore not homologous, and the slowing down of enamel secretion is similarly non-homologous between the orang-utan and the African apes[20].

Thin enamel is a developmentally heterogeneous category and is therefore subdivided into two: first, thin enamel, all of which is formed at the fast (pattern 3) rate (termed thin, fast), present in gibbons; and second, thin enamel, a substantial portion of which is formed at the slow (pattern 1) rate (termed thin, slowed), present in the African apes. The intermediate/thin and the intermediate/thick categories could also be developmentally heterogeneous and are similarly subdivided. Thick enamel has been found only in species in which all of the enamel was formed at the fast (pattern 3) rate, and is therefore unlikely to have been developmentally heterogeneous in hominoids (Fig. 3*a*). This study therefore provides seven relevant categories of

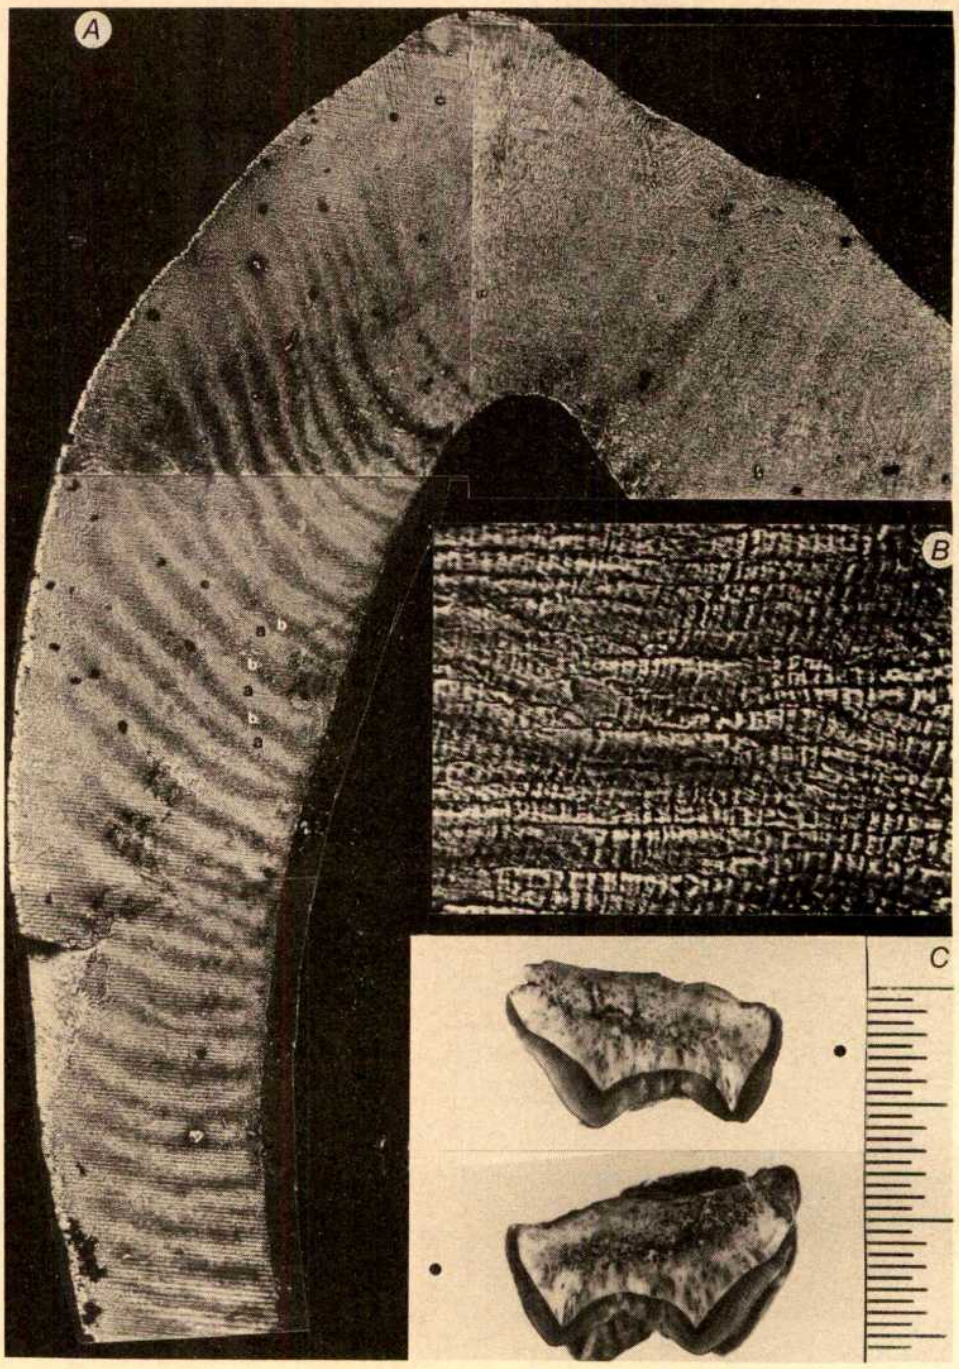

Fig. 2 Enamel thickness and structure in extant and extinct Hominoidea. ***A***, Montage of the enamel of the lingual cusp of a lower second molar of *Sivapithecus alpani* (BP 13) from Pasalar, Turkey (~14 Myr BP), with the enamel/dentine junction to the right. The cut face was lightly polished with 1-μm diamond and then etched with 0.5% H_3PO_4 for 30 s. Hunter-Schreger bands extend across most of the enamel thickness, even where it is thickest. Only the region above the tip of the dentine cusp has no prism decussation. Parazones (a) and diazones (b) are labelled and result in the Hunter-Schreger band pattern. Field height, 4.27 mm. ***B***, Cross-striations in a slowly formed region of the outer lingual enamel in a *Pongo pygmaeus* upper second molar. Cervical is towards the top, tooth surface to the left. The specimen was prepared by diamond polishing the cut face to a 1-μm finish and then etching it with EDTA *p*H 7.2 for 18 h to remove the smeared enamel and to reveal the enamel prism boundaries and cross-striations. The micrograph is a back-scattered electron image[26,27] which produces atomic number contrast, that is, a density-dependent image, when topographic relief is low. Field width, 146 μm. ***C***, Coronal longitudinal section through the mesiodistal cusps of a maxillary first molar (M^1) of *S. sivalensis* (M 13365). The upper section shows the anterior face revealed by the saw cut and the lower section the posterior face (350 μm apart); the buccal side of the tooth is indicated by a black spot. The scale bar is marked with 0.5-mm divisions. Some variation in any enamel thickness data will be the result of imperfect measurements and imperfect sectioning. Oblique sections act to increase the apparent enamel thickness[20], and this effect has been minimized here by taking minimum, and therefore more nearly radial, measurements (of enamel thickness) from the two cut faces in conjunction with maximum values for all dentine/pulp measurements[20]. When the saw cut has passed through the maximum diameter of the dentine horns, minimum values from both faces are used for enamel dimensions and maxima for dentine/pulp. When the saw cut has missed the plane of the maximum diameter of the dentine cusps (as with this *S. sivalensis* specimen), one face will be closer to the ideal plane of measurement than will the other[20]. The posterior face of M 13365 lies closest to the ideal plane of section, as it produces minimum values for all enamel thickness measurements and maximum values for all dentine/pulp measurements, and was used for measurement.

enamel thickness/formation for assessment in fossil species, in comparison with the two ('thick enamel' and 'thin enamel') used previously[7,8,13-15,17-19,22].

Figure 3*b* shows the conditions of enamel thickness and formation rates in the common ancestors of the various hominoid clades as interpreted from the data presented here. They provide the basis for the assessment of the relationships of *Sivapithecus* and *Dryopithecus* (see Fig. 3*b* legend).

Thick-enamelled, human-like teeth have previously been used to support the hominine status of *Ramapithecus*[1,17,18] and more recently *Sivapithecus*[4-8] and even *Pongo*[9], but these features are interpreted here to be primitive within the great ape and human clade (Fig. 3*b* legend). Thick enamel, having been considered the most important character in the assessment of the affinities of Miocene hominoids, turns out to be the least diagnostic of the enamel thickness categories and of no relevance to the taxonomic placement of *Sivapithecus* (including '*Ramapithecus*') within the great ape and human clade[20].

Thick pattern 3 enamel does not define a hominid. Moreover, the common ancestor of the great apes and man, and of the African apes and man, would have had teeth resembling those of hominids. This should be considered when attempting to establish the earliest record of hominids from deposits of later Miocene to early Pliocene age. Of the living members of the great ape and human clade, only *Homo sapiens* retains the condition of enamel thickness and development from the common ancestor of that clade (Fig. 3*b*) and may therefore be regarded as the most dentally primitive member of it.

This work was carried out in the Department of Palaeontology, British Museum (Natural History) and the Departments

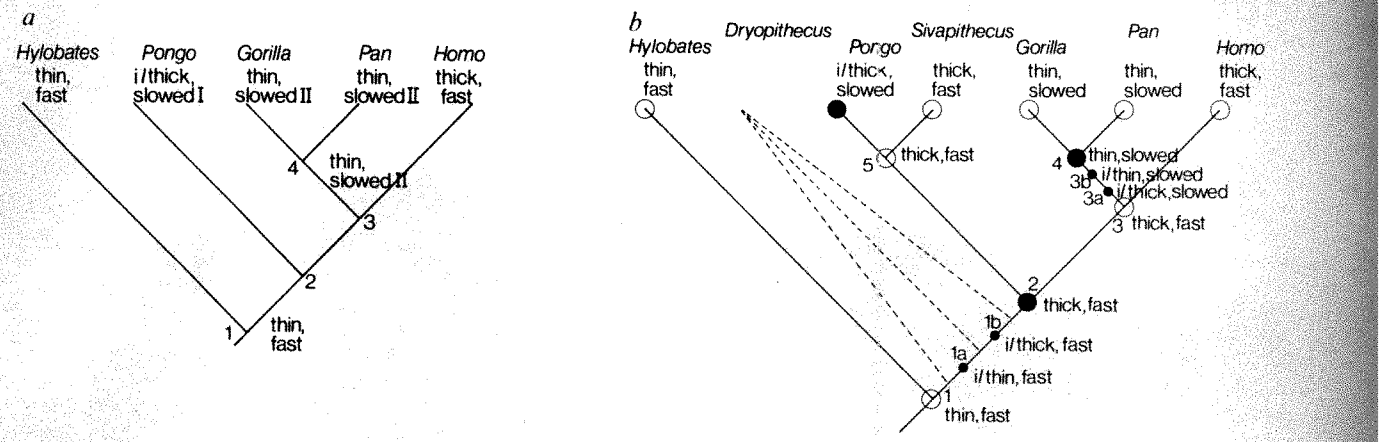

Fig. 3 Interpretations of the evolution of hominoid enamel. *a*, Enamel thickness and formation rates in extant great apes and humans; *b*, positions of *Sivapithecus* and *Dryopithecus*. The relationships among the living members of the great ape and human clade are based on cladistic interpretation of overall morphological pattern[3-8,10-20,22,28,29]. The recently proposed close relationship between human and orang-utan[9] depends very largely on the interpretation of thickened enamel as a shared derived character between these two genera, but as this has not been shown to be the case, and as our main aim here is to determine ancestral conditions, this view is not accepted here. *a*, Thin enamel predominates among cercopithecoids, platyrrhines, tarsiers and strepsirhines[4,15,18] and in *Hylobates*, so that it is parsimonious to interpret the condition in the last common ancestor (LCA) of the Hominoidea as being with thin, fast-formed (pattern 3) enamel (node 1), with this condition being retained in extant gibbons. Similarly, because both *Pan* and *Gorilla* have thin slowed-down enamel, it is likely that they retained this condition from their common ancestor (node 4). The situation for the LCA of the great ape and human clade (node 2) and for other contained clades is less clear. There are seven possibilities for the condition of enamel thickness/development at node 2 (see text). On the grounds that: (1) the thin enamel in gibbons and African apes is not homologous; (2) the slowed-down enamel in the African apes and the orang-utan is not homologous; and (3) the slowed-down pattern 1 enamel is developmentally derived from pattern 3 type with a relatively long total developmental period, in hominoids, the most parsimonious explanation for the distribution of enamel thickness and development among extant great apes and humans is that of thick enamel all of which formed at the fast, pattern 3 rate in the LCA of the great ape and human clade. *b*, This interpretation has considerable implications for the placement of fossil hominoids based on enamel thickness and structure. *Sivapithecus* is shown according to facial morphology[13,14,16,20,28,29], and this position is in accordance with enamel thickness data. Fossil taxa that do not have thick enamel could belong to several positions in hominoid phylogeny. If any of these taxa should be found to have either intermediate/thin or intermediate/thick fast formed enamel, it could be placed as the sister group of the great ape and human clade (nodes 1a, 1b). *Dryopithecus* is shown placed according to its possession of other derived characters shared with the great ape and human clade[20,29]. Its position could be more completely determined if it were known whether *Dryopithecus* had thin, intermediate/thin or intermediate/thick enamel. Closed circles at nodes indicate derived conditions with respect to the previous ancestral node; open circles indicate nodes at which the ancestral condition is retained primitively. According to this interpretation, the common ancestor of the Hominoidea (node 1) had thin enamel all of which formed at the fast, pattern 3 rate. The common ancestor for the great ape and human clade (node 2) had thick enamel, all of which was formed at the fast, pattern 3 rate. Nodes 1a and 1b represent hypothetical common ancestors at probable stages of enamel evolution, node 1a with intermediate/thin enamel and node 1b with intermediate/thick enamel, all of which formed at the fast, pattern 3 rate. No living hominoids display these conditions, but we might expect to find these derived conditions in fossil hominoid species from the middle or late Miocene (such as *Dryopithecus* and/or *Kenyapithecus*). Thick, fast-formed pattern 3 enamel is primitively retained at node 3, the common ancestor of the African ape and human clade, and node 5, the common ancestor of *Sivapithecus* and the orang-utan. This condition is modified in the *Pongo* portion of the clade, with a secondary reduction to intermediate/thick enamel. This stage should be detectable in fossil pongines from the later Miocene or Pliocene or Pleistocene. Thick, fast-formed enamel is also primitively retained in the exclusively hominine clade. The common ancestor of the African apes (node 4) had thin enamel, much of which formed at a reduced daily rate and which is therefore interpreted as being secondarily reduced. Nodes 3a and 3b represent hypothetical ancestors of the African apes at stages of enamel evolution through which they must have passed.

Atrial natriuretic factor— a circulating hormone stimulated by volume loading

R. E. Lang, H. Thölken, D. Ganten, F. C. Luft, H. Ruskoaho & Th. Unger

German Institute for High Blood Pressure Research and Department of Pharmacology, University of Heidelberg, Im Neuenheimer Feld 366, D-6900 Heidelberg, FRG

The cardiocytes of mammalian cardiac atria contain granules very similar to those in endocrine cells[1,2]. The number of these atrial granules is related directly to salt loading and blood volume[3]. Furthermore, crude extracts of rat atria and granule preparations have powerful natriuretic and diuretic effects[4,5]. These effects are mediated by peptides identified previously as atrial natriuretic factor (ANF). The peptides are derived from a common precursor, whose structure has been elucidated recently[6–15]. Although there is indirect evidence from morphological studies that at least some of these peptides may be released into the blood and function as hormones, their presence in the blood has not yet been demonstrated. Here we describe a sensitive and specific radioimmunoassay for ANF and its stimulation on volume loading.

The rat synthetic peptides used here were the 21-amino acid atriopeptin I (AP I), the 23-amino acid atriopeptin II (AP II) and the 24-amino acid atriopeptin III (AP III)[8]. To obtain antibodies, New Zealand White rabbits were injected with AP II coupled to bovine thyroglobulin. AP III, which corresponds to the sequence of AP II extended at the C-terminus by a tyrosine residue, was iodinated with ^{125}I as a tracer. The radioimmunoassay for ANF was performed at a final antibody dilution of 1:80,000 and AP III was used for the construction of standard curves. All concentrations of ANF-like immunoreactive material were expressed as weight equivalents of AP III (see Fig. 2 legend).

When extracts from rat atria prepared as described in Fig. 1 legend were examined by radioimmunoassay, the mean concentration of ANF-like immunoreactive material was 86.9 ± 14.3 ng mg^{-1} wet weight. Serial dilution of the extracts inhibited the binding of tracer to anti-ANF antiserum in parallel with the standard curve of ANF III.

Analysis of atrial extracts by HPLC revealed several immunoreactive peaks (Fig. 1*a*). Small amounts of ANF-like material were detected in the fractions where the synthetic standards eluted, but neither of the two major peaks corresponded to the position of these standards. Most of the immunoreactive material eluted with the upper third of the gradient, indicating a higher lipophilicity. The major peak appeared with a retention time of 54 min. Subsequent molecular mass sieving studies (not shown) indicated that this material represents higher relative molecular mass (M_r), consistent with the idea that it may represent precursor peptides. We studied the release of ANF-like material from rat atria *in vitro* using a modification of the isolated perfused heart preparation[16]. The heart was perfused with constant pressure through the aorta and buffer added to the right atrium via the upper vena cava. Increasing the perfusion rate gave a rise in right atrial pressure, monitored by a pressure transducer connected to a cannula in the lower vena cava. When right atrial pressure was raised by 1 mm Hg, the rate of ANF-like material release into the perfusate was doubled. A several-fold increase was observed after elevation of the pressure by 5 mm Hg (Table 1).

Figure 1*b* shows a HPLC–radioimmunoassay analysis of the perfusate collected at 5 mm Hg right atrial pressure. In contrast to the distribution of ANF-like material on HPLC of atrial extracts, the major fraction eluted with a retention time between that of AP II and AP III, whereas little high-M_r material was present. Muscle stretch is therefore a strong stimulus for liberation of ANF-like immunoreactive material from atria; small ANF peptides rather than precursor molecules are released.

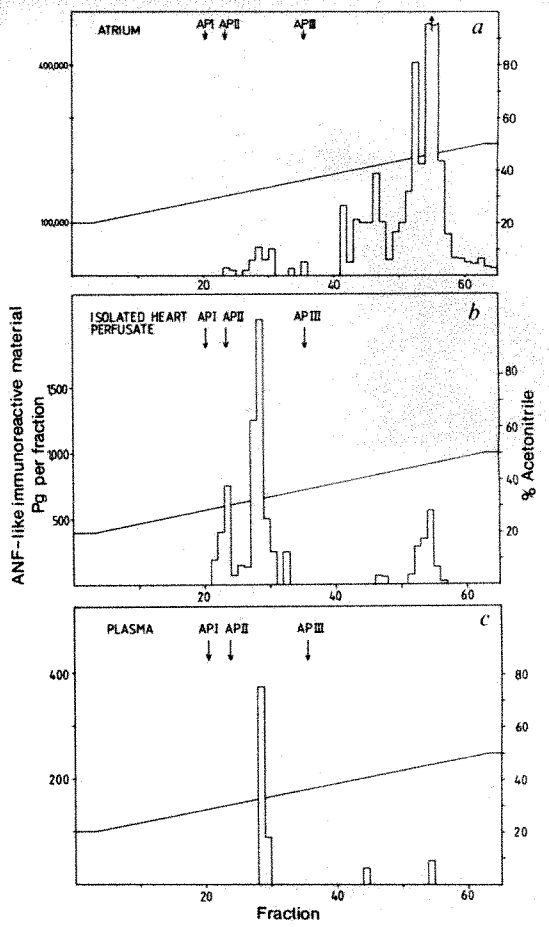

Fig. 1 Characterization of ANF-like immunoreactive material in: *a*, atrial tissue extracts; *b*, perfusate from isolated perfused rat heart; *c*, plasma, by reverse-phase HPLC using a Waters 2 Pump system and BondaPak C 18 column (40 cm × 1 cm). A linear gradient elution system was used from 20 to 50% over 60 min; solvent A, 0.01 M NH_4-trifluoroacetic acid (TFA) in water; solvent B, 0.01 M NH_4-TFA in acetonitrile; flow rate 1.0 ml min^{-1}. Fractions (1.0 ml) were collected, lyophilized and assayed for ANF-like material by radioimmunoassay (see Fig. 2 legend). Arrows indicate the elution positions of the synthetic peptides AP I, AP II and AP III, respectively. The recovery of these peptides was between 85 and 90% as determined by radioimmunoassay.
Methods. *a*, Separation of extracts from rat atria. For extraction the tissue was minced and boiled for 15 min in 0.1 M HCl to avoid proteolysis. The cooled tissue was homogenized subsequently using a Polytron tissue homogenizer and centrifuged for 30 min at 3,000 *g*. The resulting supernatant was extracted using ODS-silica cartridges as described for plasma in Fig. 2 legend, and subjected to HPLC. *b*, Analysis of ANF-like material in the perfusion buffer from the isolated perfused rat heart (see Table 1). Perfusate was collected during pressure stimulation of the right atria (5 mm Hg) and extracted by using ODS-silica cartridges before application to the HPLC column. *c*, Characterization of rat plasma ANF-like material. After insertion of chronic catheters into the femoral vein, rats were anaesthetized with pentobarbital and loaded with 8 ml normal saline as described in Fig. 2 legend. Blood was withdrawn from the aorta after laparotomy, centrifuged and plasma-extracted by passing through ODS-silica cartridges according to the procedure in Fig. 2 legend. The material subjected to HPLC corresponded to 2 ml plasma. Note that the retention time of the peak fraction is identical to that from the perfusate in *b*.

ANF-like material was also found in rat plasma. When extracted according to the procedure described in Fig. 2 legend, the mean plasma concentration in barbiturate-anaesthetized rats was 54.6 ± 13.9 pg ml^{-1} (mean ± s.d., $n = 10$). Plasma levels showed marked and dose-dependent increases on volume expansion (Fig. 2). Infusion of 2 ml normal saline produced a

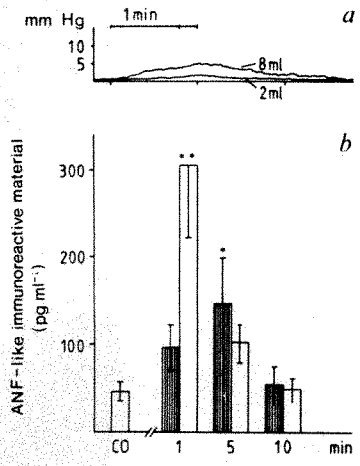

Fig. 2 Influence of volume expansion on ANF-like material in rat plasma. Values are expressed as weight equivalents of AP III (mean ± s.d., $*P < 0.05$; statistical analysis by Bonferoni test). Seventy male Wistar rats (370–420 g) in which catheters had been inserted in the femoral vein, were divided into seven groups of 10 animals. Three groups received either a 2-ml (*b*, shaded columns) or 8-ml (*b*, open columns) saline infusion i.v. under pentobarbital anaesthesia. The remaining group served as a control. Infusion time 1 min. Changes in right atrial pressure during volume load were measured in four animals by means of a catheter inserted into the right atrium through the jugular vein. *a*, Two representative traces.

Methods. Preparation of blood samples: Following laparotomy, blood was taken from the aorta either 1, 5, or 10 min after termination of volume load into plastic syringes containing aprotinin (1,000 kallikrein inactivator units ml^{-1}), soybean trypsin inhibitor (100 α-*N*-benzoyl-L-arginine ethyl ester units ml^{-1}) and EDTA (1 mg ml^{-1}). Plasma was separated by centrifugation and processed for extraction of ANF-like material as follows: 2 ml of each sample were diluted with 3 vol of 4% acetic acid and after centrifugation pumped at a rate of 4 ml min^{-1} through a small column containing ODS particles (Porasil; Machrey and Nagel). After a wash with 5 ml water, the absorbed peptides were eluted with 86% ethanol in 4% acetic acid. After evaporation and lyophilization, the dry residue was dissolved in radioimmunoassay buffer for determination of ANF-like material. Radioimmunoassay of ANF-like material: Synthetic rat AP II (Bachem) was used for immunization. The peptide was coupled to bovine thyroglobulin using carbodiimide[21] and 100 μg of the conjugate in 1 ml saline were emulsified with the same volume of complete Freund's adjuvant and injected intradermally at multiple sites on the backs of NZW rabbits. The first four immunizations were given at weekly intervals; subsequent booster injections were made every month. Rat AP III was used for labelling. Iodination with ^{125}I was performed according to the chloramine-T method[22]. For separation of the labelled peptide from free iodine, the reaction mixture was passed through ODS-silica cartridges and eluted as described above including a wash with 10% ethanol in 4% acetic acid before the final elution step. The specific activity of the tracer was 80–100 μCi μg^{-1}. The radioimmunoassay was performed in 0.1 M Tris buffer, *p*H 7.4, containing 0.1% gelatine. Synthetic AP III (1.95–1,000 pg per tube) was used to construct standard curves. The incubation mixture consisted of 0.2 ml buffer, 0.1 ml standard or sample and 0.1 ml antibody (final dilution 1:80,000). Tracer (4,000 c.p.m. per tube) was added after 48 h at 4 °C. After an overnight second incubation, separation of free from antibody-bound ^{125}I-peptide was achieved by adding 0.2 ml dextran-coated charcoal. Using this procedure, the lowest concentration of AP III yielding a binding significantly different from that in the absence of standard at the 95% confidence interval, was 2 pg per tube. The 50% intercept was at 41 pg per tube. The inter-assay variation was 14.1% ($n = 6$), and the intra-assay variation was 14.1% ($n = 6$), and the intra-assayy variation 7.1% ($n = 10$). A complete cross-reaction was observed with AP I and AP II. The antibodies did not (<0.001%) cross-react with the following peptides: angiotensin I and II, corticotropin-releasing factor, adrenocorticotropin, oxytocin, vasopressin, β-endorphin, α-neo-endorphin, dynorphins of different chain lengths, enkephalins, neuropeptide Y, somatostatin, vasoactive intestinal polypeptide. For studies on the recovery of ANF from plasma, various dilutions of synthetic AP III were added to plasma treated with charcoal for elimination of endogenous peptides. Using the ODS cartridges procedure for extraction, the recovery of synthetic AP III ranged from 62 to 70% both in the upper and lower ranges of the standard curve. The serial dilutions of extracts from rat plasma as well as atrial tissue and heart perfusate inhibited the binding of tracer to antibody in parallel with the standard curve of AP III.

:wo- to threefold rise in plasma ANF-like material. Administra-ion of 8 ml, corresponding to a ~30% volume expansion, gave i sixfold increase. The peaks in right atrial pressure in these experiments were 1–1.5 and 5 mm Hg, respectively. Similar esults were obtained in experiments using whole blood obtained rom Wistar rats of the same age and sex. In these conditions the peak values appeared at 6 min after infusion (data not shown).

For characterization of the ANF-like immunoreactive material in plasma, the blood volume of five rats was expanded by intravenous (i.v.) administration of 8 ml saline. The animals were bled 1 min after the infusion, the blood was pooled, the plasma extracted as described in Fig. 2 legend and subjected to HPLC. Radioimmunoassay revealed one major peak between the positions of AP II and AP III (Fig. 1*c*), corresponding exactly to the major peptide in the heart perfusate (Fig. 1*b*). In addition, very small amounts of ANF-like material were detected in the position of the high-M_r peptides of atrial extract. When the addition of aprotinin and soybean trypsin inhibitor to the blood was omitted, the peak fraction of the plasma HPLC was shifted to the position of AP III, indicating that degradation by plasma enzymes affects ANF metabolism.

This represents the first time that ANF has been demonstrated and characterized in the blood, although many attempts have been made to identify a natriuretic hormone that could increase renal excretion of salt and water[17,18]. Material having biological natriuretic activity has been reported in the blood and urine of several species[19] and its concentration was found to increase when the volume of blood or extracellular fluid was expanded experimentally[17–20]. Our HPLC–radioimmunoassay data show for the first time that rat plasma contains a substance immunologically related to the natriuretic peptides in and released from rat atria[6–15]. The plasma concentration is increased by physiological stimuli such as volume expansion.

Cardiac tissue contains many natriuretic peptides derived from the same precursor molecule. It is not yet known which of these are extraction artefacts and which occur naturally. In the plasma, we found a single peptide identical to the one released from the heart. Plasma ANF is closely related to but not identical with AP I, AP II and AP III, provided there is adequate protection from enzymatic degradation, in accordance with the suggestion that these peptide fragments would not occur in the heart if proteolysis was prevented during the extraction procedure from the atria[10]. Elucidation of the nature of circulating ANF will be possible when more ANF peptides have been synthesized and are available as reference substances. The knowledge of the exact amino-acid sequence is probably not crucial, as the peptides so far described usually exhibit variations in length of the amino-terminal region, which seem not to affect their biological function.

The elution pattern of ANF-like immunoreactive material obtained from atrial extracts indicates that most of it is not identical to the plasma peptide, but probably represents storage

Table 1 Effect of mean right atrial pressure on the rate of release of ANF-like immunoreactive material from the isolated perfused rat heart (pg min^{-1})

Expt no.	Change in right atrial pressure: Control	1 mm Hg	5 mm Hg
1	768	972	—
2	575	740	—
3	533	883	—
4	585	—	1,763
5	345	—	1,250
6	408	—	845

Rat hearts were removed and perfused through the aorta with Krebs/Ringer's solution at a constant pressure (122 mm Hg). The upper vena cava was cannulated and buffer infused into the right atrium at various rates to increase the mean right atrial pressure by either 1 or 5 mm Hg. The atrial pressure was monitored continuously by a pressure transducer connected to a catheter inserted into the lower vena cava. Mean atrial pressure varied between −0.5 and +0.2 mm Hg under basal conditions. Perfusate was collected and 1-min fractions extracted using the octadecasilyl (ODS)-silica cartridges technique for the radioimmunological determination of ANF-like immunoreactive material. The 5 mm Hg perfusate was used for HPLC characterization (see Fig. 1*b*).

forms of ANF serving as biosynthetic precursors for the ANF released into the blood. Our data demonstrate that, on stimulation, small concentrations of this precursor peptide are also released into the blood. Whether the conversion to the hormonal plasma peptide occurs mainly in the heart, lung or plasma remains to be elucidated. Our experiments on the isolated perfused heart suggest that most of the plasma ANF is formed in cardiac tissue, similar to other hormones.

The release of ANF-like immunoreactive material in response to volume load is rapid. We find an increase of plasma concentration as soon as 1 min after stimulation. The exact mechanism involved in the mediation of release is unclear. As shown here, the stretch of atrial cardiocytes produced by volume expansion may induce secretion of the natriuretic and diuretic peptides. Whether, in addition, higher centres in the brain are involved via neuronal reflex arcs will be the subject of future experiments.

Homogeneous interferon-inducing 22K factor is related to endogenous pyrogen and interleukin-1

***In vitro* stimulation of mononuclear cells from human peripheral blood with mitogens causes the release of factors (monokines and lymphokines) which possess distinct biological activities. One such factor, termed 22K, can induce production of human β-interferon (HuIFN-β) in cultured human fibroblasts, thereby rendering these cells resistant to virus infection[1–3]. Here we report the complete purification and partial sequencing (39 N-terminal amino acids) of this factor, whose relative molecular mass was estimated by SDS-polyacrylamide gel electrophoresis to be 17,000 (17K). In addition to an antiviral effect, the pure protein exhibits several other biological activities. Most significantly, intravenous (i.v.) injection of the factor in rabbits caused fever and granulopenia at doses of 0.1–1 μg per kg, effects which we attribute to a monokine called endogenous pyrogen (EP). *In vitro*, the protein was scored as positive in a LAF (lymphocyte-activating factor) assay at 0.1–1 ng ml^{-1}. LAF and EP are considered to be members of one family of monokines, called interleukin-1 (IL-1)[4]. For this reason, and also because the amino-acid sequence of the 22K factor is at least partially homologous to a complementary DNA-derived IL-1 sequence, we postulate that the 22K factor also belongs to the IL-1 family.**

Electrophoretically pure 22K was obtained from crude human lymphokine preparations by a four-step purification schedule summarized in Fig. 1 legend. The protein migrated on SDS-polyacrylamide gel electrophoresis (SDS-PAGE) as a single Coomassie blue-stained band with a relative molecular mass (M_r) of 17,000. A parallel unstained gel was sliced, each slice eluted and the eluates tested for antiviral activity. The antiviral activity coincided with the single stained band. We also determined the N-terminal amino-acid sequence of the protein using a gas-phase sequenator. Figure 2 shows the sequence of 39 N-terminal amino acids obtained from three runs, each using ~15 μg of protein. At most of the 39 positions, only a single residue was found in each of the three runs, indicating that the 22K-containing fractions obtained by fast protein liquid chromatography (FPLC) had a high degree of purity. At several positions two or three different residues were seen, suggesting that the factor is microheterogeneous. This microheterogeneity may reflect allelic polymorphism or the existence of a multi-gene family.

Although originally discovered by virtue of its IFN-β-like antiviral effect[2], 22K may have biological significance not related to the interferon system. In fact, the interferon-like antiviral effect of 22K is restricted in several ways: only certain diploid cell strains or continuous cell lines are sensitive and these may lose sensitivity on passage[3]; inhibition of the cytopathic effect is often incomplete, even with high doses of 22K; the reduction of virus yield generally does not exceed 3–10-fold; induction of HuIFN-β and its mRNA is detectable only when 22K is aided by cycloheximide or a combination of cycloheximide and actinomycin D[5].

Several experiments were done to determine whether 22K has biological activities previously assigned to 'factors' released by mononuclear cells; Table 1 summarizes the results. Pure 22K preparations did not inhibit the growth of cells on which they exerted an antiviral effect, nor did the factor show any activity in standard assay systems for lymphotoxin[6], interleukin-2 (IL-2)[7] and natural killer (NK) cell stimulation[8], while the LAF test for IL-1 (ref. 9) was positive. 22K preparations, including those consisting of electrophoretically homogeneous material, were able to replace crude lymphocyte supernatants as granulocyte-macrophage colony-stimulating factor (GM-CSF) in human bone marrow cultures[10], suggesting that 22K may cause the release of such factors from a subpopulation of bone marrow cells.

Strong inflammatory responses were seen when partially purified 22K preparations were injected intracutaneously in man, monkey or rabbit. Macroscopically, the reaction consisted of mild swelling and redness, maximal at 16 h post-injection and subsiding after 36–48 h. Microscopic examination of rabbit skin biopsies, taken 24 h after injection, revealed infiltration by polymorphonuclear cells, suggesting a direct or indirect chemotactic effect of the injected material. When fractions from gel filtration runs were tested in rabbits, the peak of skin reactivity coincided with that of antiviral activity. At this stage of purification, 22K may be presumed to still contain bioactive impurities, for example, IL-2, some of which may be responsible for the skin reactivity. However, on FPLC, skin reactivity also co-eluted with the electrophoretically pure antiviral factor.

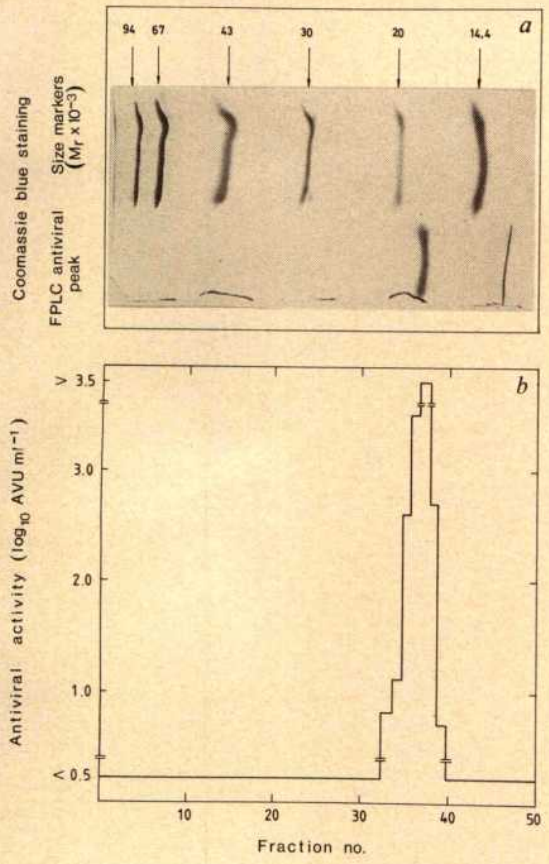

Fig. 1 SDS-PAGE of a pure preparation of 22K protein. Crude lymphokine/monokine preparations from Concanavalin A-induced mononuclear cell suspensions were concentrated and partially purified by adsorption to silicic acid and elution with 50% ethylene glycol containing phosphate-buffered saline (PBS) at *p*H 7.4 or with glycine buffer at *p*H 2.0 as described previously[2]. These eluates had an average specific activity of 10^4 AVU per mg protein; 1 AVU ml^{-1} is defined as the minimal concentration required to inhibit the cytopathic effect of vesicular stomatitis virus on sensitive human MG-63 cells, using a regular interferon microtitre assay system[2]. These preparations contained several lymphokines, including γ-interferon (IFN-γ) and IL-2 (results not shown). The second purification step consisted of adsorption of impurities to DEAE-Sephacel in 20 mM Tris-HCl buffer, *p*H 8.0. The DEAE-Sephacel-unadsorbed fraction (specific activity $10^{5.1}$ AVU mg^{-1}) was concentrated further and fractionated by gel filtration on Ultrogel AcA 54. Antiviral activity eluted in fractions corresponding to a M_r of 45,000 (fractions characterizable as IFN-γ) and 22,000 (fractions characterizable as IFN-β-like antiviral protein). The 22K fractions had a specific activity of $\geq 10^{6.5}$ AVU mg^{-1}; they were free of IFN-γ (M_r ~45,000), but were contaminated with IL-2 (M_r ~25,000). The 22K peak fraction from gel filtration was finally purified to homogeneity by FPLC using a Mono S cation-exchange column (Pharmacia Fine Chemicals); the activity was applied in 50 mM formiate buffer, *p*H 4.0. The Mono S column was then subjected to a linear NaCl gradient (0–0.65 M) at a flow rate of 1 ml min^{-1}. The antiviral activity invariably eluted as a single peak at 0.37 M NaCl. The specific activity was increased to $\geq 10^{7.0}$ AVU mg^{-1}. Fractions with high biological activity were pooled and analysed by SDS-PAGE on a linear 12% gel in reducing conditions. Coomassie blue-stained protein bands are shown in *a*. A parallel unstained gel was sliced and each slice was eluted with PBS; the eluates were stabilized with human serum albumin and dialysed against PBS to localize the antiviral activity (in *b*). For several experiments there was good quantitative agreement between the presence of the stained band and antiviral activity. Gels loaded with too little 22K failed to show the stained band and all fractions scored negatively. The protein content of antivirally active fractions, obtained at different purification steps, was measured by a fluorimetric assay, as described[2]. For fractions also containing Tris buffer protein, determinations were done using a Coomassie brilliant blue G-250 binding assay (Bio-Rad). In both cases bovine serum albumin was used as a standard.

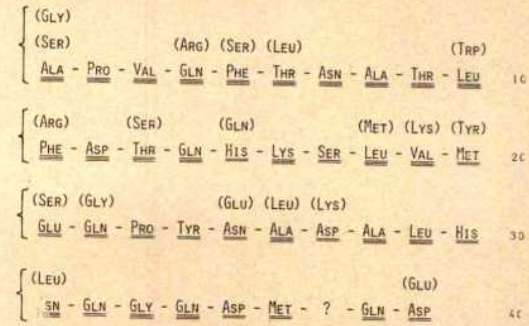

Fig. 2 N-terminal amino-acid sequence of the 22K factor. The number of lines beneath each residue indicates the number of runs in which the amino acid was observed. Brackets indicate detection of other residues.

Methods. Aliquots (~15 μg) of protein obtained from three FPLC runs (see Fig. 1 legend) were sequenced in a gas-phase sequenator[15] (Applied Biosystems, model 470A). The samples were not carboxymethylated before sequence analysis, so that cysteine residues could not be detected. The phenylthiohydantoin (PTH) amino acids obtained from the sequencer were identified by HPLC on an IBM cyanopropyl column (0.46 × 25 cm) using a separation procedure similar to that described by Hunkapiller and Hood[16]. The equipment used was the Waters Intellink system supplemented with a Perkin Elmer LC75 and a Pye Unicam LCUV detector set at 269 and 323 nm respectively.

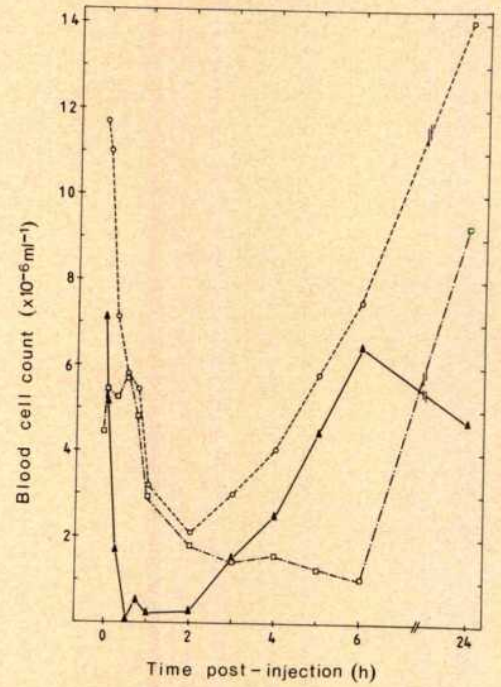

Fig. 3 Effect of i.v. injection of 22K protein on peripheral leukocyte counts in rabbits: ○ - - - ○, leukocytes (total); □ - - - □, lymphocytes; ▲—▲, granulocytes. The material injected was a FPLC-purified preparation (see Fig. 1 legend) containing ~1 μg of protein and $10^{4.3}$ AVU. Rabbits injected with saline or heat-treated (90 °C, 30 min) 22K factor did not show alterations in total or differential leukocyte counts.

Pure preparations of 22K were injected intravenously (i.v.) in rabbits to study the possible acute toxicity. Depending on the dose, increases in rectal temperature of up to 1.5 °C were noted; this effect was not due to contamination by bacterial endotoxins. Indeed, the injected 22K preparations lost their pyrogenicity after heat treatment (90 °C for 30 min), while the pyrogenicity of an *Escherichia coli* lipopolysaccharide preparation was heat-resistant. Pure preparations were also free of lipopolysaccharide as tested by the *Limulus* amoebocyte lysate assay (≤0.6 ng lipopolysaccharide in the highest injected dose, 3,000 antiviral units (AVU) per kg). Figure 3 shows that i.v. injection of pure 22K in rabbits caused a virtually immediate, but reversible, leukopenia. Granulocytes disappeared from the

Table 1 Biological properties of homogeneous 22K factor

Biological activity	Test system	Result (minimum effective dose or highest dose tested)
In vitro		
Antiviral effect	Inhibition of cytopathic effect in human diploid cells and MG-63 cells	Positive (1)*
CSF	Granulocyte-macrophage colony formation in human bone marrow cultures	Positive (1-3)*
IL-1	^{3}H-thymidine incorporation by human thymocytes	Positive (1)*
IL-2	^{3}H-thymidine incorporation by IL-2-dependent cytotoxic T-lymphocyte line	Negative (>500)*
NK-cell stimulation	Increase in natural cytotoxicity of human peripheral blood mononuclear cells against K-562 cells (^{51}Cr-release)	Negative (>100)*
Lymphotoxin	Cytolysis of mouse L-929 cells (subline α) pretreated with mitomycin C	Negative (>250)*
Cell growth	^{3}H-thymidine incorporation in log-phase cultures (human MG-63 and HEp-2)	Negative (>100)*
	Viable cell counts in log-phase cultures (human MG-63, HEp-2, U-937, HL-60 and diploid cells)	Negative (>100)*
In vivo		
Skin reactivity	Local inflammation after intracutaneous injection in rabbits	Positive (10,000)†
Pyrogenicity	0.5 °C Increase in rectal temperature after i.v. injection (3, 100 and 3,000 AVU per kg)	Positive (100 per kg)†
Leukopenia	Total and differential leukocyte counts after i.v. injection in rabbits (100, 1,000 and 10,000 AVU per kg)	Positive (1,000 per kg)

* Antiviral units (AVU) ml^{-1} as measured on MG-63 cells; † AVU.

circulating blood within 30 min after injection; lymphocyte counts decreased from 5,000 to a minimum of 2,000 cells per mm^3 in 2 h. Granulocytes reappeared from 2 h onwards and reached normal counts after 6 h; lymphocyte counts took 24 h to return to normal. The new cells were morphologically normal. Erythrocyte counts remained unaffected. The mechanism of this leukopenia is unclear, but present knowledge suggests a temporary adherence of the cells to the endothelia of the blood vessels and/or lymphoreticular organ system; however, other explanations are possible.

The *in vitro* antiviral effect of 22K occurred at doses of the order of 0.1-1 ng ml^{-1}, the systemic *in vivo* effect (leukopenia and pyrogenicity) at doses of 0.1-1 μg per kg. The molecule can thus be counted among the pharmacologically very active substances, such as lymphokines, interferons, neuropeptides, etc. Therefore, it seems reasonable to assume that 22K is a cytokine; the fact that it is released after mitogenic stimulation of leukocytes suggests that lymphocytes or monocytes are the producing cells and that 22K is generated in the body at sites where cellular immune reactions occur (for example, delayed-type hypersensitivity reactions, transplant rejection sites, etc.).

The strong pyrogenicity and haematological effects of 22K are both reminiscent of endotoxin-induced reactions[11], and suggest that 22K is related or identical to endogenous pyrogen. This monokine is considered to be related to IL-1 and to be involved in granulopoiesis[12], probably by stimulating production of CSFs. The conclusion that the 22K factor is essentially (an) endogenous pyrogen is therefore consistent with the fact that it has activity in a LAF assay and that it can replace CSF preparations in bone marrow cultures. The antiviral effect, which apparently is due to activation of the HuIFN-β system may, for reasons already mentioned, be of lesser physiological importance.

After submission of this paper, there have been reports on the isolation and sequencing of cDNA clones of human and murine IL-1 (refs 13, 14); these predict IL-1 gene products of M_r 31,000, which probably are 'precursor' proteins of the much smaller natural IL-1 products. The N-terminal amino-acid sequence of our 22K factor shows extensive homology with the middle part of the cDNA-derived human IL-1 precursor sequence. Alignment of the two sequences allows us to unambiguously define the position of the N-terminal amino acid of the biologically active human IL-1 in the precursor sequence determined by Auron *et al.*[13]. This provides further evidence that our 22K factor must be considered to be IL-1. Moreover, the fact that the homology was incomplete, together with the observation of multiple residues at several positions in the sequence, supports the notion that IL-1 comprises a microheterogeneous family of molecules.

We thank Drs W. E. Fibbe, J. Vilček, L. Schandene, C. Peeters, T. Goethals, H. Claeys and H. Heremans for performing various biological assays (Table 1). We also acknowledge the Belgian Red Cross for providing buffy coats; I. Ronsse, J. P. Lenaerts, W. Put and R. Conings for technical assistance; and C. Callebaut and J. Putzeys for editorial help. This work was supported by grants from the Belgian General Savings and Retirement Fund (ASLK/CGER) and from the National State Department of Science Policy (GOA). M. De L. is a Research Associate and G.O. a Research Assistant of the National Fund for Scientific Research (Belgium). J. Van B. thanks the National Fund for Scientific Research for a grant providing the gas-phase sequenator.

Immunoglobulin E (IgE; see ref. 1) has a central role in allergic reactions although it rarely exceeds 5 μg ml^{-1} even in the serum of severely allergic individuals. Both mast cells and basophils possess receptors which bind the Fc portion of IgE with high affinity; crosslinking of membrane-bound IgE by allergen results in degranulation of the cell and release of a variety of pharmacologically active mediators including histamine. Myeloma IgE

has been successfully used to block the skin sensitizing activity of allergic sera[2]; however, human myeloma IgE is clearly in limited supply. The emergence of techniques allowing the stable introduction of immunoglobulin gene DNA into myeloma cells[3–5] has allowed us to construct a mouse cell line that secretes a chimaeric IgE, λ1 antibody whose heavy chain is composed of a human C_ε constant region fused to a mouse variable (V_H) region. This chimaeric IgE is specific for the hapten 4-hydroxy-3-nitrophenacetyl (NP) and can, when crosslinked by antigen, trigger the degranulation of human basophils. When not crosslinked, however, the chimaeric IgE can prevent the passive sensitization of these cells by sera from allergic subjects.

The mouse plasmacytoma J558L secretes λ1 light chains but does not produce an immunoglobulin heavy chain[3]. The strategy used in the production of the recombinant IgE antibody was to introduce a plasmid that encodes a complete immunoglobulin ε heavy chain into J558L and thus direct the production of an IgE, λ1 antibody. The plasmid used for this purpose, pSV-$V_{NP}H\varepsilon$ (see Fig. 1), consists of an immunoglobulin ε heavy-chain gene cloned into the vector pSV2gpt (ref. 6). The heavy chain consists of a mouse variable region and a human ε constant region. This heavy chain, in combination with the λ1 light chain expressed by the J558L myeloma, should produce an antibody specific for the hapten NP. In plasmid pSV-$V_{NP}H\varepsilon$, the exons encoding the variable (V_H) and constant (C_H) regions of the heavy chain are separated by only 300 base pairs of intron; this contrasts with the normal *in vivo* situation where the two sets of exons are separated by an intron of ~8 kilobases (kb). The transcription enhancer element[4,7,8], which normally lies between V_H and C_H, is located upstream of the V_H exons in pSV-$V_{NP}H\varepsilon$; we have shown previously that the enhancer is active on the V_{NP} promoter at this position[4].

pSV-$V_{NP}H\varepsilon$ was introduced into J558L cells by spheroplast fusion, and stably transfected clones were selected as described previously[9]. Transfectants were obtained with a frequency of between 10^{-3} and 10^{-4} in different experiments. Culture supernatants of these transfectants were assayed for production of λ1-bearing anti-NP antibody by radioimmunoassay; between 50 and 80% of the clones were positive. Antibody was purified from culture supernatants of several transfected clones by affinity chromatography on a hapten–Sepharose column, with a yield of ~2 mg of antibody per litre.

Binding inhibition assays were used to demonstrate that the purified antibody displayed human ε antigenic determinants (Fig. 2). The affinity-purified chimaeric antibody competes with the binding of radiolabelled human myeloma IgE to both monoclonal (Fig. 2*a*) and polyspecific (Fig. 2*b*) anti-ε antisera. Furthermore, binding of radiolabelled myeloma IgE to the anti-ε antiserum was inhibited completely (Fig. 2*b*), indicating that the chimaeric antibody displays all the ε antigenic determinants recognized by this polyclonal antiserum. The chimaeric antibody competed with the binding of the radiolabelled myeloma IgE to the anti-ε antisera better than did the unlabelled myeloma

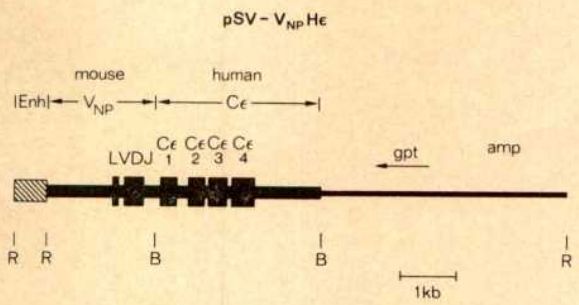

Fig. 1 Structure of plasmid pSV-$V_{NP}H\varepsilon$. Immunoglobulin DNA is represented by thick lines, pSV2gpt vector sequences by thin lines and the mouse C_H locus transcription enhancer element by a hatched box. Restriction endonuclease cleavage sites: R, *Eco*RI; B, *Bam*HI.

Methods. The *Eco*RI-*Bam*HI fragment of plasmid pSV-Vμ1 (ref. 4), which includes the V_H exons, was cloned between the *Eco*RI and *Bam*HI sites of plasmid pSV2gpt[6] to yield pSV-V_{NP}. The *Bam*HI fragment of phage λε1.2 (ref. 14), which includes exons C_ε1 to C_ε4 of the human ε gene, was cloned into pSV-V_{NP}, and plasmid pSV-$V_{NP}H\varepsilon$ completed by including in its unique *Eco*RI site the *Xba*I-*Eco*RI enhancer-containing fragment of the mouse heavy-chain locus.

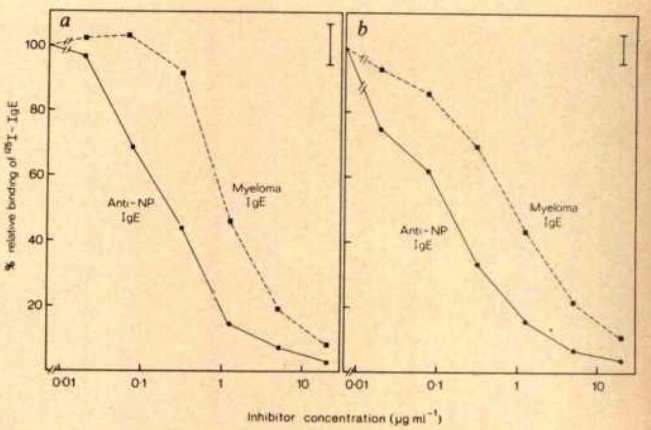

Fig. 2 Serological analysis of chimaeric IgE by binding inhibition assays. Assays were performed in which the binding of a radioiodinated human myeloma IgE to either a monoclonal (*a*) or polyclonal (*b*) anti-human ε antiserum was inhibited by various concentrations of unlabelled chimaeric IgE (●) or unlabelled myeloma IgE (■).

Methods. Wells of a Dynatec microtitre plate were coated with a solution containing either 1 μg ml^{-1} of a monoclonal mouse anti-human ε antibody (antibody RB6-2; given by M. D. Cooper) or 3 μg ml^{-1} of a polyclonal sheep anti-human ε antiserum (Seward Laboratory). After blocking of unreacted sites with bovine serum albumin, a human myeloma IgE (Serotec) that had been radiolabelled with ^{125}I was incubated in the wells in the presence of different concentrations of either chimaeric IgE or unlabelled myeloma IgE itself.

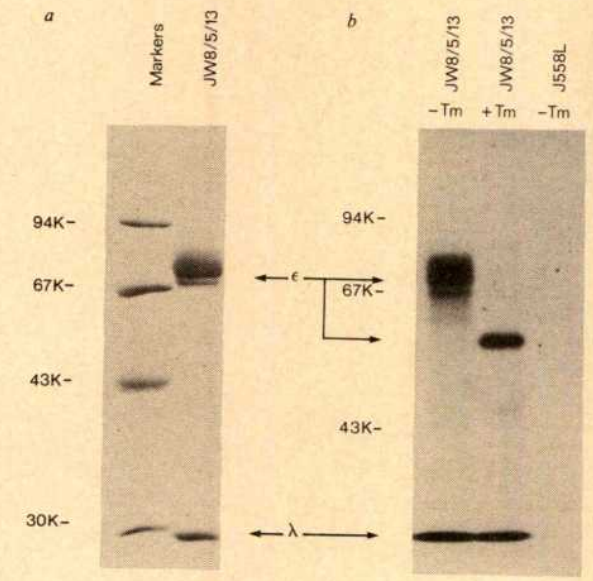

Fig. 3 Analysis of chimaeric IgE by SDS-polyacrylamide gel electrophoresis. *a*, Purified antibody (30 μg) from a cloned pSV-$V_{NP}H\varepsilon$ transfectant of J558L (JW8/5/13) was boiled in the presence of 2-mercaptoethanol, subjected to electrophoresis through a 9% gel and stained with Coomassie blue. *b*, Biosynthetically labelled antibody from either J558L or the transfectant JW8/5/13 was purified on NIP-Sepharose columns and analysed on a 7% gel after reduction. Samples purified from cells labelled in the presence of tunicamycin are marked +Tm. The positions of relative molecular mass markers are indicated (94K = relative molecular mass 94,000). Biosynthetic labelling with [L-^{35}S]methionine and purification of both labelled and unlabelled samples on hapten–Sepharose columns were performed as described previously[9].

Table 1 Histamine release triggered from human basophils passively sensitized with chimaeric IgE

Antigen	% Histamine release (±s.e.m.)
—	6.4 ± 0.8
10 μg ml^{-1} NIP-BSA	18.4 ± 2.4
1 μg ml^{-1} NIP-BSA	36.0 ± 5.6
0.1 μg ml^{-1} NIP-BSA	31.2 ± 12.0
0.01 μg ml^{-1} NIP-BSA	26.4 ± 2.4
0.001 μg ml^{-1} NIP-BSA	7.2 ± 1.6
0.0001 μg ml^{-1} NIP-BSA	5.2 ± 1.2
20 μg ml^{-1} Antigen P1	4.5 ± 0*

Mononuclear cells were prepared from peripheral blood by sedimentation through dextran-EDTA[11]; these preparations contained 1-2% basophils. Cells were incubated in duplicate at 37 °C for 2 h in complete Tyrode's buffer[12] with 1.5 μg ml^{-1} chimaeric anti-NP IgE. Cells were then centrifuged and resuspended in complete Tyrode's buffer containing the indicated concentrations of $(NIP)_{30}$-BSA. After 15 min, the histamine released into the supernatant was extracted and assayed fluorimetrically[11]. The maximum histamine release that could be obtained by incubating the cells at 100 °C was 62.5 ng ml^{-1}. The results are expressed as percentage histamine release: (antigen-induced histamine release [ng ml^{-1}]) × 100/maximum histamine release obtainable (ng ml^{-1}). The mean background percentage release obtained in repeated experiments was 6.0 ± 2.5. Both NIP-BSA (1.0 μg ml^{-1}) and antigen P1 (20 μg ml^{-1}) alone repeatedly failed to induce histamine release above background levels.

* Data obtained in a separate experiment using cells from the same donor.

Table 2 Blocking of histamine release by preincubation with chimaeric IgE

Concentration (μg ml^{-1}) of chimaeric anti-NP IgE in preincubation	Serum from allergic subject	Antigen P1	% Histamine release (±s.e.m.)
—	+	+	20.5 ± 2.7
0.01	+	+	16.9 ± 2.4
0.1	+	+	7.2 ± 0
1	+	+	8.2 ± 1.0
10	+	+	7.2 ± 1.0
10	−	−	8.4 ± 1.2
—	−	+	7.5 ± 1.7

Mononuclear cells were prepared as described in Table 1. A 2-h preincubation with different concentrations of chimaeric anti-NP IgE was followed by a 2-h incubation with allergic serum (diluted 1:30 in complete Tyrode's), prior to a 15-min exposure to antigen P1 (20 μg ml^{-1}). The allergic serum used had a total IgE level of 4,800 IU ml^{-1}, and 1,600 BA units ml^{-1} of IgE specific for *D. pteronyssinus* antigen P1 (ref. 13). The maximum histamine release obtained by incubating the cells used in this experiment at 100 °C was 10.4 ng ml^{-1}.

IgE itself, probably because the purified chimaeric antibody is essentially homogeneous (see Fig. 3), whereas the commercial sample of myeloma IgE is not.

The structure of the chimaeric protein was investigated by SDS-polyacrylamide gel electrophoresis (SDS-PAGE). Examination of reduced anti-NP IgE reveals a band co-migrating with mouse λ1 light chains and a diffuse heavy-chain band of relative molecular mass (M_r) ~72,000 (72K) (Fig. 3*a*); this is considerably larger than the M_r of the ε polypeptide chain as predicted from the DNA sequence. However, this discrepancy is resolved by SDS-PAGE of biosynthetically labelled anti-NP IgE secreted by cells labelled in the presence of tunicamycin (Fig. 3*b*). Incubation with this glycosylation inhibitor reduces the apparent relative molecular mass of the secreted anti-NP IgE from 72K to the predicted value of 62K. Thus the chimaeric IgE, like IgE from human myeloma[10], is heavily glycosylated. The electrophoretic mobility of unreduced anti-NP IgE in SDS-polyacrylamide gels (not shown) is consistent with it having an $\varepsilon_2\lambda_2$ structure.

Two types of assay were performed to determine whether the chimaeric anti-NP IgE antibody exhibits the physiological effector functions of authentic human IgE. In one type of assay, we tested the ability of the antibody to trigger histamine release from human basophils. A preparation of mononuclear cells from peripheral blood containing 1-2% basophils was passively sensitized with the chimaeric antibody before incubation with hapten (5-iodo-4-hydroxy-3-nitrophenacetyl caproate, NIP) coupled to bovine serum albumin (NIP-BSA). The results (Table 1) indicate that, after preincubation of basophils with the chimaeric IgE, NIP-BSA is able to trigger a dose-dependent release of histamine. A heterologous antigen, antigen P1 of the house dust mite *Dermatophagoides pteronyssinus*, failed to induce histamine release. Similarly, only background levels of histamine release were obtained with either the chimaeric antibody or NIP-BSA alone. These results indicate that the anti-NP IgE, like authentic human IgE, will not cause degranulation by itself, but will trigger histamine release following crosslinking with antigen.

In a second assay, we demonstrated that incubation with anti-NP IgE could also block the subsequent passive sensitization of basophils by atopic sera containing high IgE levels. Table 2 shows that house dust mite antigen P1 can induce the release of histamine from basophils preincubated with serum containing anti-P1 IgE antibody. However, this same serum failed to effect histamine release when the cells had been incubated previously with the chimaeric antibody at concentrations >0.1 μg ml^{-1}.

The results described here demonstrate that transfection of DNA into mouse myeloma cells is an effective way of producing large amounts of chimaeric antibodies in which mouse *V* regions provide antigen-binding specificity and human C_H regions provide human effector functions. The known antigen-binding specificity of such an antibody makes its purification extremely simple. Production of a chimaeric IgE in this way has proved particularly attractive as no monoclonal human IgE of known antigen specificity was previously available. The chimaeric antibody may, therefore, prove useful in routine clinical assays. We have demonstrated that this monoclonal IgE is able to block the release of histamine from human basophils which can be triggered *in vitro* by sera from allergic subjects. It will clearly be important to discover whether analogous blocking can be achieved *in vivo* using skin sensitization assays.

We thank S. Morrison for the J558L myeloma, M. D. Cooper for the monoclonal anti-ε antibody and R. R. Coombs for critical reading of the manuscript.

Note added in proof: Morrison *et al.*[15] and Boulianne *et al.*[16] have recently described the construction of chimaeric IgG antibodies.

The gene encoding the T-cell receptor α-chain maps close to the *Np-2* locus on mouse chromosome 14

Serological and molecular genetic analyses of T-cell clones have shown that the T-cell antigen receptor[1] apparently comprises two glycosylated, disulphide-linked polypeptide chains (α and β), both of which span the cell membrane. Cloning of the genes encoding the two chains from mouse and human DNA has shown that the α- and β-chains are composed of variable (V) and conserved (C) regions in agreement with peptide mapping data[2–11]. Gene segments encoding variable and conserved domains of the β-chain have been identified and undergo rearrangements during T-cell differentiation. The genes encoding the α-chain, so far described at the level of complementary DNA clones, also identify DNA rearrangements. Thus, the genes encoding the T-cell receptor show the same structure and dynamic behaviour as immunoglobulin genes, indicating that the two gene families belong to the same supergene family[5,12,13]; this evolutionary relationship is supported by the fact that the genes encoding the β-chain of the T-cell receptor are closely linked to immunoglobulin κ light-chain genes on chromosome 6 in mouse[14]. In man, however, the β genes map to chromosome 7 (ref. 14) whereas the κ-chain genes are located on chromosome 2, indicating that linkage between the two gene families is not needed for proper expression. Here we describe genomic clones encoding the constant portion of the T-cell receptor α-chain and map the gene to chromosome 14 in mouse, close to the gene for purine nucleoside phosphorylase (*Np*-2) which, in man, has been associated with T-cell immunodeficiencies.

The strategy used to clone the mouse α-chain gene involved the synthesis of a 33-nucleotide long oligomer based on published sequences[9,10] of α-chain cDNA clones. The oligomer, corresponding to the 5′ end of the constant region, was used to screen a BALB/c mouse thymocyte cDNA library constructed in the phage vector λgtII and consisting of ~10^6 independent clones. About 30 positive clones were scored, one of which was picked, rescreened, grown up and subcloned in the plasmid vector pUC9. This clone (T1.2), containing a cDNA insert of 1,100 base pairs (bp), was then characterized with five different restriction enzymes; the map obtained (Fig. 1) agrees completely with those published for α-chain cDNA clones[9,10]. The comparison also indicated that clone T1.2 contains *V*, joining (*J*), and 3′-untranslated region sequences. DNA sequence determination of a portion of the variable and constant region of T1.2 further confirmed its identity as an α-chain cDNA clone (E. Karjalainen, personal communication).

The *Nco*I fragment (probe 1 in Fig. 1) was then used to screen a mouse cosmid library constructed with BDFL 1.1 DNA. BDFL 1.1 is a cytotoxic T-cell clone obtained from a (C57BL/6J × DBA/2J)F_1 mouse and is specific for fluorescein in association with H-2D^d (W. Haas, unpublished data); 28 positive clones were detected initially, 5 of which were selected finally after screening with probe 2 (see Fig. 1). Mapping of these 5 cosmid clones with 14 different restriction enzymes showed that they all contain overlapping DNA sequences. Four enzymes, however, detected four polymorphic restriction sites; these sites defined two groups of overlapping cosmid clones, presumably representing the two constant-region alleles present in BDFL 1.1. Figure 2 shows one clone for each group of cosmid clones representing the two alleles; both of these clones contain the gene for the constant region of the α-chain, as shown by

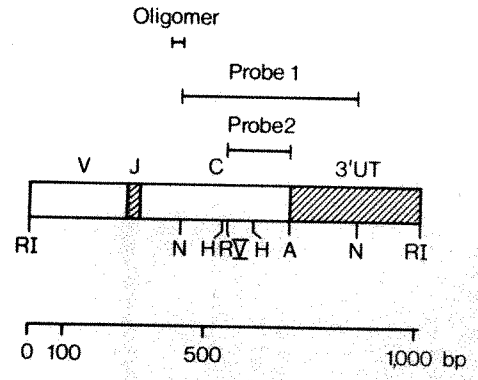

Fig. 1 Restriction enzyme map of the insert of cDNA clone T1.2. Restriction enzymes are: A, *Ava*II; H, *Hin*dIII; RI, *Eco*RI; RV, *Eco*RV. The *Hin*dIII site in the pUC9 vector molecule is located to the left. The locations of the oligomer and probes 1 and 2 are indicated.

Methods. The cDNA library was constructed with BALB/c thymocyte mRNA in λgtII as described elsewhere[28] and screened with a 33-nucleotide long oligomer corresponding to amino-acid residues 141–151 (ref. 9) of the constant region of the T-cell receptor α-chain. The oligonucleotide was synthesized on controlled-pore glass as support, using phosphite chemistry[29]. Hybridization with T4 kinase-labelled oligomer was done in 50% formamide, 5 × SSC, 0.1% SDS, 5 × Denhardt's solution, 10% dextran sulphate, 50 mM sodium phosphate (*p*H 7), 1 mM sodium pyrophosphate, 100 μM ATP, 50 μg ml^{-1} *Escherichia coli* DNA and 50 μg ml^{-1} poly (A) at 42 °C overnight. Filters were washed in 6 × SSC, 0.1% SDS twice for 20 min each at 42 °C and exposed to X-ray film. Of 30 positive clones, one was picked, rescreened, grown up and the *Eco*RI insert subcloned into pUC9 using standard procedures[30]. The clone (T1.2) was mapped by single and double digestions using the restriction enzymes indicated.

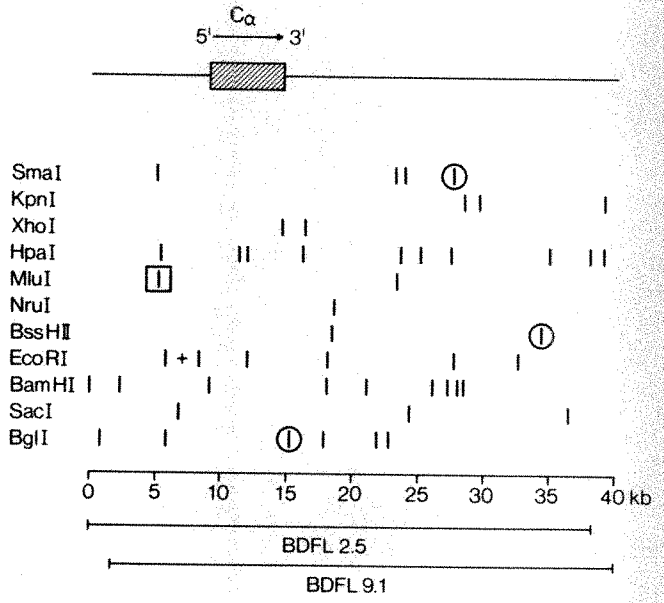

Fig. 2 Molecular map of a 40-kb region of DNA around the constant-region gene of the T-cell receptor α-chain. The region is defined by the two cosmid clones BDFL 2.5 and BDFL 9.1 derived, respectively, from the DBA/2 and the C57BL/6 chromosome of the cytotoxic T-cell clone BDFL 1.1 (see text). Restriction enzymes sites are indicated by vertical bars; those specific for the C57BL/6 allele are circled and the DBA/2-specific site is indicated by a square. No sites were found for *Sal*I, *Cla*I or *Sac*II. + Indicates that one additional *Eco*RI site is present in the segment marked. The extent of the C_α gene is only approximate and was determined by Southern blot hybridization of restriction fragments from the cosmid clones with the probes described in Fig. 1 legend. The cosmid library of BDFL 1.1 DNA was constructed using the vector pNNL and screened with oligo-labelled[31] probe 1 (Fig. 1) as described elsewhere[32]. Cosmid clones were analysed by restriction enzyme digestion and hybridization as described[32,33].

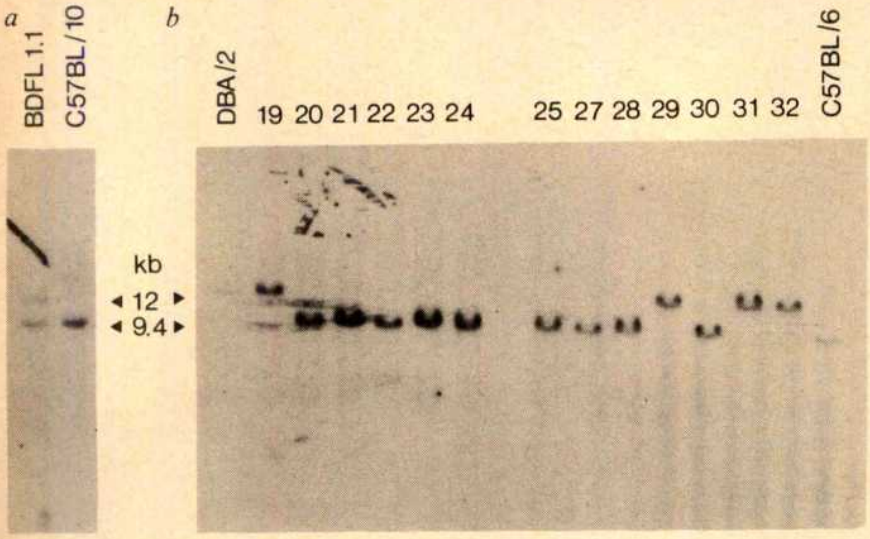

Fig. 3 Southern blot analysis of *Bgl*I-digested mouse DNA with a C_α probe. *a*, DNA from C57BL/10 mouse liver and the BDFL 1.1 cell clone. *b*, DNA from DBA/2 and C57BL/6 mouse livers and 13 recombinant inbred strains of the BXD series (see Table 1). DNA (5–10 μg of each sample) was digested to completion and separated on a 0.6% agarose gel, transferred to nitrocellulose filters and hybridized with oligo-labelled[31] probe 2 (Fig. 1) as described previously[33]. BXD DNAs were obtained from the Jackson Laboratory.

hybridization with the cDNA probes 1 and 2 and the synthetic oligomer. Hybridization of distinct restriction fragments to the oligomer (5′ probe) and the *Nco*I fragment (3′ probe) defined the 5′ to 3′ orientation of the constant-region gene (Fig. 2). As DNA rearrangements, resulting from *V–J* joining, are presumed to occur upstream of the constant-region gene, we are uncertain as to whether the polymorphism revealed by the *Mlu*I site is a result of a possible *V–J* joining on one or both chromosomes.

To confirm that the polymorphic restriction sites on cosmid clones 9.1 and 2.5 do indeed characterize the α-chain alleles derived from DBA/2 and C57BL/6 DNA, we performed Southern blotting experiments using probe 2. As expected from the cosmid clones, two *Bgl*I fragments of 12 and 9.4 kilobases (kb) were identified in BDFL 1.1 DNA (Fig. 3*a*). These fragments were identical in size to the 12-kb *Bgl*I fragment detected in DBA/2 DNA and the 9.4-kb fragment found in C57BL/10 or C57BL/6 (Fig. 3*b*) DNA, indicating that cosmid clone 2.5 corresponds to the DBA/2 allele whereas cosmid clone 9.1 represents the C57BL/6 allele.

The restriction site polymorphism revealed between DBA/2 and C57BL/6 DNA immediately suggested the use of recombinant inbred strains of mice to determine the location of the α-chain gene in the genome of the mouse. Recombinant inbred strains are derived by crossing two genetically distinct progenitor strains and establishing multiple independent strains from the F_2 generation by continuous brother-sister inbreeding[15]. The chromosomes of recombinant inbred strains consist of alternating segments derived from the two progenitor strains, the boundaries of which are determined by chance fixation of crossovers during the inbreeding process. Once inbred, the recombinant strains are typed for genetic loci that discriminate between the progenitors to obtain a strain distribution pattern characteristic for each locus. As closely linked genes will tend to become fixed in the same combination as they entered the cross, recombinant inbred strains are useful for detecting linkages and for estimating recombination frequencies.

Table 1 Strain distribution pattern of the *Bgl*I polymorphism of the α gene

Strain	Restriction fragment	Strain	Restriction fragment
BDFL 1.1	12 kb(D), 9.4 kb(B)	BXD 16	D
DBA/2	D	BXD 18	D
C57BL/10	B	BXD 19	D
C57BL/6	B	BXD 20	B
BXD 1	B	BXD 21	B
BXD 2	D	BXD 22	B
BXD 5	B	BXD 23	B
BXD 6	D	BXD 24	B
BXD 8	D	BXD 25	B
BXD 9	D	BXD 27	B
BXD 11	D	BXD 28	B
BXD 12	D	BXD 29	D
BXD 13	B	BXD 30	B
BXD 14	D	BXD 31	D
BXD 15	D	BXD 32	D

*Bgl*I fragments detected with probe 2 (Fig. 1) in the various recombinant inbred strains listed were either 12 kb (derived from DBA/2, D allele) or 9.4 kb (derived from C57BL/6, B allele) long. The heterozygous BDFL 1.1 cell clone (C57BL/6 × DBA/2) contained a 12- and a 9.4-kb *Bgl*I fragment (compare with Fig. 3).

The BXD series of recombinant inbred strains consists of 26 strains derived from crossing C57BL/6J with DBA/2J mice[16]. Over 150 loci have now been typed. We tested DNA of the 26 strains after *Bgl*I digestion with probe 2 and obtained the strain distribution pattern for the α-chain gene shown in Fig. 3*b* and Table 1. This pattern shows perfect concordance with the strain distribution pattern of the *Np-2* locus, indicating with 95% certainty that the α-chain gene maps within 3.3 centimorgans of *Np-2* (ref. 17). The probability of finding complete concordance for two unlinked loci by chance alone is $<1\times10^{-7}$ in the BXD series.

The *Np-2* locus is closely linked to the *Np-1* locus[18] on chromosome 14 in the mouse[19]. Thus, neither the α- nor the β-chain gene for the T-cell receptor is located on chromosome 12 in the mouse, which carries the immunoglobulin heavy-chain genes. The finding of immunoglobulin allotype-linked idiotypes on T cells therefore remains unexplained[20,21].

In C57BL mice, *Np-2* controls an erythrocyte-specific isozyme of purine nucleoside phosphorylase, an enzyme important for the catabolism of purine nucleotides[22]. The common form of this enzyme found in all inbred strains studied, including C57BL, is encoded by the *Np-1* locus. Interestingly, in man, deficiencies of purine nucleoside phosphorylase have been shown to be associated with severe T-cell immunodeficiencies[23]. It has been proposed that elevated levels of dGTP accumulating in the absence of the enzyme are toxic to T lymphocytes[24]. Given the apparent close linkage between the genes for the T-cell receptor α-chain and nucleoside phosphorylase in the mouse, it is likely that the human α-chain gene is also linked to the nucleoside phosphorylase locus[25]. If this is the case, at least some of the phosphorylase-linked T-cell deficiencies in man might be the result of genetic defects affecting both loci; this can be tested as the location of the phosphorylase gene in man is known (incidentally also on chromosome 14; ref. 26) and the gene has been cloned[27].

Complete concordance between the strain distribution patterns for the *Np-2* locus and the α-chain gene is also observed

in the BXH (12 strains) and CXB (7 strains) series of recombinant inbred strains. Furthermore, the two *H-8* congeneic mouse strains, B6.C-*H-8*^{c}/By and B10.D2 (57N)/Sn, contain the BALB/c and DBA/2 alleles, respectively, at both the *Np-2* and α-chain gene loci. We propose *Tcra* as a symbol for the T-cell receptor α-chain gene locus.

We thank W. Haas for the BDFL 1.1 T-cell clone, F.-W. Shen for construction of the thymocyte cDNA library, G. R. Dastoornikoo for DNA isolation, M. Kiefer for nitrocellulose filters containing *Bgl*I-digested BXD DNAs, K. Fischer Lindahl and H. v. Boehmer for critically reading the manuscript, K. Karjalainen for discussions, H. P. Stahlberger for artwork and Lynn Gisler for preparation of the manuscript. Part of the work was supported by NIH grant GM 18684 to B.A.T. The Jackson Laboratory is fully accredited by the American Association for Accreditation of Laboratory Animal Care. The Basel Institute for Immunology was founded and is supported by F. Hoffmann-La Roche, Ltd.

† Centre for Cancer Research and Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

The T-cell receptor for antigen has been identified as a disulphide-linked heterodimeric glycoprotein of relative molecular mass (M_r) 90,000 comprising an α- and a β-chain[1-3]. The availability of complementary DNA clones encoding mouse[4] and human[5] β-chains has allowed a detailed characterization of the genomic organization of the β-chain gene family and has revealed that functional β-chain genes in T cells are generated from recombination events involving variable (*V*), diversity (*D*), joining (*J*) and constant (*C*) gene segments[6,7]. Recently, cDNA clones encoding mouse[8,9] and human[10] α-chains have been described; the sequences of these clones have indicated that functional α-chain genes are also generated from multiple gene segments. It is possible that chromosomal translocations involving T-cell receptor α- and β-chain genes have a role in T-cell neoplasms in much the same way as translocations involving immunoglobulin genes are associated with oncogenic transformation in B cells[11]. In the latter case, the chromosomal localization of the immunoglobulin genes provided one of the first indications of the involvement of such translocations in oncogenic transformation. The chromosomal assignment of the α- and β-chain genes may, therefore, provide equally important clues for T-cell neoplastic transformation. The chromosomal location of the mouse and human β-chain gene family has been determined: the murine gene lies on chromosome 6 (refs 12, 13) whereas the human gene is located on chromosome 7 (refs 13, 14). Here we use a cDNA clone encoding the human α-chain to map the corresponding gene to chromosome 14.

The α-chain cDNA clone used in this study was isolated from a $\phi\lambda$gt10 library, constructed from messenger RNA isolated from the human T-cell line Jurkat[15], by cross-hybridization with a homologous mouse probe[8]. The sequence of the insert corresponds exactly to that of a previously published α-chain cDNA clone isolated from HPB-MLT[10] and comprises about three-quarters of the constant region plus almost the entire 3′-untranslated region of the human α-chain (M.K.L.C., M.J.O., G.T. and S.T., manuscript in preparation).

The insert (~900 base pairs, bp) from the $\phi\lambda$gt10 clone was subcloned into pBR322 and the resulting plasmid (pJ6α2) used to screen human and mouse DNA, and a panel of mouse/human somatic cell hybrid DNAs using Southern hybridization analysis. Human DNA digested with *Hin*dIII and hybridized with the pJ6α2 insert shows two bands of 4.2 and 2.9 kilobases (kb)

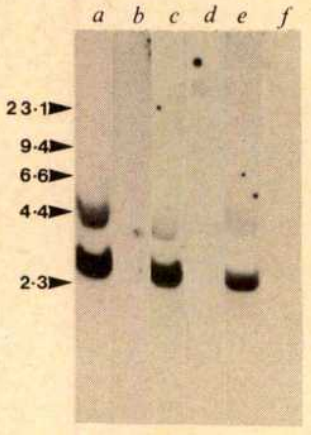

Fig. 1 Southern hybridization analysis of mouse/human somatic cell hybrid DNA. DNA of high M_r was prepared according to Maniatis *et al.*[34] and 20 μg was digested with *Hin*dIII and electrophoresed through 0.8% agarose, blotted onto nitrocellulose and hybridized with oligo-labelled[35] insert from pJ6α2. Hybridization was carried out at 65 °C in 3×SSC. The filters were washed at 65 °C in 0.2×SSC. The sizes of the DNA fragments were determined by reference to the mobilities of $\phi\lambda$*Hin*dIII markers. *a*, Human fibroblast (Bu) DNA; *b*, mouse L-cell (1R) DNA; *c*, hybrid F4SC13 C19 DNA; *d*, hybrid HORL411B6P DNA; *e*, hybrid FIR5R3 DNA; *f*, hybrid DT1.2R DNA.

Table 1 Segregation of a human α-chain gene in somatic cell hybrids

Note that several of the hybrids have been recloned and recharacterized since their description in the original reference. Human chromosomal constitution was determined by a combination of karyotypic[25], isozyme[36] and antigenic analysis[30]. Batches of cells for DNA production were checked by isozyme analysis.

*The hybridization conditions are given in Fig. 1 legend. Under conditions of high stringency only the 4.2- and 2.9-kb human bands were detected. In all cases where the hybrids were scored positive both bands were visible.

†A human fibroblast line derived from a human ovarian teratoma. This line was obtained from Dr S. Povey (MRC Biochemical Genetics Unit, London).

(Fig. 1*a*). This result is consistent with the nucleotide sequence of the human α-chain (ref. 10 and G.T. and S.T., unpublished observation), in which a *Hin*dIII site is located in the constant region, and suggests that a single constant-region gene segment is present in the human genome. One hybridizing band of 6 kb was detected with *Hin*dIII-digested mouse DNA probed at low stringency (data not shown). As the 4.2- and 2.9-kb bands were apparently specific to human DNA and the mouse-specific bands could be removed by washing at high stringency (Fig. 1*b*), the presence of the 4.2-kb and 2.9-kb fragments in *Hin*dIII-digested mouse/human somatic cell hybrid DNA could be used to determine the chromosomal location of the α-chain gene. Figure 1*c–f* shows Southern blotting analysis of DNA from four such hybrids. For hybrids positive for the human α-chain gene, both human-specific bands were always detected (see, for example, Fig. 1*c*, *e*). Inspection of the human chromosomal content of a panel of hybrids (Table 1) reveals that the human α-chain gene maps to chromosome 14. We, and others, have shown previously that the human β-chain gene family maps to chromosome 7 (refs 13, 14). Thus, the α- and β-chain genes lie on different chromosomes. The human β-chain genes also lie on a different chromosome from the immunoglobulin *Igh*, *Igk* and *Igl* loci. In contrast, the human α-chain gene is syntenic with the *Igh* loci, which have been localized in the region 14q32.33-14qter[16]. The human oncogene c-*fos* has also been localized to chromosome 14 in the region 14q21-q31[17].

A conserved linkage group between human chromosome 14 and mouse chromosome 14 occurs at the nucleoside phosphorylase (*Np*) locus (at 14q13.1 in human; reviewed in ref. 18). In man, nucleoside phosphorylase deficiency has been associated with severe T-cell immunodeficiency[19]. Interestingly, the gene encoding the mouse α-chain has been mapped to chromosome 14, close to the *Np-2* locus[20,21]. This observation suggests that the human α-chain gene may also lie close to the *Np* locus in a conserved linkage group. If this is the case, the human α-chain gene, although on the same chromosome, must reside a considerable distance from the *Igh* locus.

Abnormalities of chromosome 14 have been associated with human B-lymphocyte malignancies. Thus, Burkitt lymphomas are often associated with 8;14 translocations resulting in a juxtaposition of the c-*myc* and *Igh* loci[11]. Inversions of chromosome 14 due to breaks near q11 and q32 are found in T-cell chronic lymphocytic leukaemia and lymphomas, and simple translocations involving chromosome 14 have also been observed in T-cell malignancies[22–24]. For example, a translocation involving chromosomes 10 and 14 with a breakpoint at 14q11.2 has been found in a T-cell lymphoma cell line[24]. The involvement of the 14q11 region in these inversions and translocations suggests that it is related to T-cell function and that rearrangements involving this region may be involved in T-cell malignancies. If the human α-chain gene is located, by analogy with the linkage in the mouse, at or near the *Np* locus, it would be a candidate for such a gene. We are presently performing *in situ* hybridization analysis to test this possibility.

We thank our colleagues D. Swallow, S. Povey, M. Parkar and D. Simon for help with characterizing the hybrids.

Stimulation of the Na/H exchanger of sea urchin eggs by phorbol ester

Karl Swann & Michael Whitaker

Department of Physiology, University College London, Gower Street, London WC1E 6BT, UK

On fertilization of a sea urchin egg, marked changes occur in the cytoplasmic concentration of calcium and hydrogen ions. These ionic signals represent the necessary and sufficient stimuli for the increased metabolism, protein synthesis and DNA synthesis that constitute egg activation[1–3]. Cytoplasmic alkalinization, the major immediate cause of the increased rate of protein synthesis which

occurs at fertilization[4], arises because the sperm-induced intracellular calcium transient activates a coupled flux of sodium ions and hydrogen ions across the oolemma[5–7]. The experiments reported here suggest that the second messenger which links the activation of the Na/H exchange to the calcium transient may be a substance which stimulates protein kinase C[8], as 12-*O*-tetradecanoyl phorbol acetate (TPA), a known activator of protein kinase C[9], appears to stimulate protein synthesis by turning on the Na/H exchanger and causing a cytoplasmic alkalinization. Our data indicate that one consequence of treating other tissues with TPA, a tumour promoter, may be an increase in intracellular *p*H[10–12].

The synthesis of proteins from maternal mRNA is necessary for the normal development of the sea urchin embryo[13]. Figure 1 shows that a concentration of TPA that supports proliferation in cultured mammalian cells[14] increased the rate of incorporation of amino acid into protein in unfertilized sea urchin eggs (*Lytechinus pictus*). The increased incorporation of amino acid into protein was slower in onset and of lesser magnitude than that stimulated at fertilization or by treatment with the calcium ionophore A23187 (refs 1, 4). Fertilization or treatment with ionophore stimulated a 10-fold increase in the rate of protein synthesis which is first detected 15 min after fertilization, whereas 320 nM TPA caused a fourfold increase in the rate after a lag of 30 min. At fertilization and on treatment with ionophore, calcium is released from a store within the egg and the cytoplasmic calcium concentration increases[15,16]. In contrast, treatment of eggs with up to 3 μM TPA caused none of the morphological changes associated with the increased cytoplasmic calcium concentration and consequent cortical granule exocytosis. The cortical granule exocytosis is a sensitive *in situ* assay for an increased intracellular calcium concentration[15,17]. As no cortical granule exocytosis occurred on treatment with TPA and since TPA itself does not, we have found, inhibit exocytosis *in vitro* or *in vivo* at these concentrations, we infer that no substantial increase in the calcium concentration, such as that which normally occurs at fertilization, occurred when the egg was treated with TPA.

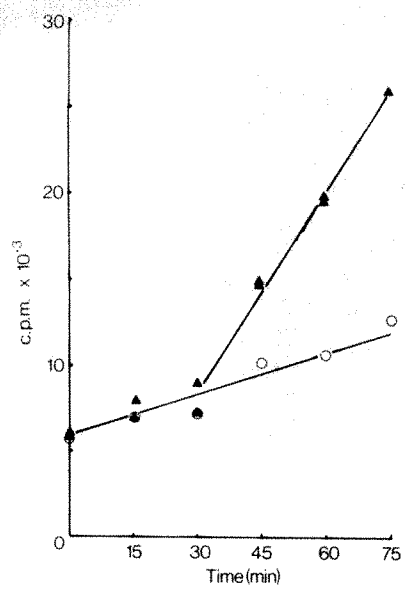

Fig. 1 TPA stimulates the incorporation of [4, 5-^{3}H]leucine into egg trichloroacetic acid (TCA) precipitates. Incorporation was measured using published methods[23]. Eggs were pre-loaded with radioactive amino acid and the TCA precipitate collected on glass-fibre filters. ▲, 320 nM TPA (Sigma) was added at $t = 0$ to eggs in artificial sea water (450 mM NaCl, 50 mM $MgCl_2$, 10 mM KCl, 11 mM $CaCl_2$, 2.5 mM $NaHCO_3$, *p*H 8.0). ○, Controls. The data shown are from two experiments. The mean increase in rate of [4, 5-^{3}H]leucine incorporation was 3.2 ± 0.1-fold (mean ± s.e.m., $n = 4$). TPA-treated eggs have an intact intracellular calcium store as they will raise normal fertilization membranes on insemination or addition of calcium ionophore. Temperature 16 °C.

Other parthenogenetic activators exist which stimulate protein synthesis in sea urchin eggs without releasing the egg's internal calcium store[4,18]. These are penetrating weak bases which stimulate protein synthesis by raising the egg's cytoplasmic *p*H[19]. Figure 2 presents data which indicate that TPA may be acting in a similar manner: unfertilized eggs loaded with fluorescein by incubation with fluorescein diacetate show a stable

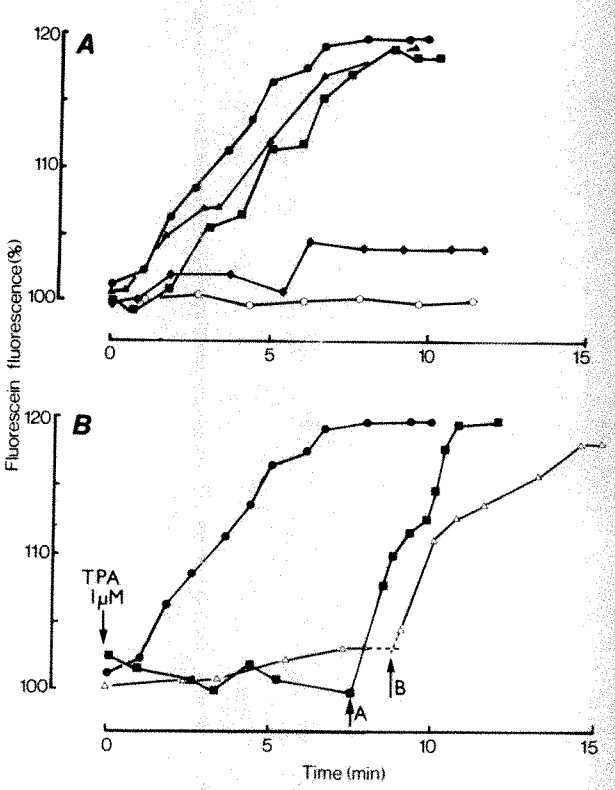

Fig. 2 The increase in fluorescein fluorescence in eggs treated with TPA and its less potent methyl analogue, 4-*O*-methyl-tetradecanoyl phorbol ester. Fluorescein fluorescence was measured in individual eggs using a Leitz Diavert fluorescence microscope and a photomultiplier as described previously[2]. *A*, Extent of the increase in fluorescein fluorescence at various concentrations of TPA: ●, 1,000; ▲, 200; ■, 100; ◆, 50 nM. The increase in fluorescence at maximal TPA concentrations was 117 ± 1.8% (mean ± s.e.m., $n = 9$). The increase in fluorescein fluorescence at fertilization in identical experimental conditions is 119 ± 3.1% (mean ± s.e.m., $n = 7$)[3]. To illustrate the pharmacological specificity of the response, open circles show the lack of response to the less potent analogue, MeTPA. *B*, Inhibition of the response to 1,000 nM TPA (●) by complete replacement of sodium in sea water by choline (■, $NaHCO_3$ was replaced with $KHCO_3$) or by addition of 100 μM dimethylamiloride (△). When sodium-containing sea water was re-admitted at the time indicated by the arrow labelled A, or dimethylamiloride removed at the time indicated by arrow B, the response was immediate.

Methods. Eggs were loaded with fluorescein by incubating them in sea water containing 50 μM fluorescein diacetate (Molecular Probes, Junction City, Oregon) for 3–5 min and washed three times before being lightly attached with polylysine to a coverslip on the microscope stage. Excitation was provided by a mercury vapour lamp provided with a 3 OD neutral density filter and 450–490-nm bandpass filter. Epifluorescent illumination was achieved with a 510-nm dichroic mirror. Emitted light was collected by a photomultiplier in the image plane provided with a 510-nm long-pass filter. The intensity of the 520-nm fluorescein fluorescence peak is sensitive to *p*H over the physiological range and provides information as to relative changes in *p*H. Exciting light was applied intermittently to minimize fluorescence bleaching. In these conditions the fluorescence signal remains constant for extended periods (> 1 h), indicating that the dye is neither lost from the eggs nor significantly bleached. We suppose that the fluorescence which we measure primarily reflects cytoplasmic *p*H, an assumption borne out by the similarities between the results obtained with this method and with that using intracellular *p*H microelectrodes[2]. Temperature 16 °C.

fluorescence signal[2] which increases when the eggs are treated with 100–1,000 nM TPA. The increase in fluorescein fluorescence is similar in magnitude to that seen at fertilization or after treatment with A23187, and can be attributed to an increase in cytoplasmic *p*H[2]. Though it might be argued that a proportion of the TPA-induced increase in fluorescein fluorescence is the result of fluorescein uptake into mitochondria[20], the absolute requirement for external sodium ions and the identical time course of the fluorescein increase and *p*H microelectrode potential under a variety of conditions[2] makes a substantial mitochondrial contribution to the fluorescence increase unlikely. That the TPA-induced increase in intracellular *p*H requires external sodium ions also suggests, by analogy with fertilization, that it is the exchange of external sodium ions for internal hydrogen ions that is responsible for the cytoplasmic alkalinization of TPA-treated eggs. This conclusion was confirmed by the finding that dimethylamiloride, a drug which specifically inhibits electroneutral Na/H exchange[21], inhibits the TPA-induced cytoplasmic alkalinization in eggs (see Fig. 3*B*).

The activation of the Na/H exchanger at fertilization leads to a transient net efflux of hydrogen ions from the egg[5–7]. Figure 3 shows that TPA induced an efflux of hydrogen ions that behaved very similarly to the hydrogen ion efflux which occurs at fertilization. Figure 3 also shows that 4-*O*-methyltetradecanoyl phorbol ester (MeTPA), a less potent TPA analogue, was ineffective at these concentrations. The TPA-induced efflux rate was maximal at 2.5 min and had fallen to control levels by 5 min after treatment. The efflux was sodium-dependent; it was sensitive to external sodium ion concentration in the range 0.1–5 mM at *p*H 8.0. This dependence on external sodium concentration is identical to that of the fertilization-induced Na/H exchange, which also requires only a small fraction of the normal sodium concentration of sea water for full activation[22]. The TPA-induced hydrogen ion efflux was half-maximal at 100 nM TPA, representing a net efflux of 20 nmol ml^{-1} of a 1% egg suspension at *p*H 8.0. The fertilization-induced efflux under similar conditions was 30 nmol ml^{-1} of a 1% egg suspension. The Na/H exchanger has been reported to contribute three-quarters of the total acid efflux occurring at fertilization[5] and is inhibited by amiloride[5,7]. We find that the TPA-induced hydrogen ion efflux is half-maximally inhibited by 40 μM dimethylamiloride, the concentration which half-maximally inhibits A23187-induced hydrogen ion efflux (see Fig. 3*B*). We conclude that TPA stimulates the Na/H exchanger of unfertilized eggs to extrude a quantity of hydrogen ions equivalent to the quantity extruded at fertilization. Activation of the Na/H exchange is a sufficient explanation of the effects of TPA on the intracellular *p*H.

A simple hypothesis for the mechanism by which TPA stimulates protein synthesis is that it acts primarily on the Na/H exchanger, and that it is the ensuing increase in intracellular *p*H which is responsible for the increase in the rate of incorporation of amino acid into protein. This simple hypothesis is supported by the data of Fig. 4. The increase in the rate of incorporation of amino acid into protein induced by TPA is similar to that induced by treatment with the weak base

Table 1 Effect of dimethylamiloride and removal of Na ions on TPA-induced increase in protein synthesis

	c.p.m. in protein at:	
	45 min	60 min
Control	2,110 ± 531	3,690 ± 284
320 nM TPA	4,783 ± 515*	5,265 ± 461†
320 nM TPA + 100 μM dimethylamiloride	2,773 ± 461 ($n = 3$)*	—
320 nM TPA in Na-free sea water	—	3,592 ± 702†

The c.p.m. values are the mean ± s.e.m. of four experiments of the type described in Fig. 1 legend.
* $P < 0.05$; † $P < 0.01$, Student's *t*-test.

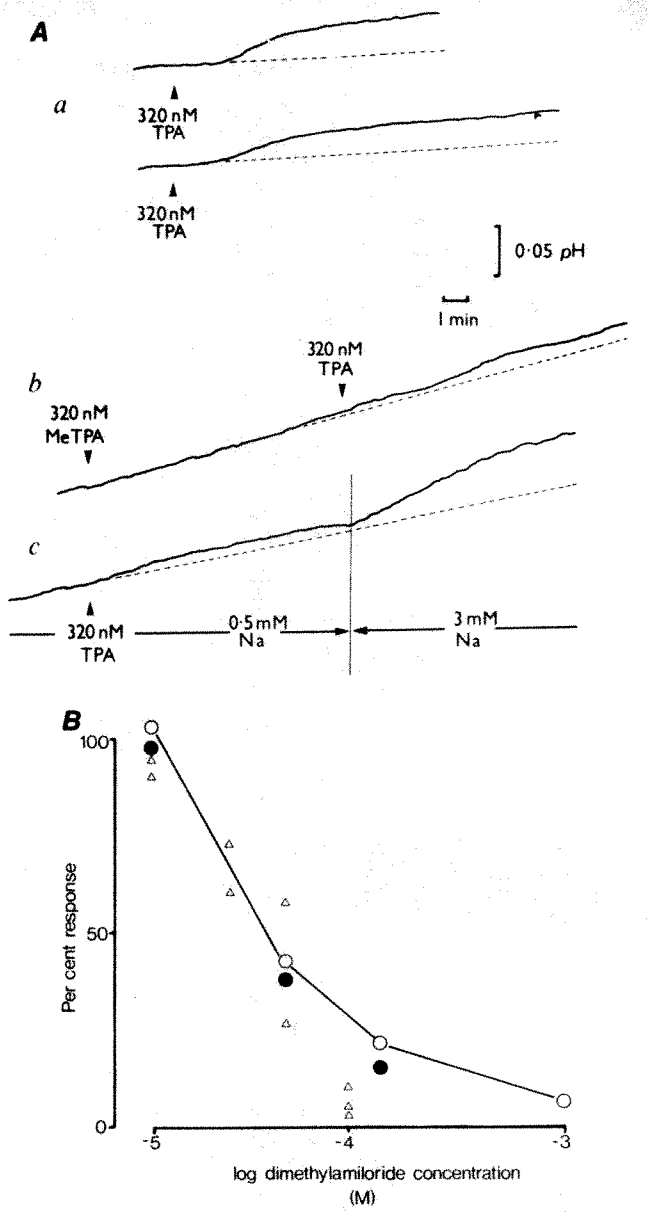

Fig. 3 The hydrogen ion efflux from unfertilized eggs measured with an external *p*H electrode in a 2% egg suspension in artificial sea water. The sea water was buffered normally and the external *p*H change kept to a minimum as the extent of the hydrogen ion efflux depends on the external *p*H[6]. ***A***: *a*, Two representative examples of the external acidification observed when the egg suspension was treated with 320 nM TPA (added from a 320 μM stock solution in dimethyl sulphoxide (DMSO); DMSO did not itself induce any of the changes shown in this or the other figures). The extent of the acid efflux was determined by back-titration with sodium hydroxide[5]. *b*, MeTPA (1,000 nM) caused no significant increase in acid efflux. A significant though attenuated response to 320 nM TPA was seen subsequently. *c*, The response to 320 nM TPA in artificial sea water containing 0.5 mM Na (choline-substituted) is one-fifth of the response in normal sea water. Further reduction in the sodium concentration completely abolishes the response (not shown). When sodium was added to increase the sodium concentration to 3 mM externally, the full TPA-induced hydrogen ion efflux was observed. The broken line is an extrapolation of the increase in extracellular *p*H which occurs in stirred, dense unfertilized egg suspensions in these conditions. Suspensions rapidly attained this linear rate of acid production, which was recorded for 5 min in each experiment before addition of the drug. ***B***, The TPA-induced hydrogen ion efflux is inhibited by dimethylamiloride[21] (●), as is the hydrogen ion efflux caused by the calcium ionophore A23187 (○). Also shown (△) is the inhibition by dimethylamiloride of the TPA-induced fluorescein fluorescence, measured as described in Fig. 2 legend. Sea water containing 50 mM sodium. Dimethylamiloride was given by Dr E. J. Cragoe Jr. Temperature 18 °C.

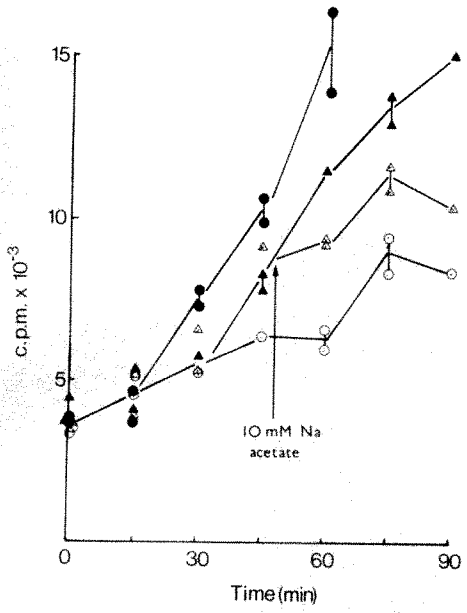

Fig. 4 TPA-induced protein synthesis and intracellular *p*H. The data are from two experiments. ●, 10 mM NH_4Cl induces a similar increase in the rate of protein synthesis to that obtained on treatment with 320 nm TPA (▲). When 10 mM sodium acetate in artificial sea water (*p*H 6.5)[19] is added to eggs which have been treated with 320 nM TPA (△), the rate of protein synthesis falls to that of controls (○). Conditions and methods are identical to those of the experiments of Fig. 1.

ammonium chloride, which is known to increase the rate of protein synthesis largely via its effects on intracellular *p*H[19]. Moreover, if the egg cytoplasm is made less alkaline after treatment with TPA by adding acetate, a weak acid[19], to the sea water in which the eggs are suspended, then the rate of protein synthesis falls back to the rate seen in the untreated egg. Finally, Table 1 shows that the TPA-induced increase in protein synthesis is prevented by the presence of 100 μM dimethylamiloride or by the removal of sodium ions from the sea water in which the eggs are suspended. These data indicate that the TPA-induced increase in intracellular *p*H is a necessary stimulus for protein synthesis.

Our results strongly suggest that TPA stimulates protein synthesis in unfertilized sea urchin eggs by activating a Na/H exchange at the oolemma, which in turn leads to a cytoplasmic alkalinization similar in magnitude to that observed at fertilization. We believe that these effects occur without the participation of a calcium transient of the magnitude observed at fertilization, though we cannot exclude the possibility that small alterations in cytoplasmic calcium occur. The absence of a calcium transient in TPA-treated eggs accounts for the disparity between the rates of protein synthesis in fertilized and TPA-treated eggs: it has been shown that maximal rates of protein synthesis are achieved only if both the calcium concentration and intracellular *p*H increase[23]. The prevailing idea is that many of the actions of TPA may be explained by its ability to promote phosphorylation of specific membrane proteins through activation of a membrane protein kinase, protein kinase C[9,24]. Protein kinase C is thought to be regulated *in vivo* by diacylglycerol, one of the two putative second messengers generated by the hydrolysis of plasma membrane polyphosphoinositides[25]. We have shown that the other second messenger, inositol trisphosphate, will activate eggs and that physiological calcium concentrations promote the hydrolysis of egg membrane polyphosphoinositides[26]. We suggest that diacylglycerol may be the second messenger that links the stimulation of the Na/H exchange to the calcium transient of the egg at fertilization and so promotes mitosis and cell division.

We thank Professor P. F. Baker, Dr M. J. Berridge, Dr R. A. Steinhardt and Dr C. Frelin for their advice and criticisms and Dr E. J. Cragoe for the gift of dimethylamiloride. This work was supported by grants from the SERC, the Wellcome Trust, the Royal Society and the Dale Fund of the Physiological Society.

Note added in proof: A stimulation of Na/H exchange by phorbol ester and diacylcylcerol has recently been reported to occur in cells in culture[27].

Focus formation in rat fibroblasts exposed to a tumour promoter after transfer of polyoma *plt* and *myc* oncogenes

Gisèle Connan, Minoo Rassoulzadegan & François Cuzin

Unité INSERM 273, Centre de Biochimie, Université de Nice, Parc Valrose, 06034 Nice, France

The gene encoding the large-T protein of polyoma virus (*plt*), the E1A genes of adenoviruses, the viral *myc* gene (v-*myc*) or rearranged forms of the cellular c-*myc* gene confer on rat embryo fibroblast (REF) cells in primary culture a series of new properties ('immortality', reduced serum requirement and sensitivity to transformation by viral and activated cellular oncogenes) but do not induce the appearance of transformed foci[1–6]. We now report that focus formation can be induced after transfer of these genes into either REF or established FR3T3 rat cells by subsequent exposure to the tumour promoter 12-*O*-tetradecanoylphorbol 13-acetate (TPA)[7,8]. Frequencies of transformation are in the same range as those usually observed for transformation with complete polyoma DNA or with a mixture of cloned *myc* and *ras* oncogenes. These results further characterize the 'immortalized' state induced by *plt* and *myc* as one in which the cells maintain a normal growth control in many respects but can be further acted upon to produce a neoplastic progeny.

Complete transformation of REF cells first requires the establishment of immortalization, a complex phenotype induced by *plt*, adenovirus E1A or v-*myc* and c-*myc* oncogenes (group I). The activity of these genes allows subsequent transformation by a second class of oncogenes (group II) which includes polyoma virus *pmt* (middle-T protein), adenovirus E1B, retroviral and activated cellular *ras* genes[2–5]. Transfer of *plt*, rearranged *myc* or adenovirus E1A genes into REF cells results in all cases in the same alterations of growth control in culture,

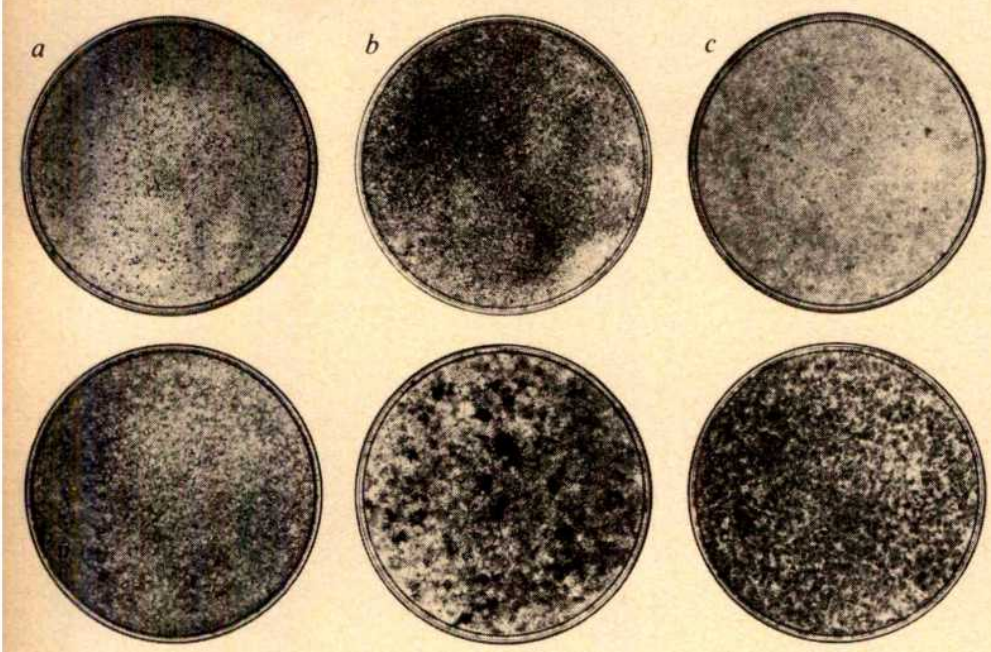

Fig. 1 Effect of TPA on FR3T3 cells immediately after transfer of the *plt* gene and on FR3T3-LT1 cells, which express constitutively the polyoma virus large-T protein[1]. Experimental conditions are described in the text and in Table 1 legend. *a*, FR3T3; *b*, FR3T3 after transfer of plasmid pPyLT1; *c*, FR3T3-LT1. Upper row, control cultures treated with DMSO alone; bottom row, TPA-treated cultures.

most characteristically the acquisition of unlimited growth ability and reduced requirements for serum factors (refs 2, 6 and our unpublished results). Apart from these changes, immortalized cells retain the low saturation density and anchorage dependence of normal fibroblasts and thus cannot be selected by the usual transformation procedures (focus formation, growth in suspension). However, although still normal in many respects, *plt*- and *myc*-immortalized lines exhibit an increased probability of further oncogenic transformation. Tumour promoters transform cells which have first undergone an 'initiation' event[7,8] induced by carcinogens, which have been shown independently to immortalize rodent embryo fibroblasts[9,10]. We therefore investigated whether cells immortalized by *plt* or *myc* could be transformed further by treatment with TPA.

The effect of a 12-day exposure to TPA (2×10^{-5} M in 0.01% dimethyl sulphoxide, DMSO) after transfer of the polyoma *plt* gene was first studied in REF cells. Control cultures either were not treated at all or were treated after gene transfer with DMSO in the absence of TPA or were treated only with TPA. Foci developed in cultures treated with TPA after gene transfer (data not shown), but precise quantitation was hampered by the background of cells growing past confluency in primary REF cells, especially after treatment with TPA, which is known to have mitogenic effects[11]. Selection for colonies in agarose-gelified medium, however, produced unambiguous results (Table 1). Whereas neither treatment with TPA nor transfer of *plt* alone led to colony formation, the combination of the two treatments resulted in the appearance of clones that produced large colonies in suspension after the removal of TPA. Establishment of cell lines from such colonies (not shown) confirmed that they stably maintained their transformed phenotype. Transfer of the polyoma *pmt* gene (middle-T protein), with or without TPA treatment, conferred on REF cells only the ability to grow for a limited number of generations in suspension, as expected from the absence of an immortalization function.

We then investigated whether TPA produced the same effect in cells of the established line FR3T3. This would imply that the spontaneous immortalization event that gave rise to the line is not equivalent to immortalization by *plt* or *myc* genes, as has been suggested for FR3T3 rat cells[6] and BALB/c3T3 mouse cells[12] by studies on the reduced requirement for serum growth factors in culture which is conferred by group I oncogenes. TPA treatment, in the same conditions as in the previous experiments, did not affect FR3T3 cell growth; however, following transfer of the *plt* gene, foci appeared within 4–6 weeks of TPA removal (Fig. 1). The same result was obtained when *plt* was replaced by the viral *myc* gene or by a rearranged mouse c-*myc* gene (carried on plasmids pSV-v-myc and pSV-c-myc-1, respectively[4]; Table 2). The numbers of foci per plate after *plt* and TPA treatment were in the same range as obtained after transfer of

Table 1 Colony formation in agarose medium by REF cells after transfer of isolated polyoma genes and subsequent treatment with TPA

Transfer of plasmid	Viral protein	TPA treatment	No. of colonies per plate (2×10^5 cells)	Size of colonies
None	–	–	0, 0, 0	–
None	–	+	0, 0, 0	–
pPyLT1	Large-T	–	0, 0, 0	–
pPyLT1	Large-T	+	2, 5, 8, 1, 3, 10	$>10^4$ cells*
pPyMT1	Middle-T	+	21, 13, 10, 17, 25, 19	<50 cells

REF secondary cultures were prepared as described previously[2] and DNA of plasmids pPyLT1 (*plt* gene) and pPyMT1 (*pmt* gene)[14,15] transferred by the protoplast fusion technique also as described elsewhere[1]. Cells were maintained for a total of 12 days with three medium changes in DMEM supplemented with 10% newborn calf serum (Gibco) and containing either 2×10^{-5} M TPA (Sigma) in 0.01% DMSO or 0.01% DMSO without TPA. Cells were then trypsinized and seeded in agarose medium[1] at a density of 2×10^5 cells per plate (three to six identical plates). The number of colonies in each plate was counted 3 weeks later.

* Macroscopically visible colonies.

Table 2 Focus formation by FR3T3 cells after transfer of *plt* and *myc* genes and subsequent treatment with TPA

Transfer plasmid	TPA treatment	Foci per plate (2×10^5 cells)
None	–	0, 0, 0
None	+	0, 0, 0
pPyLT1	–	0, 0, 2
pPyLT1	+	7, 15, 18
pSV-v-myc	–	0, 0, 1
pSV-v-myc	+	3, 4, 9
pSV-c-myc-1	–	0, 0, 0
pSV-c-myc-1	+	16, 22, 24

DNA of plasmids pPyLT1[15], pSV-v-myc and pSV-c-myc-1[4] was transferred into FR3T3 cells by the protoplast fusion technique as described in ref. 1 and TPA treatment was applied as described in Table 1 legend. Foci were counted following Giemsa staining after 6 weeks.

Table 3 Stability of the transformed phenotype during prolonged growth in the absence of TPA in cell lines derived from foci induced by TPA after transfer of the *plt* and *myc* oncogenes

Cell line	Plating efficiency in agarose medium (%)
FR-PLTTPA-32	10
FR-CMYCTPA-3	14
FR-VMYCTPA-3	8
FR3T3	<0.001

Cell lines FR-PLTTPA-32, FR-VMYCTPA-3 and FR-CMYCTPA-3 were isolated after transfer of plasmids pPyLT1, pSV-v-myc and pSV-c-myc-1, respectively, and subsequent TPA treatment as described in Table 2. For focus formation, the cultures had been maintained in DMEM without TPA for 4 weeks. Cells picked from foci were then grown in the same medium for three successive passages (~10 generations), still in the absence of TPA, and eventually seeded in agarose-gelified DMEM (2×10^5 cells per plate), in parallel with control FR3T3 cells. The number of colonies per microscope field, counted after 1 week, is expressed as a percentage of the input.

a wild-type polyoma genome expressing both the *plt* and *pmt* genes (data not shown; see ref. 1). When cells picked from such foci were grown further in Dulbecco's modified Eagle's medium (DMEM) in the absence of TPA, they still exhibited the characteristic morphology of transformed cells, and their efficiency of plating in agarose medium (10–20%) was comparable with that of typical virus-transformed lines[13] (Table 3). Cells that permanently expressed immortalizing oncogenes were also treated with TPA. Such cell lines had been derived previously from FR3T3 cells after transfer of *plt* and *myc* and selection by colony formation in medium supplemented only with 0.5% serum[1,6]. Unlike the original FR3T3 cells, such cultures reacted to TPA treatment by a dramatic change in their growth properties, showing an increase in saturation density within 2 weeks of TPA removal (Fig. 1).

Expression of polyoma virus *plt*, v-*myc* and rearranged c-*myc* genes therefore not only confers on normal rodent fibroblasts a set of new growth properties, such as immortalization or serum independence, but also allows further transformation by activated *ras* and polyoma *pmt* genes[1–6]; these genes bring the cells into a state where they now respond to environmental stimuli that do not induce permanent transformation of the original normal cell. Our results further demonstrate that the phenotype induced by group I oncogenes is not equivalent to that of the spontaneously immortalized 3T3 cells, as previously indicated by studies on growth factor requirements[6,12]. From a practical viewpoint, we note that, as found previously using other biological assays[6,12], gene transfection combined with TPA treatment may provide a means of discovering new oncogenes of this group possibly activated in human and experimental tumours.

We thank L. Carbone, F. Tillier and M. L. Varani for technical assistance and Dr R. A. Weinberg for plasmids pSV-v-myc-1 and pSV-c-myc-1. This work was supported by grants from the Association pour la Recherche sur le Cancer (France).

The synthesis and secretion of growth hormone (GH) by the somatotropic cells of the anterior pituitary is under complex hormonal regulation. The hypothalamic peptides, growth hormone releasing factor (GHRF) and somatostatin, respectively stimulate[1–3] and block[4] GH release. We have shown that treatment of primary cultures of rat anterior pituitary cells with GHRF stimulates transcription of the GH gene, as well as GH release, and that this reflects the response of pituitary cells *in vivo*[5]. Gick *et al.* have shown a stimulation of GH mRNA levels in normal pituitary cells in response to GHRF[6]. Because normal pituitary cells are the physiological target for GHRF and because they exhibit both transcriptional and release responses to the hormone, they provide a valuable system with which to examine the important possibility of a link between hormone synthesis and release in secretory cells. Using this system, we demonstrate here that GHRF stimulates GH gene transcription independently of GH release and, conversely, that other agents can stimulate GH release without affecting transcription of the GH gene.

Treatment of primary cultures of pituitary cells with GHRF leads to a rapid rise in intracellular levels of cyclic AMP[7]. This event, which has been previously shown to stimulate the release of GH from pituitary cells[8–12], suggests that the effects of GHRF are mediated, at least in part, by a cyclic AMP-dependent mechanism. GHRF- or cyclic AMP-stimulated GH release is blocked by agents that block voltage-dependent calcium channels, such as verapamil[7–12], demonstrating that the release of stored GH is calcium-dependent. Therefore, it seems that the sequence of events leading to GHRF-induced GH release includes both a rise in cyclic AMP levels and a Ca^{2+}-dependent step that causes GH release. Our experiments were designed to investigate the possible link between GHRF-stimulated GH release and transcription, by determining which, if any, of the events leading to GH release are also involved in stimulation of GH gene transcription. We measured GH-specific transcription and GH release, as well as intracellular cyclic AMP levels, for each treatment described. Cell treatments were performed for 1 h, at which time nuclei were collected, and GH-specific transcription was determined by nuclear run-off assay[5]. GH release and intracellular levels of cyclic AMP were monitored by radioimmunoassay (RIA).

To determine whether release of stored hormone is required for the transcriptional stimulation by GHRF, we used several treaments to block GH release. We performed experiments in media containing either 2.5 mM EGTA, to chelate Ca^{2+}, or 100 μM verapamil, to block voltage-dependent Ca^{2+} channels. In both cases, GHRF induction of GH release was blocked, but stimulation of GH gene transcription and intracellular cyclic AMP levels were not diminished (Fig. 1). Treatment with 10 nm somatostatin lowered basal GH release as well as GHRF-stimulated GH release (Fig. 2). The rise in cyclic AMP was diminished by somatostatin, as expected[7] (60% reduction), but there was no inhibitory effect on basal, or GHRF-stimulated, GH gene transcription. These results indicate that the transcriptional response to GHRF is not dependent on GH release or on extracellular Ca^{2+}.

§ Present address: Department of Biological Sciences, Stanford University, Stanford, California 94305, USA.

Although the above experiments show that GH release is not required for GHRF stimulation of GH gene transcription, they do not address the possibility that GH release alone can stimulate transcription of the GH gene. To examine this possibility directly, we used several different treatments to stimulate GH secretion. Depolarizing concentrations of K^+ have been shown to release GH from pituitary cells[13,14]. A 1-h treatment with 58 mM K^+ caused GH release without affecting either intracellular cyclic AMP levels or the rate of transcription of the GH gene (Fig. 3). Treatment of pituitary cells with the tumour promoter, phorbol myristate acetate (PMA)[15,16], caused GH release[17], but failed to stimulate cyclic AMP production or GH gene transcription (Fig. 3). Forskolin, a diterpene compound

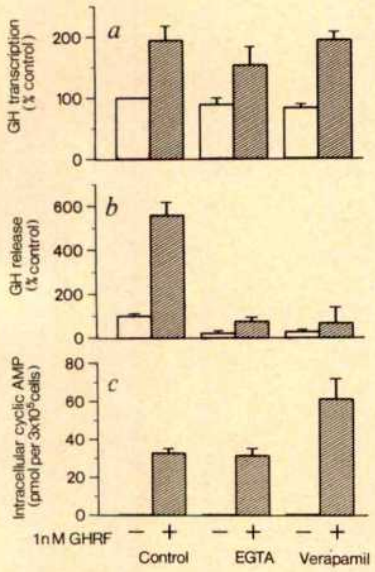

Fig. 1 Effects of EGTA and verapamil on GHRF stimulation of GH gene transcription (*a*), GH release (*b*), and intracellular cyclic AMP levels (*c*). Parallel plates of cells were treated with 1 nM GHRF (+) or GHRF dilution buffer (−). Where indicated, the medium contained 2.5 mM EGTA or 100 μM verapamil. GH-specific transcription and GH release were determined from the same experiment and are expressed as % of control. Cyclic AMP was measured in a separate parallel experiment and is expressed as pmol cyclic AMP per 3×10^5 cells.

Methods. *a*, *b*, Primary cultures of anterior pituitary cells were prepared as described previously[5,25,26] and plated at a density of 5×10^6 cells per 60-mm dish in medium containing 5 nM dexamethasone and 30 pM triiodothyronine. After 3 days in culture, the cells were washed by multiple medium change with B-PJ medium containing 0.1% bovine serum albumin and 2.5×10^{-4} M ascorbic acid[26] and returned to the incubator. After 1 h of incubation, they were treated with 1 nM rat hypothalamic GHRF (rhGHRF, synthesized by J. Rivier[3]) or a comparable volume of GHRF dilution buffer (1 mM acetic acid), in fresh B-PJ medium (control) or B-PJ containing 2.5 mM EGTA or 100 μM verapamil. After 1 h of treatment, the medium was removed from the cells and assayed for immunoreactive GH by RIA[7]. Cells were lysed, nuclei were prepared and elongation of nascent RNA chains was carried out as previously described[5,27]. RNA was prepared [27] from the nuclei and hybridized to excess plasmid DNA immobilized on nitrocellulose filters. The filters were washed, RNase-treated, dried and counted in toluene scintillation fluid. GH gene transcription was measured by quantifying RNase-resistant hybridization to a full-length GH cDNA clone. Background hybridization was determined by hybridization to pBR322 and the background values were subtracted from the GH hybridization values to give specific hybridization. GH-specific hybridization was determined as p.p.m. of total input RNA, and expressed as % of control (mock-treated). In reporting the data, no corrections were made for the size of the hybridization probe or the efficiency of hybridization. Each point represents treatment of a single plate of cultured cells and all experiments were repeated at least twice. Hybridizations were done in triplicate and data are presented as the mean ±s.e. for triplicate hybridizations from two similar experiments. *c*, Cells were prepared as in *a*, except that they were plated at 3×10^5 cells per well, in Linbro 24-well Petri dishes. Cell treatments were carried out as in *a*. After 1 h of treatment, cells were processed for cyclic AMP extraction as described previously[28]. All treatments were carried out in triplicate wells. Cyclic AMP was assayed[7] by RIA.

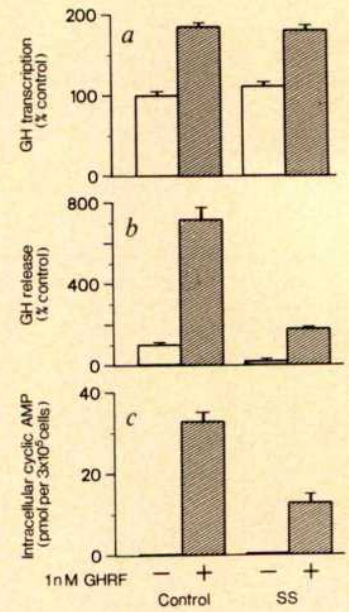

Fig. 2 Effect of somatostatin (SS) on GHRF stimulation of GH gene transcription (*a*), GH release (*b*), and intracellular cyclic AMP levels (*c*). Parallel plates of cells were treated with 1 nM GHRF (+) or dilution buffer (−), in the presence or absence of 10 nM SS in the medium.

Methods. Same as for Fig. 1. The experiment was repeated three times with similar results, and the data shown are from one representative experiment.

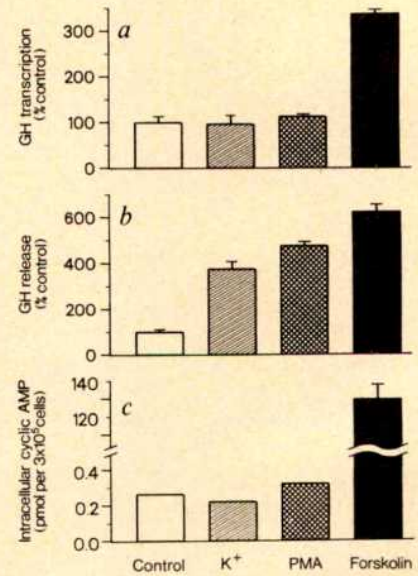

Fig. 3 Effects of K^+, PMA and forskolin on GH gene transcription *a*, GH release *b*, and intracellular cyclic AMP levels *c*. Parallel plates of cells were incubated in the presence or absence of 58 mM K^+, 100 nM PMA, or 10 μM forskolin. In *a* and *b*, values for each treatment are expressed as per cent of the control value for that treatment. In *c*, absolute values are shown. Controls for *c* did not differ significantly.

Methods. Same as for Fig. 1, except that K^+ treatment was carried out in Krebs' Ringer's buffer with 11 mM glucose. Treatments were performed at least twice with similar results, and results reported are from one representative experiment. Where error bars are not shown, the standard error was too small to plot.

that activates the catalytic subunit of adenylate cyclase[18], also stimulated GH release, but, unlike K^+ and PMA, forskolin caused a rise in intracellular cyclic AMP levels and stimulated GH gene transcription also (Fig. 3).

Exposure of pituitary cells to GHRF provokes several cellular responses, including a rise in intracellular cyclic AMP levels and a Ca^{2+}-dependent step that leads to GH release. We have shown that GH release is not the stimulus for the increase in transcription, by demonstrating that the transcriptional induction occurs in conditions that inhibit GH release, and that two treatments that stimulate GH release in the absence of GHRF have no effect on transcription of the GH gene. As GHRF stimulation of GH gene transcription is not dependent on external Ca^{2+}, it also follows that the Ca^{2+}-dependent step in the release response is not the stimulus for the transcriptional response.

As the physiological inhibitor of GHRF action, it might be expected that somatostatin would block the transcriptional effects of GHRF. Somatostatin reduces, but does not eliminate, the GHRF-stimulated rise in cyclic AMP[7], and has been shown to activate the N_i (inhibitory) subunit of adenylate cyclase[19]; but there is much evidence to suggest that somatostatin exerts another inhibitory effect on GH release at the calcium-dependent step(s) in the release pathway, distal to the elevation of cyclic AMP levels. Somatostatin blocks stimulation of GH release by cyclic AMP derivatives[20] and agents that raise cyclic AMP levels[7,11], as well as treatments which cause influx of Ca^{2+} (refs 13, 14). Furthermore, Stachura has proposed that somatostatin has no effect on GH synthesis, based on the observation that dibutyryl cyclic AMP causes a build-up of stored GH behind a somatostatin block[21,22]. Our results show that somatostatin inhibits GH release without influencing GHRF-stimulated transcription of the GH gene, which is consistent with Stachura's model.

Of the agents we used to stimulate GH release in the absence of GHRF, forskolin caused a rise in cylic AMP levels, whereas PMA and K^+ did not. Of the three agents, only forskolin stimulates GH gene transcription. These data, together with our observation that neither EGTA, verapamil, nor somatostatin eliminates the GHRF-induced rise in cyclic AMP, suggest a link between the rise in intracellular cyclic AMP levels and stimulation of GH gene transcription. If cyclic AMP were responsible for the stimulation of GH gene transcription, such an effect might be mediated by phosphorylation of putative nuclear regulatory proteins. Phosphorylation of nuclear proteins has been associated with the stimulation of prolactin transcription by thyrotropin-releasing hormone[23] and cyclic AMP[24]. In our system we have observed phosphorylation of H1 histone at serine 37 in response to treatment with GHRF or 8-bromo cyclic AMP (M.B. and M. Waterman, unpublished observations). Taken together, the data presented here clearly show that GHRF stimulation of GH gene transcription occurs independently of GH release and suggest a role for cyclic AMP as the mediator of the transcriptional stimulation.

We thank Jean Rivier for supplying GHRF and Gayle Yamamoto for the preparation of the pituitary cell cultures and for helpful discussions. We also thank Marian Waterman and Geoffrey Murdoch for their advice and comments, Kelly Mayo for critical reading of the manuscript and Diane Jolley for performing the GH RIAs. M.B. acknowledges predoctoral support from the Department of Biology at the University of California, San Diego. L.M.B. is supported by NIH postdoctoral fellowship no. AM 06864. This research was supported by NIH grants GM 26444 and AM 26741 and conducted in part by the Clayton Foundation for Research, California Division.

The discovery of human pancreatic growth hormone releasing factors (GHRFs)[1,2] and subsequent characterization of human hypothalamic GHRF[3] has led to studies on the role of these peptides in stimulating growth hormone (GH) release[4–6], and attempts to use GHRF peptides to increase growth rates in short children are already underway[7]. However, there is no experimental evidence in animals that exogenous GHRF promotes growth *in vivo*. Although anaesthetized rats release GH reproducibly in response to GHRF injections[4,8], the responses in conscious male rats are much more variable[5,6], perhaps because of their highly episodic endogenous GH secretory pattern[9]. In contrast, female rats secrete GH in a more continuous pattern[10] and respond reproducibly to repeated injections of GHRF. We report here that it is possible to establish a 'male' type of GH secretory pattern in normal female rats by long-term pulsatile intravenous (i.v.) infusions of the active human GHRF fragment GHRF (1–29)NH_2. We found that this treatment accelerates growth and increases pituitary GH content, whereas continuous infusions of this GHRF fragment at the same daily dose are ineffective. Pulsatile, but not continuous GHRF also stimulates growth in animals made GHRF-deficient by neonatal monosodium glutamate treatment. Thus exogenous GHRF will stimulate growth in both GHRF-deficient and normal animals provided it is administered in an appropriate pattern.

Injections of hGHRF(1–29)NH_2 (1 μg) were given i.v. every 3 h to a group of six conscious female rats (Fig. 1*a*). This treatment produced plasma GH profiles in female rats which were very similar to the endogenous GH secretory pattern in male rats (Fig. 1*b*). There was no evidence of endogenous secretory episodes between the exogenously induced GH pulses, and all the animals became entrained, responding uniformly to successive injections with peak plasma GH levels exceeding 1 μg ml^{-1}. Using a chronic i.v. infusion system with programmable multi-channel infusion pumps[11,12], groups of eight female rats were given saline or hGHRF(1–29)NH_2 either as a continuous infusion (8 μg per day) or as 1-μg pulses every 3 h for 12 days. The ability of this long-term pulsatile GHRF treatment to elicit pulses of GH secretion was assessed by withdrawing

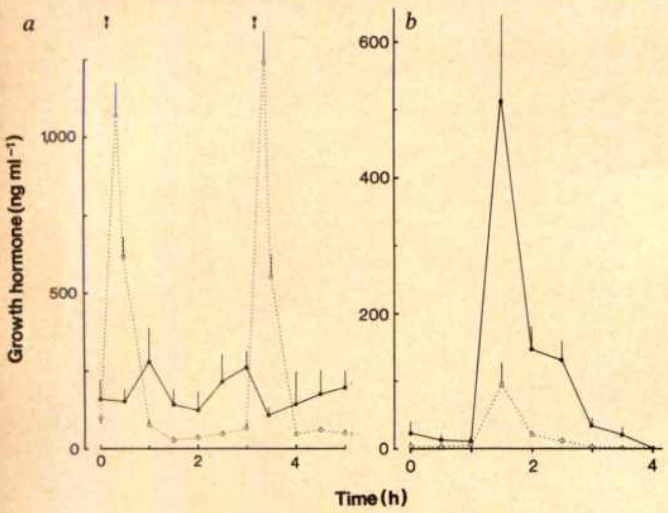

Fig. 1 Effects of hGHRF(1-29)NH_2 (*a*) and monosodium glutamate (*b*) on plasma GH levels. *a*, Six normal female rats (dotted line) received 1-μg injections of hGHRF(1-29)NH_2 (Bachem, UK, or Kabi-Vitrum, Sweden) via the i.v. cannulae at 9 a.m., 12 a.m., 3 p.m. and 6 p.m. Before and after the third and fourth injections (arrows), blood samples (100 μl) were withdrawn and the plasma separated and frozen. A second group of four female rats were given injections of saline to serve as controls (solid line). *b*, Newborn male rat pups received five subcutaneous injections of MSG (4 mg per g body weight) every second day from birth. Littermate controls received 10% saline. When 8 weeks old, the animals were catheterized as in *a* for blood sampling. Five MSG-treated rats (open circles) showed endogenous GH pulses which were blunted compared with those occurring in four normal male rats (solid circles). As endogenous GH pulses are not synchronized with respect to clock time, the peak concentrations for each individual rat have been aligned in this figure.

Methods. Sprague–Dawley rats (150–180 g) were housed individually in metabolic cages in a light- and temperature-controlled room and fed a powdered diet and distilled water *ad libitum*. Animals were anaesthetized with halothane/N_2O/O_2, and a silicone rubber catheter was inserted into the right jugular vein and exteriorized dorsally. Daily weight and food intake measurements showed that animals quickly resumed their normal growth. Sequential blood samples were obtained from conscious animals via extension cannulae attached to the catheters. Plasma GH levels were determined by RIA on 5- and 20-μl plasma samples using reagents supplied by NIADDK.

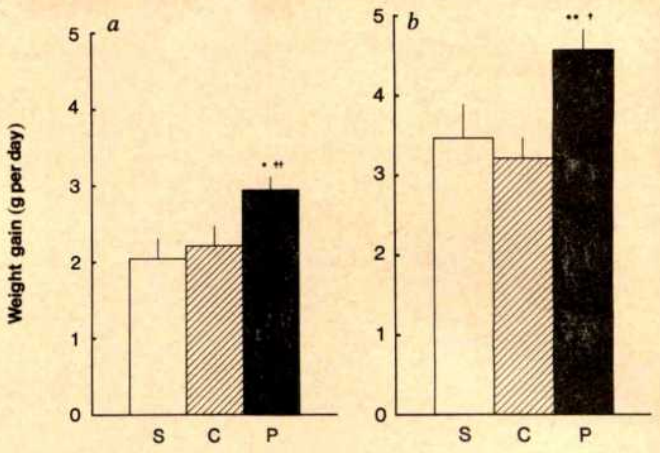

Fig. 2 Effects of continuous and pulsatile administration of hGHRF(1-29)NH_2 on growth in normal female (*a*) and MSG-treated male (*b*) rats. Values shown are means ± s.e.m. In both experiments, analysis of variance showed significant differences between the three treatment groups (P, pulsatile hGHRF (1-29)NH_2, solid bars; C, continuous hGHRF(1-29)NH_2, hatched bars; S, saline infused controls, open bars). In female animals (*a*), pulsatile GHRF produced significantly greater weight gains than either continuous GHRF ($^*P < 0.05$) or saline treatment ($\dagger\dagger P < 0.025$). In MSG-treated male rats (*b*), pulsatile GHRF again was most effective ($\dagger P < 0.05$ vs. saline, and $^{**}P < 0.005$ vs. continuous GHRF).

Methods. Sprague–Dawley rats (150–180 g) were anaesthetized, a silicone cannula was placed in the right jugular vein, a head plate screwed to the occipital bone and the cannula passed through a protective spring to a fluid-tight swivel joint connected to multichannel peristaltic infusion pumps[11,12]. One pump ran continuously (1.6 ml per day) whereas a second pump delivered the same daily volume as a series of 200-μl pulses (2 min duration, every 3 h). The vehicle was phosphate-buffered saline (Dulbecco's 'A') containing 0.01% rat albumin and heparin (5 U ml^{-1}). The animals were weighed daily, which entailed disconnecting the continuous infusion for less than 2 min. Growth rates (g per day) were calculated by regressing the increase in body weight against time for each animal.

blood samples from three of the rats 5, 10 and 20 min after the 50th pulse of hGHRF(1-29)NH_2; the plasma GH values (mean ± s.e.m.) were 3,595 ± 1,400, 910 ± 155 and 326 ± 68 ng ml^{-1}, respectively. Pulsatile GHRF treatment produced a 30% increase in body weight gain compared with saline-infused controls, whereas the same total daily dose of hGHRF (1-29)NH_2 given as a continuous infusion for 12 days had no significant effect (Fig. 2*a*). A similar stimulating effect of pulsatile hGHRF(1-29)NH_2 on proximal tibial growth[13] was observed in the same groups of animals (controls 110 ± 5; continuous GHRF 103 ± 8; pulsatile GHRF 117 ± 2 μm per day, mean ± s.e.m.), although the difference between continuous and pulsatile GHRF treatment was less clearly established ($P = 0.056$). At the end of the experiment, the anterior pituitary glands were extracted and assayed for GH content (Table 1*a*). Pulsatile hGHRF(1-29)NH_2 treatment significantly increased the pituitary content of GH, whereas continuous infusions were without effect.

We also compared continuous and pulsatile administration of hGHRF(1-29)NH_2 in animals made deficient in endogenous GHRF by neonatal exposure to monosodium glutamate (MSG)[14]. This treatment produces stunted growth[15] and blunts endogenous GH pulses (Fig. 1*b*). However, MSG-treated rats can secrete large amounts of GH in response to exogenous GHRF. In five conscious MSG-treated male rats implanted with indwelling jugular cannulae, plasma GH values rose from 33 ± 7 ng ml^{-1} to 2,640 ± 1,070 and 131 ± 26 ng ml^{-1}, respectively, 10 and 30 min after a single i.v. injection of 1 μg hGHRF (1-29)NH_2. Using the programmable i.v. infusion system, groups of MSG-treated male rats were given saline or hGHRF (1-29)NH_2, either continuously (8 μg per day) or in a pulsatile pattern (1-μg pulses every 3 h) for 10 days. As in normal female rats, pulsatile hGHRF(1-29)NH_2 stimulated body weight gain whereas continuous infusions of this peptide did not increase weight gain (Fig. 2*b*). Pulsatile hGHRF(1-29)NH_2 also produced a significant increase in long bone and tail growth in these MSG-treated rats (Table 2).

Although neonatal exposure to MSG results in smaller anterior pituitary glands and lower GH content in the adult, the pituitary GH concentration remains unchanged[16]. Unlike in normal female rats, we could show no trophic effects of hGHRF(1-29)NH_2 on pituitary GH content in MSG-treated animals (Table 1*b*). GHRF can exert a trophic effect *in vitro* on GH messenger RNA transcription[17] in addition to its powerful secretagogue effect. However, multiple injections of GHRF do not increase the GH content of pituitary tissue autotransplanted to the kidney capsule[18]. As MSG disrupts other hypothalamic neurotransmitter systems[19] in addition to GHRF neurones[14], it is possible that the trophic effect of GHRF *in vivo* requires an intact hypothalamo-hypophysial system.

These experiments are the first to show that a GHRF peptide can induce growth in both normal female and GHRF-deficient animals, and that the amount of growth depends on the pattern of administration. The female rat has been relatively neglected in studies of GHRF *in vivo* and offers considerable advantages

Table 1 Effect of hGHRF(1-29)NH_2 on anterior pituitary stores of GH

	(*n*)	Wet weight (mg)	Anterior pituitary GH content (μg)	GH concentration (μg per mg wet wt)
a Normal females				
Saline	(8)	9.8 ± 0.3	613 ± 36	62 ± 3
Continuous GHRF	(8)	10.2 ± 0.7	623 ± 68	61 ± 5
Pulsatile GHRF	(8)	10.3 ± 0.4	834 ± 75*	81 ± 7*
b MSG-treated males				
Saline	(8)	4.5 ± 0.5	522 ± 119	104 ± 17
Continuous GHRF	(8)	4.6 ± 0.5	577 ± 112	115 ± 14
Pulsatile GHRF	(8)	5.3 ± 0.6	680 ± 161	115 ± 20

Anterior pituitary glands were removed, weighed, homogenized individually in 1 ml phosphate-buffered saline *p*H 7.4, centrifuged for 10 min at 13,000*g* and the supernatants assayed for rat GH by radioimmunoassay (RIA), using six doubling dilutions in duplicate. See text for an explanation of the different treatment groups. In female rats (*a*), pulsatile hGHRF(1-29)NH_2 for 12 days increased pituitary GH content and concentration. In male MSG-treated rats (*b*) hGHRF(1-29)NH_2 had no significant effect on pituitary GH.
* $P < 0.05$ vs. both saline and continuous GHRF.

of uniformity and availability, together with an intact hypothalamo-hypophysial system. The possibility that prolonged pulsatile GHRF treatment might alter reproductive cycles in the female rat, and thus indirectly influence body growth must be considered, although this explanation is unlikely to account for the stimulation of growth produced in male rats by pulsatile GHRF. The simplest explanation for our results is that effective GHRF levels in the hypophysial portal vessels are achieved only by giving the peptide in pulses. Continuous infusions of GHRF require higher total dose rates to stimulate GH release and can result in rapid depletion of pituitary GH stores[20]. In the case of MSG-treated animals, we are replacing the depleted GHRF secretion, whereas in normal female rats we are presumably overriding endogenous GHRF secretion. Whether or not the endogenous secretory profile of GHRF in male rats shows 3-hourly episodes, an exogenous GHRF peptide given in 3-hourly pulses produces a plasma GH profile which mimics the normal male pattern. We have previously shown in hypophysectomized male rats that the growth responses to a given dose of GH are greater if the GH is given in 3-hourly pulses[12]. The pattern of GH secretion is less pulsatile in female rats, and this may partly underlie their slower growth rates[21]. We reasoned that maintaining a male pattern of GH secretion might increase the growth rate of normal females towards that of the male rat. This proved to be the case.

Both normal female rats and MSG-treated male rats may provide useful data when considering the treatment of GHRF-deficient children with pulsatile GHRF[7], especially where this has to be given by the subcutaneous route, which inevitably reduces the pulsatility. Our demonstration that a more effective GH secretory profile can be imposed in normal, intact (female) animals by patterned exogenous GHRF may well have applicability in animal husbandry, provided suitable simple means for achieving the optimal pattern of administration can be found. The obvious corollary of this result is that a sub-optimal infusion regime might impose a less effective growth rate, which could conceivably be useful therapeutically in children with excessive rates of growth. At its simplest level, the chronically cannulated female rat offers a convenient model in which to test the effects of different routes and patterns of administration of GHRF, its analogues and inhibitors on whole body growth.

Table 2 Effect of hGHRF(1-29)NH_2 on tail and bone growth in MSG-treated rats

	(*n*)	Tail growth (mm)	Proximal tibial growth (μm per day)
Saline	(8)	15.4 ± 1.3	137 ± 12
Continuous	(8)	18.2 ± 2.6	137 ± 8
Pulsatile	(8)	20.6 ± 1.3*	159 ± 7†

Tail lengths of MSG-treated rats were measured[22] under anaesthesia at the beginning and end of the infusion experiment (see text). The differences between these measurements are shown as mean ± s.e.m. Immediately before the infusions began, each rat received an injection of oxytetracycline (2 mg per 100 g body weight, i.v.). At the end of the experiment, the proximal tibias were dissected out and cumulative bone growth assessed by fluorescence microscopy according to the method of Hansson *et al.*[13]. Results were analysed using paired *t*-tests against littermate controls.
* $P < 0.001$ vs. saline; † $P < 0.05$ vs. continuous GHRF.

We thank Teresa Burne for technical assistance, Kabi-Vitrum, Sweden, for generously providing hGHRF(1-29)NH_2, NIADDK for materials for radioimmunoassay of rat GH, and Professor O. Isaksson for teaching one of us (R.G.C.) the oxytetracycline technique in his laboratory.

Tissue-specific expression of rat myosin light-chain 2 gene in transgenic mice

Moshe Shani

Department of Cell Biology, The Weizmann Institute of Science, Rehovot 76100, Israel

One approach to determining how the differential expression of specific genes is regulated in higher organisms is to introduce cloned copies of the genes (or parts of the genes) into the genomes of individual organisms from the very beginning of their development. The way in which the exogenous genetic information behaves during the development of the experimental organisms can then provide a means of defining the DNA sequences that restrict the

expression of the gene to specific cell types and times of development. So far, several different genes have been introduced into the genomes of mice[1–15], but in only a few cases have the exogenous genes retained the tissue specificity of expression of the equivalent endogenous genes[12,14,15]. I report here that in two out of three 'transgenic' mice carrying copies of the rat gene for skeletal muscle myosin light chain 2, the exogenous gene is expressed specifically in skeletal muscle cells. The sequences contained in the cloned copy of the myosin light-chain 2 gene used in these experiments are thus sufficient to confer a tissue-specific pattern of expression.

A recombinant plasmid (pRH3MLC)[16] containing the rat skeletal muscle myosin light-chain 2 (MLC2) DNA sequences in their entirety, in a 4.7-kilobase (kb) DNA fragment, was cut with *Hin*dIII to release the rat DNA sequences from the plasmid DNA and used for injection into fertilized mouse eggs (Fig. 1*a*). Superovulated females of (BALB/c×C57BL/6J) F_1 were mated to males of (C57BL/6J×DBA) F_1. On the day after mating, fertilized eggs were recovered from the oviducts. The male pronuclei were microinjected with 1–2 pl containing ~500 molecules of the plasmid DNA. Eggs that survived the microinjection (~50%) were implanted into the oviducts of pseudopregnant CD-1 females for further development. Spleen DNA samples from 26 neonatal mice were analysed by Southern blot hybridization and four mice containing pRH3MLC sequences were identified. DNA isolated from spleens of these mice (designated MLC_1, MLC_2, MLC_3, MLC_4) and a control mouse was digested with *Hin*dIII, *Eco*RI or *Xba*I. Figure 1*b* shows an autoradiogram of a Southern blot of the fractionated DNA, hybridized to ^{32}P-labelled pRH3MLC DNA. In addition to the expected 4.7- and 4.3-kb DNA fragments in the *Hin*dIII digest, several minor fragments that hybridized to the probe could be observed in DNA from mice MLC_1, MLC_2 and MLC_4, these fragments resulting from either junction fragments with cellular DNA or rearranged sequences.

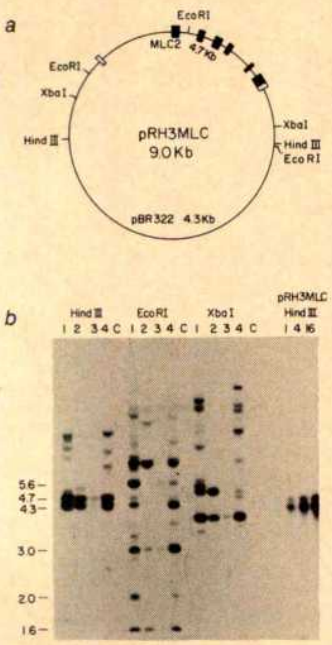

Fig. 1 Map of plasmid DNA pRH3MLC and Southern blot analysis of DNA from four transgenic mice. *a*, The 4.7-kb *Hin*dIII DNA fragment containing the rat MLC2 gene was cloned into the *Hin*dIII site of pBR322 (ref. 16). Boxes indicate the positions of the seven exons; empty boxes represent the 5′- and 3′-untranslated regions; solid boxes represent coding sequences. *b*, Total spleen DNA (10 μg) from the four transgenic mice (1–4) and a control mouse DNA (C) was digested with *Hin*dIII, *Eco*RI or *Xba*I. The DNA fragments were fractionated on a 0.8% agarose gel, transferred to nitrocellulose filter and hybridizes with ^{32}P-labelled pRH3MLC DNA. The blot was washed in stringent conditions (0.1×SSC, 0.2% SDS at 75 °C for 2 h) not allowing detection of the mouse gene. Plasmid pRH3MLC DNA samples digested with *Hin*dIII corresponding to 1, 4 and 16 copies per diploid mouse genome were included to estimate the copy number of inserted DNA in transgenic mice. Molecular sizes are shown in kb on the left.

As the pRH3MLC DNA was cut with *Hin*dIII before microinjection, multiple orientations of MLC2 and pBR322 DNA sequences were expected (Fig. 1). For example, in the *Eco*RI digests, the 1.6-kb DNA fragment seen in the four transgenic mice is a product of cleavage at the internal *Eco*RI sites of the MLC2 gene. The 2.0-kb DNA fragment in transgenic mice MLC_1, MLC_3 and MLC_4 is a product of cleavage at the 3′ end *Eco*RI site of MLC2 gene, when it is integrated next to pBR322 DNA in a head-to-tail configuration. This fragment is undetectable in mouse MLC_2 DNA; instead a predominant 6.3-kb DNA fragment appears, indicating that most of the MLC2 DNA molecules in this mouse are arranged in tandem arrays with pBR322 DNA in a head-to-head orientation. Similarly, in the *Xba*I digests, the 3.9-kb DNA fragment is a product of cleavage at the two sites when pBR322 DNA is flanked on both sides with MLC2 DNA sequences. Analysis of the restriction pattern indicated that most of the copies of the injected DNA are integrated tandemly in the mouse genome. The number of pRH3MLC DNA copies in each mouse was estimated by comparing the intensity of the hybridized fragments with those of known amounts of plasmid DNA. Thus, mice MLC_1, MLC_2, MLC_3 and MLC_4 contain ~20, 10, <1 and 16 copies per cell, respectively.

To examine the transmission of the inserted DNA sequences to progeny, each of the four transgenic mice was mated with a normal mouse. Southern blot hybridization to spleen DNA from the progeny of MLC_1, MLC_2 and MLC_4 revealed that the inserted DNA sequences were transmitted faithfully through the germ line to ~50% of the progeny (data not shown; see Fig. 2), the expected frequency if the majority of the multiple MLC2 copies are integrated tandemly at a single site of one chromosome.

In contrast to the mendelian inheritance of pRH3MLC DNA sequences in mice MLC_1, MLC_2 and MLC_4, mouse MLC_3 did not transmit the injected DNA to any of its first 60 offspring. This female mouse contains <1 copy per cell of the inserted DNA (Fig. 1*b*) and is apparently a mosaic in which the injected DNA is present in only a small proportion of its somatic cells.

To investigate whether the expression of the rat MLC2 gene in transgenic mice was tissue-specific, RNA was extracted from skeletal muscle and other organs from the progeny of two transgenic mice. The presence of rat MLC2 transcripts in these RNA preparations was determined by the S_1 endonuclease technique, using as a probe the coding strand of the 630-base pair (bp) *Hin*fI/*Hin*fI DNA fragment derived from the 5′ region of the rat MLC2 gene and labelled at the 3′ end with reverse transcriptase (see Fig. 3). In stringent hybridization conditions

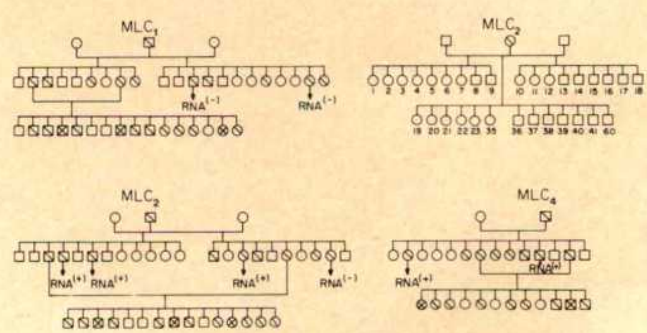

Fig. 2 Inheritance of pRH3MLC sequences in the four transgenic mice. Each transgenic mouse was mated with normal mouse Heterozygous male and female progeny of MLC_1 and MLC_2 mice were mated to give rise to normal homozygous mice. Mouse MLC_3 is probably a mosaic. Squares represent males, circles females, intersecting diagonals homozygous mice, single diagonals heterozygous mice. Mice denoted $RNA^{(+)}$ contained MLC2 transcripts in skeletal muscle whereas mice denoted $RNA^{(-)}$ did not.

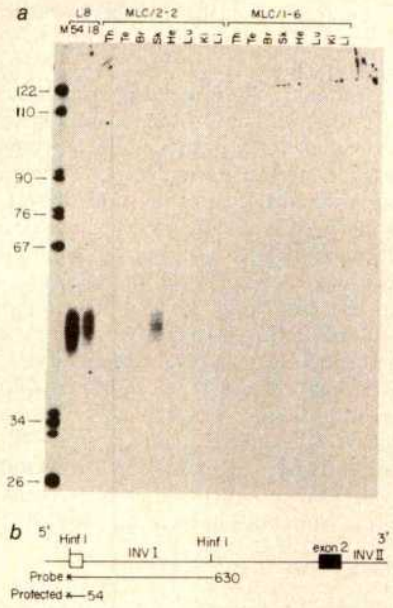

Fig. 3 S_1 analysis of rat MLC2 RNA in the progeny of transgenic mice MLC_1 and MLC_2. *a*, 25 μg total RNA from the indicated tissues and total RNA from differentiated cultures of the myogenic cell line L8 were hybridizied at 46 °C for 16 h to a 3′-end-labelled *Hin*fI/*Hin*fI DNA fragment prepared from pRH3MLC DNA (see scheme in *b*). Th, thymus; Te, testes; Br, brain; Sk, skeletal muscle; He, cardiac muscle; Lu, lung; Ki, kidney; Li, liver. Hybridization reactions were incubated with 5,000 U S_1 nuclease (Miles) for 30 min at 42 °C. S_1-resistant hybrids were sized on 5% acrylamide/7M urea gel. *b*, Map of the 5′ region of the rat MLC2 gene and the hybridization probe. Boxes, exons; solid lines, introns and 5′-flanking region; open box, 5′-untranslated exon; solid box, first coding exon. The 3′ label is indicated by an asterisk and the lengths of the probe and the protected fragment are also indicated.

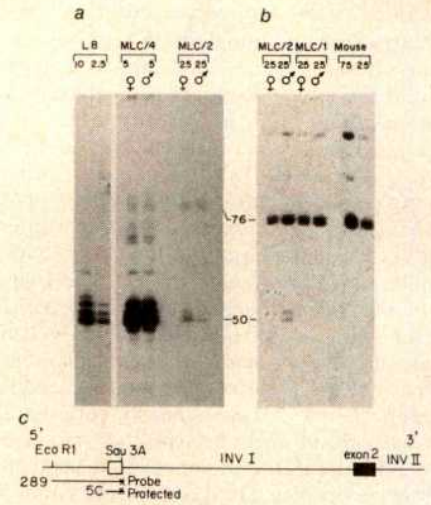

Fig. 4 The rat MLC2 gene is initiatied correctly in progeny of transgenic mice MLC_2 and MLC_4. Total RNA from skeletal muscle of male (♂) and female (♀) progeny of transgenic mice MLC_1, MLC_2 and MLC_4, RNA from skeletal muscle of control mouse and from differentiated cultures of the myogenic cell line L8 were hybridized with 5′-end-labelled *Sau*3A/*Eco*RI DNA fragment (see *c*). RNA (μg) in each hybridization reaction is indicated. *a*, Hybridization performed at 42 °C and S_1 digestion at 37 °C; *b*, hybridization at 37 °C and S_1 digestion at 32 °C. After treatment with S_1 nuclease, the resistant hybrids were sized on 5% acrylamide/7 M urea gels. *c*, Map of the 5′ region of the rat MLC2 gene and the probe used in the hybridization. Boxes, exons; solid line, introns and 5′-flanking region; open box, 5′-untranslated exon; solid box, first coding exon. The 5′ label is indicated by an asterisk and the lengths of the probe and the protected fragment are shown.

(hybridization at 46 °C and S_1 digestion at 42 °C), cross-hybridization to the endogenous mouse MLC2 transcripts did not occur. Authentic rat transcripts protect a 54-nucleotide DNA fragment from S_1 digestion. The appearance of several bands at that region probably results from S_1 nibbling at the end. Figure 3 shows that no rat MLC2 transcripts could be detected in skeletal muslce RNA or any of the other seven tissues of mouse MLC_1. In mouse MLC_2, however, transcripts were detected in skeletal muscle RNA but not in RNA from the other tissues tested. Analysis of RNA prepared from mouse MLC_4 revealed the presence of a large amount of the rat transcripts only in skeletal muscle (data not shown).

Muscle-specific transcripts in transgenic mice MLC_2 and MLC_4 could arise either from readthrough transcription initiated from upstream mouse promoter expressed in skeletal muscle or from initiation at the authentic rat MLC2 promoter. To distinguish between these two possibilities, the site of the initiation of these transcripts was determined. The coding strand of a 289-bp *Sau*3A/*Eco*RI DNA fragment ^{32}P-labelled with T4 polynucleotide kinase was hybridized to RNA from differentiated cultures of the rat myogenic cell line L8, to control mouse skeletal muscle RNA and to skeletal muscle RNA from males and females of the first generation progeny of mice MLC_1, MLC_2 and MLC_4. RNA from the rat myogenic cell line protected a 50-nucleotide DNA fragment (Fig. 4). The appearance of two bands spaced one nucleotide apart probably results from S_1 nibbling of the sequence that immediately precedes the cap site. RNA from control mouse skeletal muscle protected a 76-nucleotide DNA fragment. These unexpected results suggest that: (1) there is a similarity in the sequences of the 5′-untranslated exon and immediate flanking region of the rat and the mouse MLC2 genes and (2) the transcription of the mouse MLC2 gene is initiated ~20 nucleotides 5′ to the initiation site of the rat MLC2 gene. In more stringent hybridization conditions, such as those chosen for the *Hin*fI DNA fragment (Fig. 3), there was no cross-homology with the mouse exon. (Also, compare the intensity of the signals of the 76-nucleotide band in Fig. 4*a*, *b*.) The stringency was lowered here so that the hybridization to the mouse exon is an internal control for the intactness of the RNA preparations of mouse MLC_1 and the control mouse. RNA from three out of four progeny of transgenic mouse MLC_2 and two progeny of mouse MLC_4 protected the diagnostic 50-nucleotide DNA fragment (Fig. 4). As expected, skeletal muscle RNA of MLC_1 mice gave no detectable signal.

The MLC2 gene is a member of a large group of genes activated during terminal differentiation of muscle cells[17]. The results presented here demonstrate that in two out of the three transgenic mice tested, the injected rat MLC2 gene responded to normal developmental controls. Its expression was detected only in skeletal muscle. Thus, the 4.7-kb rat DNA fragment containing the entire MLC2 gene includes *cis*-acting sequences sufficient to specify the correct expression of this gene. RNA transcripts of this gene were found in skeletal muscle in three of four progeny of MLC_2 and in two progeny of MLC_4, and not in any other tissue. The RNA had the correct initiation site of the authentic rat MLC2 gene, which differs from the endogenous mouse MLC2 by ~26 nucleotides. Interestingly, a similar frequency of non-expressing progeny (two of eight) has been reported for transgenic mice expressing the rabbit β-globin gene in skeletal muscle[1].

The levels of expression of the inserted rat gene are ~5–10% (in MLC_2) and 5–10× greater (in MLC_4) than in differentiated cultures of the rat myogenic cell line L8. The variable levels of specific expression could result from position effect, thus integration into non-homologous chromosomal sites may influence the level of expression of the foreign gene.

Several genes have been inserted into mice[1–15]. Tissue-specific expression of introduced genes, however, has been reported

only in four other cases; the rearranged immunoglobulin in κ gene[12], the rearranged immunoglobulin heavy-chain gene[15], the rat pancreatic elastase I gene[14] and the fused gene consisting of the 5′ end of the mouse β-globin gene spliced to the 3′ end of the human β-globin gene (F. D. Constantini, personal communication). In the first three cases and in the rat MLC2 gene in mouse MLC_4, the level of expression was similar to that of the endogenous gene, whereas in the globin and rat MLC2 genes in mouse MLC_2, the level of expression was considerably lower than the endogenous counterparts. One possible interpretation is that the immunoglobulin and the elastase I genes include tissue-specific enhancer sequences that are recognized as such even when the genes are integrated at different chromosomal sites. Evidence for the dramatic effects of enhancer sequences on the efficiency of expression of genes introduced into somatic cells has been obtained[18]. There is no evidence that the injected MLC2 DNA fragment includes specific enhancer elements. Therefore, the hundredfold difference in the level of expression in the two transgenic mice could result from either the absence of such elements or their weakness. Thus, in mouse MLC_2, these sequences are neutralized easily by the local chromosomal environment at the site of integration, whereas in mouse MLC_4 they overcome the position effect.

Production of transgenic mice expressing muscle-specific genes or specifically modified genes in the appropriate tissue would allow a detailed study of the parameters affecting tissue-specific gene expression (for example, site of integration, DNA methylation or chromatin organization). Moreover, the control of expression of the inserted genes can now be analysed in myogenic and non-myogenic cells isolated from these mice.

I thank Professor David Yaffe for support, advice and encouragement, Dr Uri Nudel for fruitful collaboration, Professor Frank Ruddle and Dr John Gordon for advice on the microinjection technique and Dr Cynthia Webb for helpful suggestions. The project was supported partly by the International Cancer Research Data Bank Programme of the National Cancer Institute, NIH, under contract N01-CO-65341 (ICRETT) and partly by the International Union Against Cancer. Support was also provided under NIH grant GM-22767, the MDA and the Minerva Foundation, Munich, FRG.

Regulation of a collagen gene promoter by the product of viral *mos* oncogene

Azriel Schmidt, Chiaki Setoyama & Benoit de Crombrugghe

Laboratory of Molecular Biology, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

Oncogenic transformation of cells produces important changes in the biosynthetic pattern of certain cellular proteins[1–6]. For example, the synthesis of type I collagen in transformed fibroblasts is severely reduced as a result of changes in transcription[7–10]. Here we report the results of DNA-mediated transfection experiments using recombinant plasmids in which the promoter region of the α2(I) collagen gene is fused to an easily recognizable marker gene, and cell lines expressing the marker gene are isolated. Our data show that the expression of the marker gene fused to the cloned α2(I) collagen promoter is strongly inhibited by v-*mos* transformation, suggesting that a common mechanism inhibits both the transfected and endogeneous α2(I) collagen promoters.

The α2(I) collagen gene is very large (~40 kilobase pairs(bp) with ~50 exons)[11] and is therefore difficult to manipulate *in vitro*. To overcome this problem in studying its expression by DNA-mediated transfection experiments, we have fused the promoter region of this gene to either the bacterial gene for chloramphenicol acetyltransferase (*cat*)[12] or the gene for aminoglycoside phosphotransferase (*neo*)[13]. Although such constructions may not contain all the regulatory elements controlling the expression of the endogenous α2(I) collagen gene, they do allow us to test whether the 5′-flanking sequences of the α2(I) collagen gene which are present in these hybrid plasmids are sufficient for regulation by oncogenes. Figure 1 shows the plasmids constructed for our experiments. We first transfected NIH 3T3 cells with DNA of plasmid pHO1000, in which the chick α2(I) collagen promoter is fused to the *cat* gene. This plasmid also contains the gene for guanine phosphoribosyltransferase (*gpt*) fused to the early promoter of simian virus 40 (SV40). Clones positive for the expression of both the *gpt* and *cat* genes (AT1, AT2, AT3, etc.) were isolated. One of these clones (AT3) was examined by Southern blotting to show that the plasmid was stably integrated throughout at least two cycles of subcloning. We estimated that this cell line contains about eight copies of the α2(I) collagen promoter-*cat* DNA unit (data not shown). A Northern hybridization experiment indicated that the RNA produced by the collagen promoter-*cat* transcription unit in these cells was a discrete species ~1,600 nucleotides (Fig. 2*a*), consistent with a transcript starting from within the cloned chicken α2(I) collagen promoter and ending at the SV40 polyadenylation site present downstream from the *cat* gene in pHO1000. The results of a primer extension experiment (Fig. 2*b*) further indicate that the *cat* gene transcript starts at the correct site in the cloned α2(I) collagen promoter. In the same cells, *gpt* transcripts initiate at the major transcription start site in the early SV40 promoter (Fig. 2*b*, lane 2).

To determine whether the expression of the hybrid α2(I) collagen promoter-*cat* transcription unit was also inhibited by oncogenic transformation after it had been introduced into NIH 3T3, we first transformed three cell lines with the mouse Moloney sarcoma and leukaemia virus complex (MMSV). In all three clones, the level of CAT activity was reduced 7–14-fold after transformation (Fig. 3*a*, Table 1*a*). Dot-blot hybridizations using RNA extracted from one of these lines showed that the levels of endogenous α2(I) collagen RNA and those of *cat* RNA decreased 8–10-fold after MMSV transformation, whereas the levels of actin RNA were unchanged (Fig. 3*b*).

The plasmid construction used in these experiments also harbours the early promoter of SV40, which is fused to the bacterial *gpt* gene (Fig. 1*a*); this SV40 promoter segment includes the SV40 enhancer sequences[14,15]. To determine whether SV40 enhancer sequences are required for inhibition of the α2(I) collagen promoter after MMSV transformation, NIH 3T3 cells were transfected with pAZ1005, a plasmid in which a mouse α2(I) collagen promoter segment is fused to the *neo* gene but which does not contain SV40 enhancer sequences (Fig. 1*c*). Several colonies resistant to the antibiotic G418 (positive for the expression of the *neo* gene) were isolated and transformed either by MMSV or by a plasmid containing the

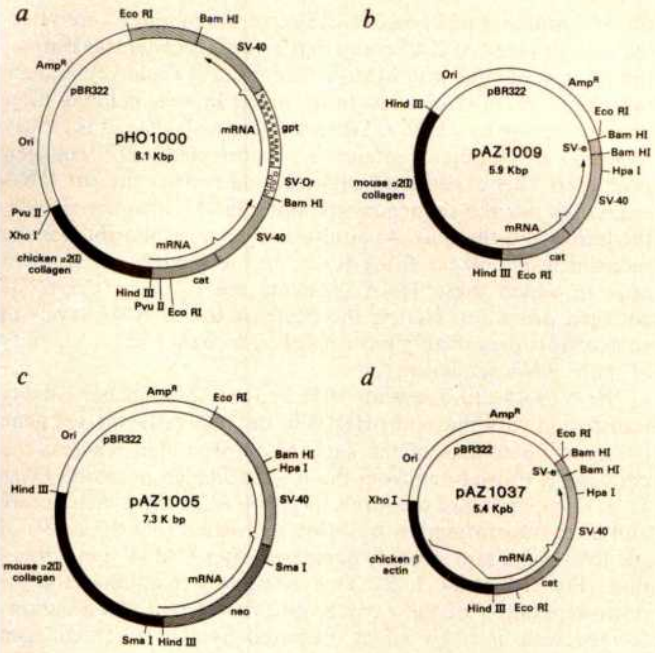

Fig. 1 Schematic representation of the recombinant plasmids used in the present work: pHO1000 (*a*), pAZ1009 (*b*), pAZ1005 (*c*) and pAZ1037 (*d*). *a*, pHO1000: This plasmid was constructed by H. Ohkubo (H. Ohkubo, in preparation). It contains a fragment of the chicken $\alpha 2$(I) gene which spans the chicken promoter region from 1,300 bp upstream of the start site of transcription to 110 bp downstream of this site[16]. This segment is fused to the gene for chloramphenicol acetyltransferase (*cat*) by means of *Hin*dIII linkers. The sequence 110 bp downstream of the start site of transcription of the $\alpha 2$(I) collagen gene does not contain the starting AUG for the collagen polypeptide. The SV40 small-T intron and the SV40 early region polyadenylation site contribute signals for RNA processing. This plasmid harbours a second transcription unit in which the early promoter of SV40 is fused to the gene for guanine phosphoribosyl transferase (*gpt*); this unit is inserted into the *Bam*HI site. This segment, which includes the SV40 small-T splice sites and intron as well as the SV40 early region poly(A) site, was isolated from pSV2-gpt[17]. *b*, pAZ1009: a *Mst*II/*Sph*I fragment of the mouse $\alpha 2$(I) collagen gene taken from plasmid pAZ1001 (ref. 18) was inserted by means of *Hin*dIII linkers into the *Hin*dIII site of the plasmid pSV0-cat (a derivative of pSV2-cat without the origin of replication and the early promoter of SV40, given by C. Gorman). This fragment contains 2,000 bp upstream of the start of transcription of the mouse $\alpha 2$(I) collagen gene (including the TATA box and CAT box) and 54 bp downstream of this site. These 54 bp do not contain the starting AUG of the $\alpha 2$(I) collagen peptide. The 3′ end of this transcription unit is composed of the SV40 small-T splice sites, the small-T intron and the SV40 early region polyadenylation site. The 884-bp *Hpa*I/*Eco*RI fragment was then replaced with a *Hpa*I/*Eco*RI fragment isolated from pPH2-a*Bam*R (a gift from S. Sarragosti). This fragment contains an SV40 segment between +113 and +270 in the SV40 map and includes one complete copy of the 72-bp enhancer and a second copy which is almost complete. The *Bam*HI and *Eco*RI restriction sites are contiguous to each other. *c*, pAZ1005: The same *Mst*II/*Sph*I fragment of the mouse $\alpha 2$(I) collagen gene as described in *b* was inserted by means of *Hin*dIII linkers into the *Hin*dIII site of the plasmid pSV0-neo (a derivative of pSV2-neo without the origin of replication and the early promoter of SV40, gift of C. Gorman). *d*, pAZ1037: The 1,350-bp *Xho*I/*Hin*cII fragment of the chicken β-cytoplasmic actin gene[19] was inserted in place of the mouse $\alpha 2$(I) collagen promoter region by means of *Xho*I and *Hin*dIII linkers. This fragment contains 350 bp preceding the start of transcription and 1,000 bp downstream of the transcription site, including the first exon, first intron and part of the second exon. The nucleotide sequences for the first 10 amino acids of β-actin are in-phase with the reading frame of the *cat* coding sequences. A similar gene fusion with a *Bacillus subtilis* fragment has been reported previously[20] in this case, although the CAT polypeptide became larger, the CAT specific activity was not affected.

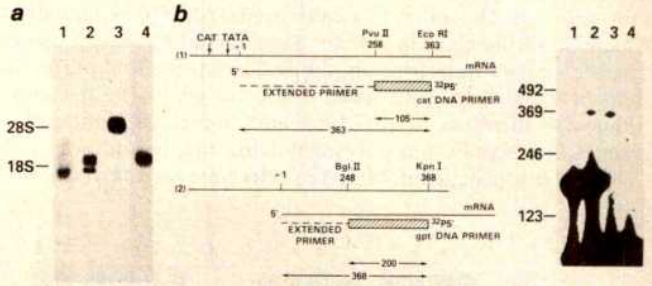

Fig. 2 Characterization of clone AT3-14, NIH 3T3 cells were transfected by the calcium phosphate method. Briefly, 3×10^5 NIH 3T3 cells grown in 10% calf serum were placed in a T-25 flask and 24 h later were transfected with 10 μg of pHO100 DNA. After a further 48 h, the cells were placed in *gpt* selection medium (25 μg ml^{-1} mycophenolic acid, 2 μM aminopterin, 2 μM thymidine, 10 μM hypoxanthine and 5 μg ml^{-1} xanthine) at 10^5 cells per 100-mm dishes. Colonies resistant to mycophenolic acid were isolated after 14 days and tested for CAT activity. ***a***, *cat* mRNA synthesis in clone AT3-14: total RNA was isolated from clone AT3 by the guanidine hydrochloride method[21]. RNA (10 μg) was fractionated by formaldehyde gel electrophoresis[22], blotted to nitrocellulose paper and hybridized to the following ^{32}P-labelled DNA probes as described elsewhere[18]: lane 1, 250 bp *Eco*RI/*Hin*dIII *cat* probe; lane 2, 350-bp *Kpn*I/*Hin*dIII *gpt* DNA; lane 3, 850-bp *Eco*RI/*Sma*I fragment of mouse $\alpha 2$(I) collagen DNA; lane 4, 1.6-kbp *Pst*I/*Pst*I fragment of a chicken β-actin cDNA clone[23] (a gift of Bruce Paterson). The positions of the 28S and 18S ribosomal RNAs are marked. ***b***, Start of transcription of *cat* and *gpt* mRNA: (1) The recombinant plasmid pAZ1009 was digested with *Eco*RI. The 5′ ends of this DNA were labelled by T4 polynucleotide kinase, then digested with *Pvu*I, generating a labelled 120-bp fragment. This fragment was used as primer and hybridized to poly(A)$^+$ RNA (16 μg) isolated from AT3-14 cells (lane 3) or to poly(A)$^+$ RNA (16 μg) of untransfected cells (lane 4) and then extended by reverse transcriptase[16]. (2) The recombinant plasmid pSV2-gpt was digested with *Kpn*I,5′-end labelled and digested with *Hin*dIII, generating a 200-bp fragment which was used as primer. The 5′-end-labelled primer was hybridized to poly(A)$^+$ RNA of clone AT3-14 (lane 2) or to poly(A)$^+$ RNA (16 μg) of untransfected NIH 3T3 cells (lane 1), and was extended by reverse transcriptase. The sizes of the resulting cDNAs were analysed by electrophoresis on a 7 M urea 5% polyacrylamide gel.

v-*mos* oncogene linked to the MMSV long terminal repeat sequence (pHT25, given by G. Van de Woude). The results (Fig. 3*c*) indicate that the levels of *neo* RNA decrease markedly in these cells after v-*mos* transformation. The presence of the SV40 enhancer sequences is therefore not required for inhibition of the transfected $\alpha 2$(I) collagen promoter.

In parallel with these experiments, we also used a plasmid in which the mouse $\alpha 2$(I) collagen promoter segment is fused to the *cat* gene. This plasmid, pAZ1009, also contains a small segment with the SV40 enhancer sequence (see Fig. 1*b*). NIH 3T3 cells were co-transfected with pAZ1009 together with pSV2-neo, a plasmid in which the *neo* gene is linked to the early SV40 promoter. Several G418-resistant colonies were isolated and transformed by MMSV. Table 1*b* shows that the levels of CAT are decreased in four of the five transformed cell lines examined, although the degree of reduction varies between cell lines, perhaps as a result of the location of plasmid integration in the genome.

As a control for these experiments, we used cell lines that had been transfected with either one of two plasmids containing the chicken β-actin promoter. The first plasmid (pβ6 actin) contains the entire chick β-actin gene cloned in PUC-8 (a gift of B. Paterson). NIH 3T3 cells were co-transfected with pβ6 actin and pSV2-neo, and G418-resistant colonies were selected. Figure 4 shows that the levels of β-actin RNA correctly initiated from the transfected β-actin promoter are not reduced after MMSV transformation, but in the same cells, the levels of endogenous $\alpha 2$(I) collagen RNA are sharply decreased (data

not shown). The other plasmid used (pAZ1037) contains a fragment of the chicken β-actin gene, including 350 bp preceding the start of transcription, the first exon, the first intron and part of the second exon fused to the *cat* gene. The plasmid is otherwise identical to pAZ1009 and, therefore, contains the same splice signals and polyadenylation site, in addition to the SV40 enhancer segment. NIH 3T3 cells were co-transfected with this plasmid and pSV2-neo, G418-resistant colonies were selected and the levels of CAT compared before and after transformation of the colonies with MMSV. The results (Table 1*c*) indicate that the levels of CAT show little change in most colonies after transformation by MMSV. When a decrease occurs, it is clearly less than in colonies containing a transfected α2(I) collagen promoter. This experiment suggests that neither the *cat* DNA sequences nor the sequences spanning the SV40 splice signals, the intron and the poly(A) addition site are responsible for the reduced levels of *cat* RNA found in the MMSV-transformed cells in which these DNA elements are fused to the α2(I) collagen promoter. Hence, the decrease in *cat* RNA levels in such cells is presumably not caused by a change in the stability of these RNA sequences.

The AT3-14 cell line is an NIH 3T3 cell that has been stably transfected with plasmid pHO1000. In these cells, the *gpt* gene is under the control of the early SV40 promoter, whereas the *cat* gene is transcribed from the α2(I) collagen promoter (Figs 1, 2). Comparison of the levels of *gpt* RNA in these cells before and after transformation by MMSV revealed that the levels of *gpt* RNA were also strongly decreased after MMSV transformation (Fig. 3*d*, lanes 1, 2). One possible explanation for the down-regulation of the early SV40 promoter in MMSV-transformed cells is a *cis* effect mediated by the α2(I) collagen promoter present on the same plasmid. NIH 3T3 cells were, therefore, co-transfected with pSV2-cat and pSV2-neo, and G418-resistant colonies were isolated and transformed by

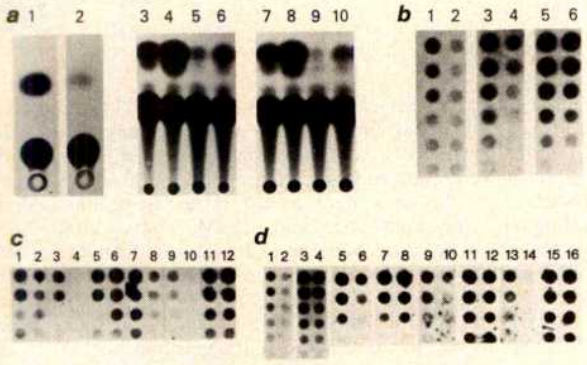

Fig. 3 Expression of the recombinant α2(I) collagen promoter (*a*–*c*) and of the recombinant SV40 early promoter (*d*) in normal and transformed cells. Clones of NIH 3T3 stably transfected with pHO1000 (*a*, *b*) or pAZ1005 (*c*) were withdrawn from the selection medium and transformed by a mixture of murine Moloney sarcoma virus and murine leukaemia virus (MMSV) or by transfection with the v-*mos* gene. *a*, Levels of CAT activity in normal and MMSV-transformed clones of NIH 3T3 cells stably transfected with pHO1000. 5×10^5 cells, normal (lanes 1, 3, 4, 7, 8) and transformed (lanes 2, 5, 6, 9, 10), were seeded in 100-mm dishes. After 48 h, the level of CAT was measured as described by Gorman *et al.*[12], except that equal amounts of proteins were used in the assays: lanes 1 and 2, clone AT3-14, 0.4 mg protein extract per assay; lanes 3–6, clone AT1; lanes 7–10, clone AT2; lanes 3, 5, 7, 9, 0.15 mg protein per assay; lanes 4, 6, 8, 10, 0.75 mg protein per assay. *b*, RNA dot blots from clone AT3-14. 1.5×10^6 AT3-14 cells (lanes 1, 3, 5) or MMSV-transformed AT3-14 cells (lanes 2, 4, 6) were seeded in 100-mm dishes. After 24 h, total RNA was extracted and twofold serial dilutions (in 20×SSC with 25 μg ml^{-1} bacterial rRNA) of total RNA (starting with 10 μg RNA per dot) were applied to nitrocellulose paper using a dot-blot template. The levels of α2(I) collagen RNA (lanes 1, 2), *cat* RNA (lanes 3, 4) and actin RNA (lanes 5, 6) were measured using the hybridization probes described in Fig. 2 legend. *c*, RNA dot-blot hybridization of clones of NIH 3T3 stably transfected with the plasmid pAZ1005. RNA was isolated and spotted for dot-blot hybridization as described in *b*. Lanes 1–6, clone AZ51; lanes 7–12, clone AZ57; lanes 1, 3, 5, 7, 9, 11 are of RNA from normal cells; lanes 2, 4, 6, 8, 10 and 12 are of RNA from v-*mos*-transformed cells; lanes 1, 2, 7 and 8 were hybridized with the same α2(I) collagen probe. Lanes 3, 4, 9 and 10 were hybridized with a *neo* probe consisting of a 1,300-bp *Sma*I/*Hin*dIII fragment of pAZ1005; lanes 5, 6, 11 and 12 were hybridized with the β-actin probe. *d*, Activity of the early SV40 promoter in normal and MMSV-transformed NIH 3T3 cells. Cells were stably transfected with plasmids pHO1000 (lanes 1–4, clone AT3-14) or pSV2-neo (lanes 5–8, clone SV7; lanes 9–12, clone SV8; lanes 13–16, clone SV9). RNA was extracted from normal cells (lanes 1, 3, 5, 7, 9, 11, 13, 15) or MMSV-transformed cells (lanes 2, 4, 6, 8, 12, 14) and twofold serial dilutions of the RNA were spotted and hybridized as described in *b*. Lanes 1 and 2 were hybridized with a *gpt* DNA probe; lanes 5, 6, 9, 10, 13 and 14 were hybridized with a *neo* DNA probe; lanes 3, 4, 7, 8, 11, 12, 15 and 16 were hybridized with a β-actin DNA probe.

Methods. Transformation by MMSV: Cells were seeded in two T-25 flasks (3×10^5 cells per flask); to one of the flasks 5 ml of medium, incubated for 3 h with established MMSV-transformed NIH 3T3 cells, were added. Both normal and infected cells were carried for 1–2 weeks before they were assayed. Transformation by v-*mos*; clones of cells stably transfected with pAZ1005 and expressing the *neo* gene were isolated as described in Fig. 2 legend with the exception that *neo* selection medium was used (600 μg ml^{-1} G418). G418-resistant clones were re-transfected by plasmid pHT25, carrying the v-*mos* gene[24] (gift of G. Van de Woude). The transformed colonies were selected by focus formation and recloned in soft agar.

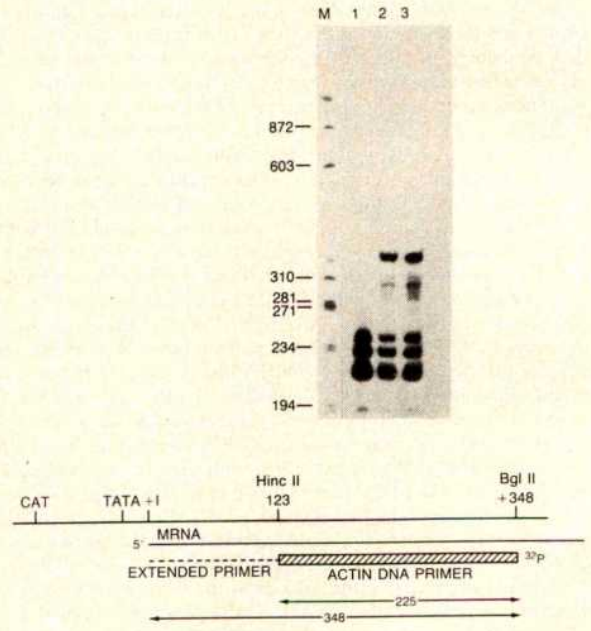

Fig. 4 Levels of chick β-actin RNA in normal and MMSV-transformed NIH 3T3 cells stably transfected by the chicken β-actin gene (pβ6 actin)[19]. A genomic DNA (18 μg) fragment containing the entire chicken β-actin gene cloned in PUC-8 (a gift of B. Paterson) was co-transfected with 2 μg DNA of pSV2-neo[13] into NIH 3T3 cells. G418-resistant clones (~100 colonies) were pooled and transformed by MMSV as described in Fig. 3 legend. Total RNA was extracted by the guanidine hydrochloride method[21] and the levels of chick β-actin RNA were measured using a primer extension method. A single-strand 225-nucleotide *Bgl*II/*Hin*cII fragment of the chicken β-actin cDNA clone, labelled with ^{33}P at its *Bgl*II 5′ end, was used as primer and hybridized to total RNA of untransfected NIH 3T3 cells (lane 1), to untransformed NIH 3T3 cells stably transfected with pAZ1037 (lane 2) and to the same cell transformed with MMSV (lane 3). The primer was extended with reverse transcriptase as described for Fig. 2 and the products were analysed by electrophoresis on a 7 M urea/5% polyacrylamide gel. The bands on the gel were quantitated by microdensitometry; the ratio of the 348-nucleotide cDNA to the 225-nucleotide primer was 0.55 in lane 2 and 0.62 in lane 3.

Table 1 Levels of activity of transfected α2(I) collagen, β-actin and SV40 early promoter in normal and MMSV-transformed cells

	Cell lines	Promoter	CAT specific activity (c.p.m. per mg protein $\times 10^4$) Normal (N)	Transformed (T)	Ratio (N/T)
a	1, AT3-14	Chick α2 type I collagen	19.5	2.8	7.0
	2, AT1		32.0	2.2	14.5
	3, AT2		18.7	1.3	14.4
b	1, AZC1	Mouse α2 type I collagen	25.8	5.4	4.8
	2, AZC2		236.9	60.7	3.9
	3, AZC4		24.1	3.9	6.2
	4, AZC5		86.1	3.9	22.1
	5, AZC6		641.5	504.7	1.3
c	1, AZA1	Chick β-actin	522.1	362.7	1.4
	2, AZA2		118.5	70.6	1.6
	3, AZA3		3.3	2.7	1.2
	4, AZA4		35.4	11.7	3.0
	5, AZA6		41.0	20.3	2.0
d	1, SV1	SV40 early region	214.2	34.7	6.2
	2, SV5		139.3	10.8	12.9
	3, SV6		0.5	0.2	2.5

NIH 3T3 cells were transfected with 10 μg pHO1000 DNA (as described in Fig. 1 legend) (*a*, 1-3) or with 10 μg DNA of pSV2-neo and pAZ1009 (*b*, 1-5), pSV2-neo and pAZ1037 (*c*, 1-5) or pSV2-neo and pSV2-cat (*d*, 1-3). The ratio of pSV2-neo DNA to the other DNA used in co-transfections was 1:10. Individual colonies resistant to mycophenolic acid (*a*) or to G418 (*b*, *c*, *d*) were isolated. Levels of CAT were measured before and after MMSV transformation of these cells as described in Fig. 2 legend.

MMSV. Table 1*d* compares the levels of CAT in these cells before and after MMSV transformation and shows clearly that the enzyme levels are strongly reduced on transformation. In a similar experiment, NIH 3T3 cells were transfected with pSV2-neo alone, and G418-resistant colonies were isolated and transformed by MMSV. Comparison of the levels of *neo* RNA in these cells before and after transformation by MMSV showed that in almost all cell lines the levels of *neo* RNA were decreased after transformation (Fig. 3*d*, lanes 5, 6; 9, 10; 13, 14). These experiments suggest that the activity of the early promoter of SV40 is also inhibited in MMSV-transformed cells and that this effect is not mediated in *cis* via the α2(I) collagen promoter. Because a wide range of changes occurs in the pattern of proteins synthesized in transformed cells, it is not unexpected that another promoter would also be inhibited in transformed fibroblasts. We speculate that the SV40 early promoter contains sequence elements that might interact with one or more proteins which also recognize the α2(I) collagen promoter in fibroblasts. One possible hypothesis is that one or more of these proteins may either be modified or may cease to be synthesized after MMSV transformation.

The decrease in *cat* or *neo* RNA levels in cells where the corresponding genes are linked to the α2(I) collagen promoter is a result of the presence in these cells of an active transforming protein. Indeed, when AT3-14 cells, a cell line in which the α2(I) collagen promoter is fused to the *cat* gene, were transformed with a mutant of the Kirsten murine sarcoma virus, temperature-sensitive for transformation, the levels of CAT activity were decreased at the permissive temperature but not at the non-permissive temperature. These changes parallel the changes in the levels of endogenous α2(I) collagen RNA (data not shown).

Thus, the activity of the α2(I) collagen promoter introduced into NIH 3T3 cells by DNA transfection is strongly inhibited after malignant transformation by the v-*mos* oncogene. This inhibition parallels the reduction in the expression of both the endogenous type (I) collagen and fibronectin[16] genes in fibroblasts. A similar decrease is seen in the activity of the transfected SV40 early promoter, but not in the activity of a transfected β-actin promoter.

We thank Ira Pastan, Michael Gottesman, Gene Liau and Cathy McKeon for discussions, Cori Gorman for pSVOcat and pSVOneo, Raji Padmanabhan for advice with tissue culture and DNA transfections, Jennie Evans for editorial assistance and Ray Steinberg for photography.

Proteins binding to specific regions of DNA with high affinity frequently govern or regulate reactions at the gene level[1-8]. We have identified a high-affinity binding site in the immunoglobulin μ gene that binds a specific nuclear protein, and have now characterized it fully using nuclear factor 1 (NF-1), a protein purified from the nuclei of HeLa cells[9,10] and required for the *in vitro* replication of adenovirus (Ad) DNA[9-12]. NF-1 protects a 25-base pair (bp) double-stranded segment of DNA which shares a consensus sequence, 5′ TGGA/CNNNNNGCCAA 3′, with similar

binding sites in the Ad-5 terminal repeat[10–12] and the human c-*myc* gene[13]. Although this site differs from the enhancer region[13–16], a biological function is suggested by the fact that it is DNase I hypersensitive in immunoglobulin-producing lymphoblastoid cells. The binding site for the NF-1 protein in the μ gene, by analogy with the site in the Ad-5 terminal repeat, may represent one component of a cellular origin of replication; alternatively, it may be responsible for the activation of the chromatin in this region.

The immunoglobulin heavy-chain genes represent a set of DNA sequences of intense transcriptional activity in immunoglobulin-producing B cells. They also represent a target for a highly specific translocation event that delivers the oncogene c-*myc* into this locus in most instances of the B-cell malignancy, Burkitt's lymphoma[17,18]. Recently, we have identified five potential regulatory sites in the *myc* gene region on the basis of their DNase I hypersensitivity[13]. Two of these sites,

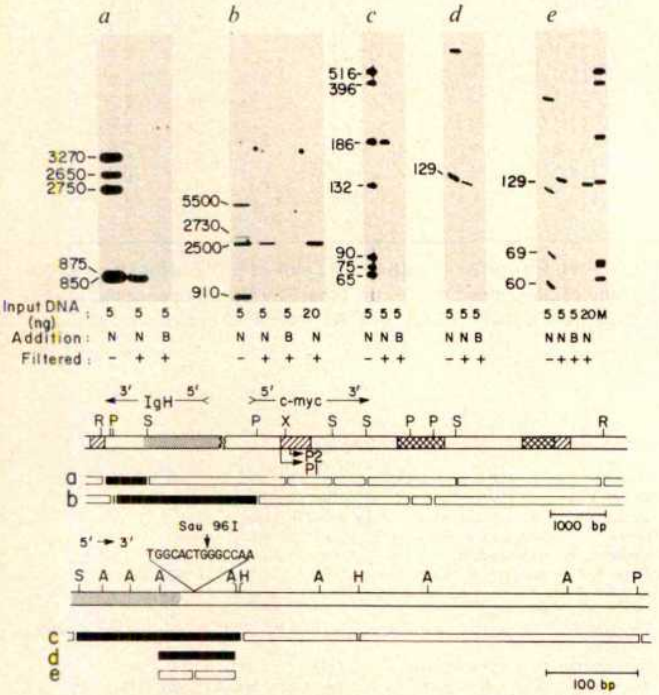

Fig. 1 Mapping of the protein binding sites on DNA fragments overlapping the human IgM and *myc* genes. Recombinant plasmids were cut with restriction enzymes and the resulting fragments were end-labelled using [α^{32}P]-dNTPs (labelled deoxynucleotide triphosphates) and the large fragment of *Escherichia coli* polymerase (Klenow)[13]. Labelled DNA was incubated with a low salt extract from Burkitt's lymphoma (BL22) nuclei (N)[13] for 30 min at 25 °C and passed through nitrocellulose filters. Protein-bound DNA, retained on the filters, was extracted[13] and analysed on agarose gels (*a*, *b*) (+) or sequencing gels (*c*–*e*) (+). The pattern of input DNA was assayed by omitting the nitrocellulose filtration step (−). Background binding of labelled fragments on nitrocellulose filters was analysed by substituting bovine serum albumin (B) for nuclear proteins. To determine protein binding sites, cloned DNA from BL22, overlapping the IgM gene and *myc* gene (pBL22 RI-RI 9.0[16], was cut with *Eco*RI, *Sst*I and *Xho*I (*a*) or with *Pst*I (*b*). *a*, *Eco*RI and *Xho*I sites; *b*, *Pst*I sites were labelled radioactively. For fine mapping, the 600-bp *Sst*I/*Pst*I fragment (sequence is shown in Fig. 2*c*) was cloned into the polylinker of the vector pUC13 (BRL) (pIgHSP0.6) and cut with *Eco*RI and *Hin*fI (*c*). Both types of ends were labelled radioactively. The *Eco*RI site is in the polylinker next to the *Sst*I site. The *Alu*I fragment covering the protein binding site was cloned into the *Sma*I site of M13mp10 RF (M13IgHA80). *d*, *e*, Binding assays where this fragment was cut out with *Eco*RI and *Hin*dIII, the sites which bracket the polylinker. *e*, M13IgHA80 cut with *Eco*RI and *Hin*dIII was recut with *Sau*96I. The 129-bp *Eco*RI/*Hin*dIII fragment is cut into two 60 and 69-bp fragments. The other two fragments are derived from M13mp10 RF. As a positive control for binding, 20 ng M13IgHA80 cut with *Eco*RI and *Hin*dIII were added to the samples to be filtered. Solid bars, DNA fragments bound by nuclear proteins; dotted regions, μ switch region; single-hatched regions indicate non-translated exon sequences. Double hatched regions indicate protein coding sequences. P1 and P2, the two promoters of the *myc* gene. A, *Alu*I; R, *Eco*RI; H, *Hin*fI; P, *Pst*I; S, *Sst*I; X, *Xho*I. As a relative molecular mass marker (M) in *e*, the plasmid pIgHSP0.6 had been digested with *Hin*fI and *Eco*RI. The visible bands indicate the following sizes: 516, 396, 186, 132, 84, 78 and 68 bp.

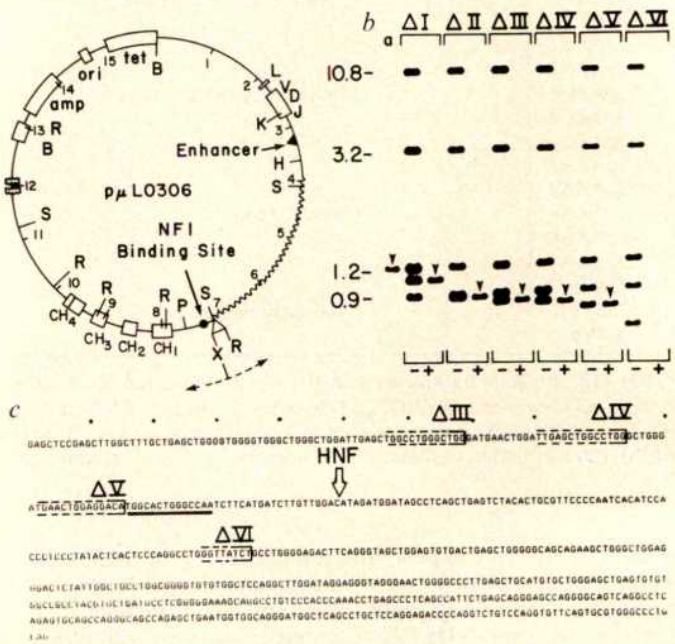

Fig. 2 Fine mapping of the NF-1 binding site in an IgM gene. *a*, Construction of pμL0306: B, *Bam*HI; K, *Kpn*I; P, *Pst*I; R, *Eco*RI; S, *Sst*I. Wavy line, μ switch region; open boxes drawn with wavy lines, IgM membrane exons, the exact location of which is not known; open boxes with straight lines represent IgM exons. *b*, Mapping the protein binding sites on the IgM plasmids carrying the *Bal*31 deletions; the sizes of the *Eco*RI fragments not subjected to *Bal*31 deletions are indicated in kb. The first lane (*a*) shows the filter-bound *Eco*RI fragment of the starting plasmid pμL0306 (filter-bound fragments are always indicated by an arrow). The numbers above the upper brackets indicate the different plasmids used. Below the lower brackets, lanes with non-filtered (−) and filter-bound (+) DNA are indicated. *c*, DNA sequence of the 603-bp *Sst*I/*Pst*I fragment. The DNA sequence was derived by using the dideoxy chain terminating method according to the BRL Manual (BRL, Inc.). The brackets indicate the endpoints of the various deletions. Sequences to the left of the brackets were deleted and replaced with *lacZ* DNA. The numbers above the brackets indicate the respective plasmid. The underlined sequence is the core of the proposed NF-1 binding site (see Fig. 3*a*). The arrow above the sequence indicates the midpoint of the DNase I hypersensitive region (HNF) (see Fig. 4).

Methods. *a*, A pBR322 molecule was linearized by *Bam*HI and, in a series of steps, ligated to three pieces of DNA from human μ libraries to produce a cloned rearranged human μ plasmid. The region from the *Bam*HI site at ~12.8 kb to the *Hin*dIII site at ~3.7 kb came from a germline library, the region from this *Hin*dIII site to the *Kpn*I site at ~2.7 kb from a lymphoma library (line LR35) and the region from this *Kpn*I site to the *Bam*HI site at 0 kb from a closely related lymphoma library (line LR36). Into the germline piece was inserted (as shown) a 268-bp *Sst*I/*Sst*I fragment containing M13mp11 sequences from the *Sst*I site in the polylinker to the *Pvu*II site in the *lac*I gene (the latter converted to an *Eco*RI site with an *Eco*RI linker), joined to pBR327 sequences from the *Eco*RI site to the *Cla*I site (the latter converted to an *Sst*I site by blunting the ends with Klenow polymerase and adding an *Sst*I linker). The unique *Xho*I site had been produced by cloning an *Xho*I linker into the M13mp11 *Sma*I site. Not all restriction sites are shown for all enzymes. Following *Bal*31 deletion starting at the unique *Xho*I site, the plasmids were re-ligated after blunting the ends with Klenow polymerase. *b*, Six plasmids carrying different deletions were cut with *Eco*RI labelled by fill-in and incubated with nuclear extract. Non-filtered (−) as well as filter-bound (+) DNA was subjected to agarose gel electrophoresis (for details see Fig. 1).

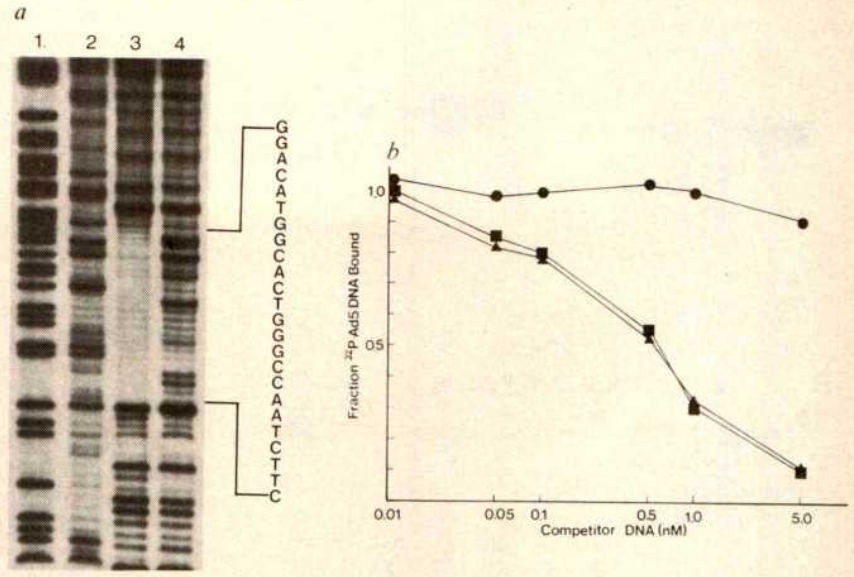

Fig. 3 *a*, DNase I footprint of the NF-1 binding site in the IgM gene. *b*, Competition nitrocellulose filter-binding assays with Ad-5 and IgM NF-1 binding sequences.
Methods. *a*, A ^{32}P-end-labelled DNA fragment from M13IgHA80 RF DNA containing a NF-1 binding site was subjected to limited DNase I digestion in the absence (lane 3) or presence (lane 4) of the phosphocellulose fraction[10] of NF-1 protein and the products were analysed on an 8% polyacrylamide urea sequencing gel. G+A (lane 1) and A+C (lane 2) sequencing reactions of the fragment were run in parallel lanes to determine the sequence of the region protected by the protein. M13IgHA80 RF DNA was linearized by restriction with *Eco*RI and the 3′ recessed ends of the fragments were filled-in and labelled using DNA polymerase I large fragment (Klenow) and [α-^{32}P]dATP (3,000 ci mmol^{-1}). The labelled DNA fragments were cut with *Hin*dIII and the fragment containing the NF-1 binding site isolated by electrophoresis in a 2% agarose gel and extracted by electroelution followed by chromatography through NACs resin (BRL). Protein–DNA binding was carried out at 0 °C for 20 min in a reaction mixture (40 μl) containing 50 mM HEPES (*p*H 7.5), 5 mM MgCl, 1 mM dithiothreitol DTT, 250 μg m^{-1} bovine serum albumin, 125 μg ml^{-1} *E. coli* DNA, 200 mM NaCl, 15 μl phosphocellulose I fraction of NF-1 and 1 ng ^{32}P-DNA fragment. The reaction mixtures were incubated with DNase I (0.075 μg) for 1 min at 23 °C, extracted with neutralized phenol and, after ethanol precipitation, the reaction products analysed as described above. *b*, The binding affinities of NF-1 to Ad-5 and IgM DNA were compared by competition nitrocellulose filter-binding assays as described previously[10]. Purified NF-1 (200 ng) and 5 fmol *Eco*RI-restricted ^{32}P-labelled pMDC10 DNA (contains 365 bp of Ad-5 left-terminal sequence) were incubated with varying amounts of unlabelled form I pMDC10 and PIgHSP0.6. The concentration of labelled pMDC10 *Eco*RI bound to NF-1 was determined by nitrocellulose filter binding. The fraction bound was calculated as the ratio of Ad-5 DNA bound to the filter in the presence and absence of competitor DNA. The following DNAs were used as competitors: ●, pUC9 (plasmid DNA); ■, pMDC10 (Ad-5/NF-1 binding site); ▲, pIgHSP0.6 (IgM/NF-1 binding site).

a putative repressor binding site and a weak NF-1 binding site, are not associated with the translocated and deregulated *myc* gene in the Burkitt's lymphoma cell line, BL22 (refs 19, 20). Therefore *myc* activation could be the result of *cis*-acting sequences in the immunoglobulin heavy-chain locus (*Igh*). To identify such DNA sequences we sought to find regions in the translocated immunoglobulin μ segment which might interact specifically with nuclear proteins. Using a nitrocellulose filter binding assay[13,21,22] and cloned DNA (pBL22 RI-RI 9.0; see Fig. 1), including the IgM/*myc* crossover region in BL22 (ref. 16). We discovered a fragment of DNA between the μ switch and the μ constant region binding specifically to protein(s) derived from a low-salt BL22 nuclear extract[13]. The binding region is in a 603-bp DNA segment between a *Pst*I and *Sst*I site (see Fig. 1*a*, *b*). Subcloned restriction fragments of this 603-bp fragment were assayed and the binding site further mapped to a 80-bp *Alu*I fragment (Fig. 1*c*, *d*). Recutting a 129-bp fragment containing the 80-bp *Alu*I fragment with *Sau*96I destroyed the ability of the resulting fragments (69 and 60 bp, see Fig. 1*e*) to be retained in the filter binding assay, suggesting that the binding site either contains the *Sau*96I site or lies very close to it. The binding site is also present in the germline configuration of the *Igh* locus (Fig. 2), indicating that mutational events in BL22 are not responsible for its appearance. Further information about the location and nature of the protein binding site was obtained using *Bal*31 deletions, sequence analysis and DNase I footprinting *in vitro* (Figs 2, 3). Using a normal μ gene, we constructed deletions starting from a unique *Xho*I site cloned into the *Sst*I site at the 3′ end of the μ switch (see Fig. 2*a*) and extending up to and through the putative binding site (Fig. 2). Whereas deletions ΔI–ΔV do not destroy the binding site, deletion ΔVI, which ends 3′ of the normally bound *Alu*I fragment (Fig. 1*d*), abolishes binding (Fig. 2*b*).

The sequence of this region suggested that the bound nuclear protein might be NF-1. This protein binds to two homologous sequences in Ad-5 (refs 10,13) and the c-*myc* gene[13]. Here we show that the homology extends to a sequence in the μ-gene fragment which is recognized in the filter binding assay (Figs 1*d*, 2*c*). To confirm this, the pure NF-1–DNA interaction was visualized by DNase I footprinting analysis (Fig. 3*a*). Although NF-I protects ~25 bp, sequence comparisons suggest that only a core sequence in the centre of the protected area is necessary for the specific protein DNA interaction (Fig. 2). By comparing the sequence in the IgM gene protected by NF-1 (Fig. 3*a*) with the published NF-1 sites in Ad-5 (refs 10,12) and the *myc* gene[13] and unpublished sites in other adenovirus serotypes as well as in the human polyomavirus JC and the human and simian cytomegalovirus (D.R., P.R., G. Hayward, P. Padmanablan and L.H., unpublished results), a consensus sequence can be derived (5′ . . . TGGA/ CNNNNGCCAA . . . 3′). In addition, replacement of the sequences upstream of the TGG . . . (Fig. 2*c*) with *lacZ* sequences (data not shown) in deletion mutant ΔV does not interfere with binding of NF-1 (Fig. 2*b*). A DNA binding protein from chicken oviduct nuclei recognizes a similar sequence in the chicken lysozyme gene region[23].

The binding site exhibits a 2-fold axis of symmetry exemplified by the TGGC . . . GCCA sequences. High binding affinity occurs when this symmetry is most pronounced, as in the IgM and Ad-5 binding sites[10,13]. Using an equilibrium competition assay, we show that the IgM and Ad-5 binding site affinities are nearly equal (Fig. 3*b*) and an order of magnitude stronger than the c-*myc* binding site, which exhibits only an approximate symmetry[13]. The 2-fold symmetry axis in the binding site suggests that NF-1 binds as a dimeric form mechanistically similar to repressor protein DNA interactions[24]. Although it is not known whether NF-1 purified from HeLa cells and the binding protein(s) from B cells are identical, we have shown that both binding activities recognize the same synthetic binding site cloned into a plasmid vector (L.H. and L. Davis, in preparation).

To assign biological significance to the NF-1 binding site in the IgM gene, we provide evidence that NF-1 also binds to this element *in vivo*. The localization of DNase I hypersensitive sites in chromatin can identify potential protein binding sites[3,25,26]. Therefore, we mapped the DNase I hypersensitive sites in the IgM gene in lymphoblastoid cells and in BL22 (Fig. 4). A probe from the μ constant region detects two DNase I hypersensitive sites in the lymphoblastoid cell line 8392 (Fig. 4*A*, *a*). One in the μ switch, approximately where the *myc*μ translocation point in BL22 is found, and one near the NF-1 binding site. NF-1 binds ~3.1 kilobases (kb) 5′ to the *Xba*I site (Fig. 4*B*, *a*) and

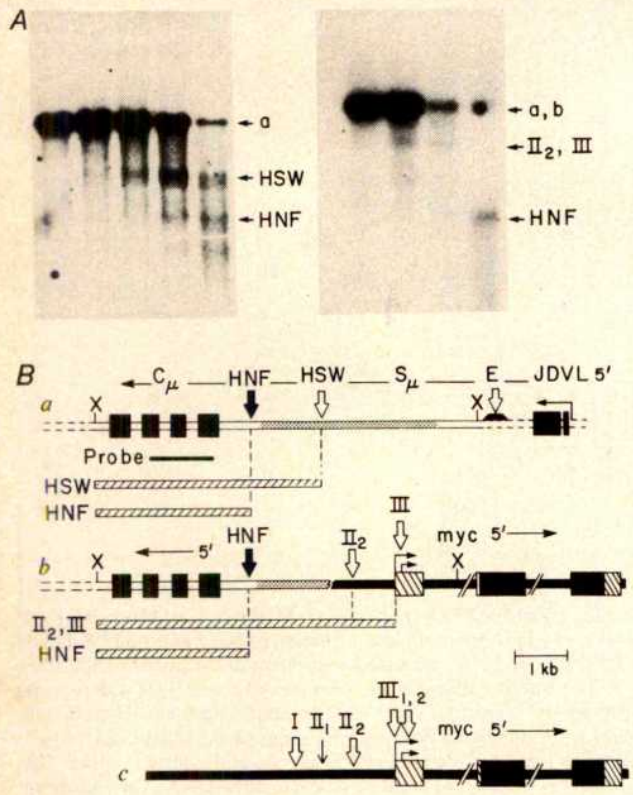

Fig. 4 *A*, Mapping of DNase I hypersensitive sites near the c-*myc* gene and IgM gene in the lymphoblastoid cell line 8392 (left) and the Burkitt's lymphoma cell line BL22 (right). Nuclei of both cells were digested with increasing amounts of DNase I as described previously[13] and then 15 μg of isolated genomic DNA restricted with *Xba*I, electrophoresed on a 0.8% agarose gel, blotted onto nitrocellulose and hybridized. A 1.2-kb *Eco*RI fragment overlapping the μ constant region was used as hybridization probe. *B*, The probe hybridizes to a germline IgM fragment (*a*) and to a fragment of similar size from the IgM *myc* translocation product (*b*). The DNase I hypersensitive sites are labelled HSW (hypersensitive switch), HNF (hypersensitive NF-1 binding site), E (enhancer)[13-16], I, II1, II2, III1, and III2 as described previously[13] and their positions are indicated on the map (*X*, *Xba*I). *a*, *b*, Solid arrow indicates the binding site for NF-1; cross-hatched bars, sub-bands in the cell lines 8392 (*a*) and BL22 (*b*). Protein coding regions of both the *myc* gene and the IgM gene are indicated by solid boxes, nontranslated regions of exons by cross-hatched boxes. Dotted regions correspond to the μ switch. The *myc* gene is not drawn to scale. *c*, Pattern of DNase I hypersensitive sites in the germline *myc* is shown[13].

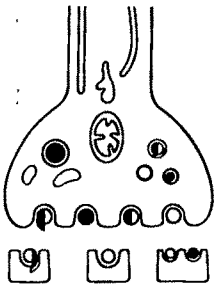
therefore falls into the DNase I hypersensitive region represented by a sub-band 3,050–3,200-bp long (Fig. 4*B*, *a*). The same probe picks up two sub-bands in BL22 (Fig. 4*B*, *b*), one representing the DNase I hypersensitive region at the NF-1 binding site and one representing closely linked sites in the *myc* gene translocated into the IgM region. This band has a size of ~5 kb and presumably corresponds to the sites II2, III1 and III2 (Fig. 4*B*, *b*, *c*) occurring in the 5′portion of the *myc* gene[13]. The co-localization of DNase I hypersensitive sites and NF-1 binding sites in the *myc*[13] and IgM genes suggests a possible NF-1 DNA interaction *in vivo*.



The function of the μ NF-1 binding site remains to be defined. It could be similar to that of the analogous sequence in adenovirus, that is, acting as one component of an origin of replication. In the HeLa cell genome, the frequency of high-affinity NF-1 binding sites is one per 100 kb[27], a spacing similar to that of cellular origins of replication[28]. Alternatively, these sites could be involved in transcriptional activation, although this is not consistent with the distribution of NF-1 binding sites in the immunoglobulin heavy-chain locus. The NF1 site is in the first intron of the μ gene just 3′ to the μ-switch region. A search in clones overlapping the γ and ε switch and constant regions failed to reveal any binding sites (data not shown). During B-cell development, a series of recombination events leads to a switch in heavy-chain constant-region class from μ/δ to either γ, ε or α[29,30]. After switching from μ/δ to any other constant region, the μ NF-1 binding site would be deleted from the resulting active heavy-chain gene. By contrast, the canonical *Igh* enhancer 5′ to the μ switch is retained during heavy-chain class switching[14-16]. This, together with the fact that equivalent binding sites do not occur at corresponding positions in the γ and ε genes, makes it less probable that NF-1 acts as a simple transcriptional enhancer. On the other hand, the loss of the μ NF-1 binding site during heavy-chain class switching could indicate that, in the *Igh* region, NF-1 is a necessary component for this 'dead end' recombination process. We are left with another, equally attractive, possibility, that the NF-1 binding sites have a more universal role in the activation of chromatin during early stages of cell differentiation, suggested by the observation that the NF-1 binding sites in the human *myc*[13] and IgM genes are located in DNase I hypersensitive regions, areas associated with the active state of chromatin.

Portions of this work were supported by grants from E. I. DuPont de Nemours and Co., Inc. and the American Business for Cancer Research Foundation. L.H. is a fellow of the Deutsche Forschungsgemeinschaft; D.D. is a fellow of the Helen Hay Whitney Foundation.

There is now compelling evidence that neurons might synthesise, store and release more than one neuroactive substance – a concept that will profoundly change our understanding of the pharmacology of the central and peripheral nervous systems. This book investigates the most representative arguments currently being put forward on this new topic.

Contents

Foreword – *Sir William Paton*; Preface; Coexistence of traditional neuro-transmitters with peptides in the mammalian brain; S-hydroxy tryptamine and substance P in the raphe and γ-aminobutryic acid and moblin the cerebellum – *V. ANNOUNCEMENT AND CALL FOR PAPERS

JOURNAL OF BIOLUMINESCENCE AND CHEMILUMINESCENCE

EDITOR-IN-CHIEF

Dr L.J. Kricka, *Department of Clinical Chemistry, Wolfson Research Laboratories, University of Birmingham, Birmingham B15 2TH, UK*

A fully international editorial board, to include regional editors, is currently being appointed.

AIMS AND SCOPE

The *Journal of Bioluminescence and Chemiluminescence* will provide comprehensive coverage of the fundamental aspects and applications of light-emitting reactions, both chemical — *chemiluminescence* — and biological — *bioluminescence.*

The journal will publish original scientific papers, short communications, technical notes, and review articles on fundamental and applied aspects of bioluminescence and chemiluminescence. It will also have a News and Events Section which will contain details of forthcoming meetings, information on new products, and book reviews. A special feature of this journal will be a quarterly survey of the recent world literature on bioluminescence and chemiluminescence.

TOPICS COVERED

Chemiluminescent and bioluminescent methods are used as research tools in many disciplines (chemistry, clinical sciences, environmental monitoring, microbiology) and the scope of the journal will reflect this diversity.

- **Instrumentation**
- **Fundamental studies**
- **Applied chemiluminescence**
- **Applied bioluminescence**
- **Luminescent immunoassay**
- **Luminescence in microbiology**
- **Phagocytosis**
- **Low level luminescence**

SUBMISSION OF ARTICLES

Articles on any aspect of bioluminescence and chemiluminescence are sought and should be submitted, in triplicate, to the Editor-in-Chief, Dr L.J. Kricka.

The first issue is scheduled for January 1986 . . . .

SUBSCRIPTION DETAILS

Quarterly _____ approx. £65.00/$99.00
(including postage worldwide)

For further details and a free sample please contact:

John Wiley & Sons Ltd.

Fresh from the test tube – Springer for biochemistry

Neurochemical Techniques in Insect Research

Editors: **H. Breer, T. A. Miller**
1985. 67 figures. Approx. 350 pages
(Springer Series in Experimental Entomology)
Hard cover DM 169,–. ISBN 3-540-13813-7

This book presents a collection of techniques and methods designed or adapted for the study of various aspects of the neurochemistry and molecular neurobiology of insects. With defined modifications, the information particular to insects may be applied to the study of all animals.

J. Havas

Ion- and Molecule-Selective Electrodes in Biological Systems

1985. 43 figures, 27 tables.
Approx. 255 pages
Hard cover DM 98,–. ISBN 3-540-13725-4
Distribution rights for Socialist Countries.
Akadémiai Kiadó, Budapest

Contents: Preface. – Equilibria in the Fluids of the Organisms. – Potentiometric Measurements in Biological Systems. – Ion-Selective Electrodes and their Applications. – Molecule-Selective Electrodes and Sensors and their Applications. – Ion-Selective Field-Effect Transistors. – References. – Subject Index

T. L. Hill

Cooperativity Theory in Biochemistry

Steady-State and Equilibrium Systems

1985. 230 figures, 8 tables
Approx. 650 pages
(Springer Series in Molecular Biology)
Hard cover DM 398,–. ISBN 3-540-96103-8

In this book, the author gives a unified treatment of the statistical thermodynamics of cooperative biological systems. The aim is to introduce, by means of a very large number of examples, the methods that can be used to treat cooperativity in both steady-state and equilibrium systems

The Chemistry and Biology of Isoquinoline Alkaloids

Editors: **J. D. Phillipson, M. F. Roberts, M. H. Zenk**
1985. 177 figures. Approx. 300 pages.
(Proceedings in Life Sciences)
Hard cover DM 108,–. ISBN 3-540-13980-X

The topics treated in this book range from an introduction to the natural occurrence, structure determination, synthesis, biosynthesis, and plant tissue culture production through to pharmacology.

Biochemistry and Function of Vacuolar Adenosine-Triphosphatase in Fungi and Plants

Editor: **B. P. Marin**
1985. 85 figures. Approx. 280 pages
Hard cover DM 84,–. ISBN 3-540-15267-9

Contents: Characteristics of Tonoplast Membranes. – Tonoplast ATPases. – Measurement of Protonmotive Potential Difference Across the Tonoplast Membrane. – Proton Pump Activity and Tonoplast Energization. – Role of Tonoplast ATPase in the Compartmentation of Solutes in Plant Cells.

The Physiological Properties of Plant Protoplasts

Editor: **P. E. Pilet**
1985 82 figures. Approx. 300 pages.
(Proceedings in Life Sciences)
Hard cover DM 115,–. ISBN 3-540-15017-X

P. Traub

Intermediate Filaments

A Review

1985 2 figures. Approx. 295 pages
Hard cover DM 168,– ISBN 3-540-15105-2

Contents: Introduction. – Distribution of Intermediate Filaments – In Vitro Assembly and Structure of Intermediate Filaments. – Synthesis of Intermediate Filament Proteins in Vitro – Posttranslational Modification of Intermediate Filament Proteins. – Cellular Function(s) of Intermediate Filaments and Their Subunit Proteins – Summary and Concluding Remarks – References. – Subject Index

Higher Plant Cell Respiration

Editors: **R. Douce, D. A. Day**
1985. 81 figures. Approx. 525 pages
(Encyclopedia of Plant Physiology, Volume 18)
Hard cover DM 298,–. ISBN 3-540-13935-4

This volume will contribute to a better understanding of plant cell respiration, plant mitochondrial structure and function and of the biochemical flexibility of plant mitochondria.

M. Luckner

Secondary Metabolism in Microorganisms, Plants and Animals

1984 338 figures, 80 tables. 576 pages
Hard cover DM 124,–. ISBN 3-540-12771-2

This book is a summary of the biosynthesis, storage, transformation, and degradation of the most important groups of secondary products, as well as their significance for the producer organisms and for human beings.

7473/4/1

DNA Methylation

Biochemistry and Biological Significance

Editors: **A. Razin, H. Cedar, A. D. Riggs**
1984. 73 figures. XIII, 392 pages
(Springer Series in Molecular Biology)
Hard cover DM 188,–. ISBN 3-540-96038-4

This comprehensive review deals especially with the enzymes involved, the role of DNA methylation in replication and repair, patterns of DNA methylation, the involvement with gene expression and mammalian development.

Eastern and Western approaches

Roy MacLeod

The Touch of Midas: Science, Values and Environment in Islam and the West.
Edited by Ziauddin Sardar.
Manchester University Press/Longwood University Press: 1984. Pp.253. £20, $35.

VISITORS to the Science Museum in London during the spring and summer of 1976 were greeted by an unusual exhibition. Conceived by Professor S.H. Nasr, then Director of the Iranian Academy of Science, there was on view a rich display of science and technology in Islam; a display of artefacts, but also of ideas and ambitions. If science exists with such powerful resonances in traditional Islam, the unstated message read, what could it say to the West today?

For generations, it has been the received wisdom in our schools that the Muslim world had, through the Dark Ages in Europe, even from the end of Alexandria to the rise of the Renaissance, acted as a cultural "carrier" — a custodian of the Graeco-Roman scientific tradition. Western eyes, closed to Islam after the fall of Constantinople in 1453, looked instead to passages and conquests overseas, eventually bringing the fruits of exploration and empire in tribute to a Europe emboldened by the "new philosophy" of the scientific revolution. In our schools we averted our eyes from Islam, portrayed as an ossified metaphysics, unproductive in the age of men committed to "the effecting of all things possible".

Yet, if one enquired, the position was never so simple. Surely the sources of discovery in Islam drew from the same wells as those which revived the "West"? Surely no historian could ignore the fundamental contributions to mathematics and medicine, optics and astronomy, pharmacy and biology, engineering and anatomy, associated with the Islamic world from North Africa to India? No student of Sarton or Miéli could ignore the discoveries of Ibn al-Haitham (Alhazen), Avicenna, al-Bīrūnī, or even Ibn al-Nafis, even if, in our pages, where ideas count for more than men, they hovered like restless shadows between the heat and cold of the desert, concealed by enveloping gardens of mystic lore. Still, Islam, as a philosophical system, had its specialists and as such could be left to one side. Language and mystery silenced our doubts; our ignorance flourished.

Within the past 15 years, several factors have helped to alter this dismal prospect. First, there came the weight of fresh scholarship, notably that of David King, David Pingree and G.S. Kennedy, and the late Willy Hartner, paralleling and complementing Joseph Needham's work on China and A. Rahman's on India. This compelled European and American attention to long-neglected sources, to evidences of scientific achievement associated with what after the seventh century AD became the Muslim world. In the process, the "Middle Ages" acquired a totally new connotation, as did our sense of "science" as a unique feature of Western civilization. As this process was at work among scholars, there came what appeared to be a renaissance of an "Islamic cultural nationalism", a phenomenon particularly noticeable in Pakistan and Iran (and one of which the Science Museum was an indirect beneficiary). That renewed interest, coupled with the oil crisis of the mid-1970s, lifted scholars with no previous experience of the Middle East or Central Asia into asking fresh questions about Islam, its political sects, its Qur'anic precepts and its conceptual and methodological legacy.

The values implicit in the legacy have now become a central subject of great importance to the West. Through the 1970s, with increasing international concern for the conservation of the global environment, came a "crisis in science", in large measure reflecting disillusionment with the politics of Western technology. This in turn bred sustained reflection and recrimination among historians and other scholars. For three centuries, the gift of Western science, the "touch of Midas", had held promise of eliminating poverty and materially developing the world; in the process, perhaps scientific solutions would eventually be found to eliminate even the boundaries and burdens of ideology. Alas, however, as the experience of the world revealed, the eutetic gifts of Midas had serious shortcomings. Western science, with its powerful belief in objective, value-free knowledge, taught us that what can be discovered must be discovered, without teaching us at what cost. Western technology had, as its basis, a categorical imperative — that everything which can be done will be done. But we were unprepared for the compromise in values this sometimes entailed. With our triumphs, now competed perils.

If the "Occident" was thus caught in a dilemma of its own making, what of Islam? Here, the question was not trivially one of cultural chauvinism, or the search for scientific priorities. The Muslim world had felt the force of the West's scientific and industrial revolutions, and now felt the weight of technological dependence. Any clash of values experienced in the West would be multiplied in the world of Islam. Where would lie the way forward, between value systems long at daggers drawn?

It is to this question that Ziauddin Sardar addresses himself in this first major publication of a programme of symposia on "Islam and the West". In conferences during 1981 and 1982, sponsored by UNESCO and IFIAS, and Islam and the West International, Sardar and 13 contributors confronted Islamic and Western approaches to science and explored answers to two questions. First, can in Islam be found a new synthesis, capable of offering Occidental rationality a humane vision of knowledge, to the benefit of all mankind? Second, can there be a distinct "Islamic science" which in some way can help reunify knowledge and responsibility?

If there is a right answer to either question, the key lies in understanding the relation between Islamic principles, precepts and practice. As M. Husain Sadr and others explain, Islam is a total epistemological system; there is no dichotomy between philosophy and science, economics and politics, or religion and society. As a holistic system, it permeates all human activity. There is, therefore, no distinction between the ends and means of knowing, and between knowing and applying that knowledge. Islamic teaching incorporates a framework of concepts — including the unity of God, trusteeship, worship, civilization, social justice and public interest. These concepts, if properly acted upon, will surely promote both social and ethical accountability. In pursuit of mutual understanding, participants explored Western and Islamic values and perspectives, debated interpretations of history, and grappled with the task of creating a common agenda.

There can be no doubt of the interest generated by their discussion, or of its importance in bridging discourses long distinct. What emerged is a shared view that ethical insights can and must be sought from Islam. But there are difficulties, as all participants recognized. For a start, as J.R. Ravetz asked, can we be certain about the problem? What, precisely, is the "crisis of science"? Is it a singularly Western phenomenon? If so, surely the ethical dilemmas of Western science must be faced within the Western tradition? Is science, as knowledge, in itself good, requiring only a renewed piety to qualify abuses and bring it to humane fulfilment? Or is science fundamentally a secular activity, owing allegiance to its own self-regulating criteria, its paymasters, and the interests and values of its practitioners? Further, what precisely is the range of these "values"? Is, as Munawar Anees would argue, God the source of all that is "valuable"? If so, in what sense are human values subjective? The bewildering complexity of such theological conundra threatens even the willing traveller.

For some, it may be that to travel hopefully is more important than to arrive. But a destination of a kind comes into view in the applications of the new "Islamic im-

perative" to the built environment. Essays by Lloyd Timberlake, Alison Ravetz, S. Parvez Munzoor and S. Gulzar Haider help both to articulate the environmental ethics of Islam, and give them practical expression. Haider's model of "habitat and values" traces architectural designs in houses and cities that embody precisely those principles of integrity, purpose and clarity which have for centuries fascinated Western travellers to the Middle East. Embracing metaphors of time and structure, he offers a bold synthesis in sand and stone.

Unavoidably, as Robert Walgate summarized, ethical exhortation can appear exceedingly nebulous when one is confronted by practical issues — from militant Islamic nationalism, to the eager acquisition of Western technology apparently regardless of what would be in the West understood as "public interest". What *can* Islam offer Western science? The jury is still undecided. The ethical debates of Western science during the past two decades have not penetrated Islam. Under the circumstances, what are the implications, ethical or economic, of the "Islamization" of science and technology, as espoused here by Ali Kettani? The faith has different aspects, revealing themselves sometimes as fundamentalism, sometimes as mysticism and sometimes worldly-wise pragmatism. Which is to form our new view of science in Islam? Presumably, Islamic science must, in a practical sense, "work". We seek operational knowledge. How do we obtain it? Can there really be no sociobiology in Islam? And what of technology — can there be an Islamic bulldozer, and, if so, how would its construction or function differ from Massey-Ferguson's finest? Finally, what are the political dimensions of Islamic science? As Robert Walgate reflected, the cult of the expert gives great power in Islam to the *Ulamā*, just as the cult of expertise is given great power (and accountability) in the West. If one wants gold, can one escape the fate of Midas?

Mr Sardar would not claim these questions have been fully answered. The discussion must go on, East and West, aided by such promising sponsorship. From it arises a challenge for Muslim scholars to find ways of encouraging the translation of beneficent principles into practical action, whether in fashioning the human environment, directing the goals of medical research, or in the conduct of everyday life. As such, the task is clearly not confined to Islam. □

Biology of paradise

Mark Williamson

Ecology and Biogeography in Sri Lanka.
Edited by C.H. Fernando.
Dr W. Junk: 1984. Pp.505. Dfl. 265, $110, £67.50.

Biogeography and Ecology of the Seychelles Islands.
Edited by D.R. Stoddart.
Dr W. Junk: 1984. Pp.691. Dfl. 300, $115, £76.50.

BOTH Sri Lanka and the Seychelles have claims to be paradise on Earth. Both also have much to offer to biogeographers and ecologists, are tropical and are in the Indian Ocean. But while Sri Lanka is a large continental island (65,000 km^2) with high mountains (up to 2,500 m), some rainforest and a long history of cultivation, the Seychelles are minute (a total land area of only some 400 km^2), in the middle of the ocean and include low coral islands, "high" limestone islands up to 8 m (of which Aldabra is the best known) and the uniquely isolated high granitic islands, rising to 900 m.

These two volumes, the latest in the *Monographiae Biologicae* series, continue a tradition of discussing interesting islands. Past volumes have covered the Canaries, New Guinea, Newfoundland and the Pityusics (Balearics). However, the intent of the series is not clear to me. The monographs are advertised as "hydrobiology", and most deal with rivers and lakes, but a case study of an ancient man-made lake in Sri Lanka (there are no natural lakes) comes in the *Developments in Hydrobiology* series from the same publisher.

So what features of island life would one expect to be covered in such a monograph? Something on geology, certainly, and something on climates. Islands have interesting relic and endemic species, so there should be something on their origin and, by now, on the rate of evolution. Since Darwin, biologists have been interested in dispersal to islands, a topic often contrasted nowadays with vicariance biogeography. The number of species, their population sizes, their turnover by immigration and extinction, the representation of this in species-area curves, and by incidence and prevalence curves, are all topics of current interest. Questions of adaptation and life history strategy naturally arise from all this, and indeed islands are generally regarded as useful experiments. But not as yet, it would seem, in the Indian Ocean.

This is not to say that some of these topics are not dealt with, and indeed dealt with quite well, in the Seychelles volume, and some of them are touched upon in the volume on Sri Lanka. But the difficulties seem to be two. The first — and this applies particularly to Sri Lanka — is that taxonomy is still fairly primitive, even in groups like mammals. But the major problem is the complexity of geological history in the Indian Ocean. During the Tertiary it resembled a dodgem stand at a fair — land whizzing in all directions, though with a pattern discernible overall; collisions here, pieces stuck there. As Braithwaite says, "if displacements in the Atlantic had been so elaborate the verification of concepts of sea-floor spreading might have been delayed for years". While the authors in the Seychelles volume do their best to get to grips with the geological background, those in the Sri Lankan volume seem mostly unaware of these phenomena, except for the occasional mention of Gondwanaland.

The volume on Sri Lanka is not so much a monograph, more a scrapbook. Interesting topics crop up, but there is little coherence. The worst chapter is "Freshwater Invertebrates, Some Comments", which comprises just two and a half pages of references to previous works. There is an account of grasslands, but not of rainforest. There are chapters on the ecology of rice fields, on Monogenea from freshwater fishes, on coastal lagoons, on parasites of the endemic and relic vertebrates, but the only vertebrate group dealt with is mammals. There is emphasis on freshwater habitats and organisms, and also on the human aspects, such as malaria, man-made lakes and land use. It is difficult to steer a course between a superficial account and a tedious catalogue, but this volume too often hits the rocks on both sides.

In contrast, the volume on Seychelles is comprehensive and stimulating, though one weakness is that the information on, say, the areas of different islands is scattered through various chapters. There are accounts of the geology and climate, coral reefs and the marine fauna, vegetation and floristics, land molluscs, terrestrial arthropods, herpetofauna, birds and on man's influence. The high Seychelles are the only small granitic islands in the middle of an ocean, and they have a remarkable fauna and flora to suit. The absence of amphibians comes into the standard definition of an oceanic island, but on the Seychelles there are five species of frogs and seven species of caecilians, burrowing legless forms; the latter at least Gondwanan relics. An introductory historical chapter includes good maps, a table of diversity and endemicity, and species-area curves.

It is really rather odd to find two volumes in the same series, appearing at the same time, which differ so much in quality. For while the monograph on Sri Lanka will be of short-lived interest, even to specialists, that on the Seychelles may well be a standard reference work for many years. □

Mark Williamson is Professor of Biology at the University of York.

● Also published by Dr W. Junk in the series *Monographiae Biologicae*, volume 56, is *The Amazon: Limnology and Landscape Ecology of a Mighty Tropical River and its Basin*, edited by Harald Sioli. The series editor is H.J. Dumont and the price is Dfl. 450, $172, £114.50.

ANNOUNCE

Biodata Handling with Microcomputers

by A B Barlow

Student's 't' test, Mann Whitney 'U' test, Wilcoxon signed rank test, 4-point assay with confidence limits, Spearman rank correlation coefficient, linear regression, Hansch analysis, enzyme kinetics by direct fit, radioimmunoassay, radioligand binding assay and much, much more

A manual giving the mathematical background to dozens of analytical methods in the biosciences, showing how they are transformed into (fully listed) BASIC programs, illustrated by worked examples.

Chapters include: Operating a computer, Some statistical programs; Line-fitting by least squares; Some applications to chemical ideas eg binding of drugs to receptors, Running other machines

'. The combination of disk and book certainly add up to a useful elementary statistical package .' *Nature*, 14 June 1984

Manual vi + 261 pages (spiral bound) ISBN 0 444 80539 7
Disk: 5¼" floppy disks (Apple II [3.3 DOS], Apple IIe – each 3 disks Commodore PET [40 or 80 col display, SD or DD, please specify] – 1 or 2 disks. Commodore 64 (also available for Vic 20) – 2 disks. IBM personal computer – 2 disks. BBC Microcomputer [40 or 80 track] – 2 or 3 disks

Mathematics, Biology and Microcomputers by A N Barrett

This book/disk package is aimed at both practitioners and students with an interest in methods for the analysis of biological data, modelling of biological processes and the determination of molecular properties

The book provides both text and program listings, with detailed documentation and examples, written in BASIC for the Apple II, IBM PC, and BBC microcomputers. The programs can easily be transferred to other computers which also run BASIC The disk contains all the programs listed in the book

Chapters cover (*I*) Definitions and explanations of the BASIC statements used in the programs, (*II*) Methods for solving non-linear equations and evaluations of polynomials, and sets of simultaneous linear equations Matrix computations including formation products and inversion Evaluation of determinants and solutions to sets of equations using Cramer's rule (*III*) Determination of molecular properties including computation of bond distances, angles and direction cosines, fitting of lines and planes to specified coordinates Coordinate systems and transformations Methods for rotation of structures about specified axes including graphics display of results and graphics representation of conic sections. Differential geometry and properties of helical structures (*IV*) Fitting of nonlinear curves to data including the parabola, hyperbola and exponential functions. Numerical methods of integration which include the Trapezium, Simpson's and Three-eighths rule. Calculations of volumes Statistical methods covering computation of means and standard deviations and evaluation of statistical distributions Numerical approach to the manipulation of sequence data using prime numbers

Manual. vi + 102 pages (spiral bound)
Disk 5¼" floppy disk (Apple II [3 3 DOS]; [BBC 40 or 80 track], IBM PC)

The Blanchaer Clinical Case Studies

A series of simulations for the Apple II computer of clinical cases of biochemical defects in metabolism They assume some knowledge of biochemistry, physiology and anatomy, and that case notes and textbooks can be referred to while working through the cases The clinical orientation provides added interest and encourages students to master in depth certain aspects of the basic science which tend to be learned superficially, and only well enough to pass an examination

Charley – *presents with extreme stiffness and reddish urine (metabolic block at glycogen phosphorylase)*
Lisa – *has a neurological problem (phenylketonuria)*
Sydney – *feverish and unconscious, has two acid-base disturbances (both due to aspirin poisoning)*
Mark – *arrives in a coma (hyperglycemic, hyperosmolar)*
Elsie – *has phlebitis and dislocated eye lenses (collagen/cystathionine synthetase defect)*
Walter – *complains of swollen legs (oedema due to lowered serum albumin)*
Dinah – *found to be obese at check up*

Each simulation available on one 5¼" disk for Apple II, 64K RAM

Expert 4 by A Rivers

An easy-to-use sophisticated disk-based 'Expert System' for the IBM PC at an incredibly low cost

EXPERT4 can be used to create and manipulate a knowledge base, which employs models of human reasoning or 'artifical intelligence' It draws on deductive and fuzzy logic, multidimensional statistics and cognitive psychology The theory behind EXPERT4 is fully discussed in the documentation which accompanies the disk

EXPERT4 offers a spreadsheet which enables the user to create files or 'domains' each of which is made up of 'elements' which have 'attributes' These have 'attribute values' For example, in a domain called 'People', 'Jane' is an element One of her attributes is 'Hair colour' Jane has brown hair hence 'Brown' is the attribute value

Inferencing facilities in EXPERT4 calculate and display relationships amongst the elements and attributes in terms of similarity and typicality Any two selected items can be compared in detail for their similarity and differences An example use would be to assist with diagnosis of a group of diseases with similar symptoms

Other potential uses of EXPERT4 are manifold, but to give the user an introduction to the program, two completed domains are incorporated on disk as examples

Package includes:
Documentation + 5¼" floppy disk for the IBM PC

High Performance Liquid Chromatography in Biochemistry

edited by **A. Henschen, K.-P. Hupe, F. Lottspeich** and **W. Voelter**

1985. Approximately XII, 564 pages. Hardcover. DM 198.–/US $ 88.00. ISBN 3-527-26057-9

It is hard to imagine what it would mean to do research in chemistry if chromatography were not available as an analytical tool. In particular, liquid chromatography in all its modes has become indispensable. Its high performance version, known as HPLC, has brought new dimensions to analytical work. Separation efficiency, speed of analysis and level of detection have shown dramatic improvements. The method can now be performed on a microscale.
This book gives an introduction to the theoretical and instrumental principles of HPLC and a detailed treatment of its application to compounds of biochemical interest. The first chapters deal with fundamental chromatographic relationships, the column and the instrumentation used in HPLC. Among the compound classes considered in the following chapters are amino acids, peptides, lipids, carbohydrates, biogenic amines, porphyrins, steroids, vitamins and organic acids.
Two lists of symbols and abbreviations facilitate the use of the literature in the field, and the detailed subject index guarantees fast and reliable access to the wealth of information provided by the book.

The Practice of Quantitative Gel Electrophoresis

by **A. Chrambach**

Series: **Advanced Methods in the Biological Sciences, Volume 1**

1985. Approximately XVI, 184 pages, 52 figures and 21 tables.
Hardcover. Approximately DM 110.–/US $ 43.60. ISBN 3-527-26039-9

Electrophoresis is one of the most important methods for the investigation of biological materials and probably the most efficient procedure for the separation and detection of proteins and other charged species. Special methods which can be summarized as gel electrophoresis, include polyacrylamide and agarose electrophoresis, isotachophoresis and electrofocusing.
This book presents gel electrophoretic procedures which are generally applicable to the identification and isolation of charged molecules. All methods have proved reliable and are used in daily laboratory work. Also, the equipment required for gel electrophoresis is described in detail. For items that are not commercially available, the reader gets all the information needed to do the construction himself. Theoretical aspects are covered to the extent that they are indispensible for the application of a method. A comprehensive index completes the book and makes it a reliable reference work.

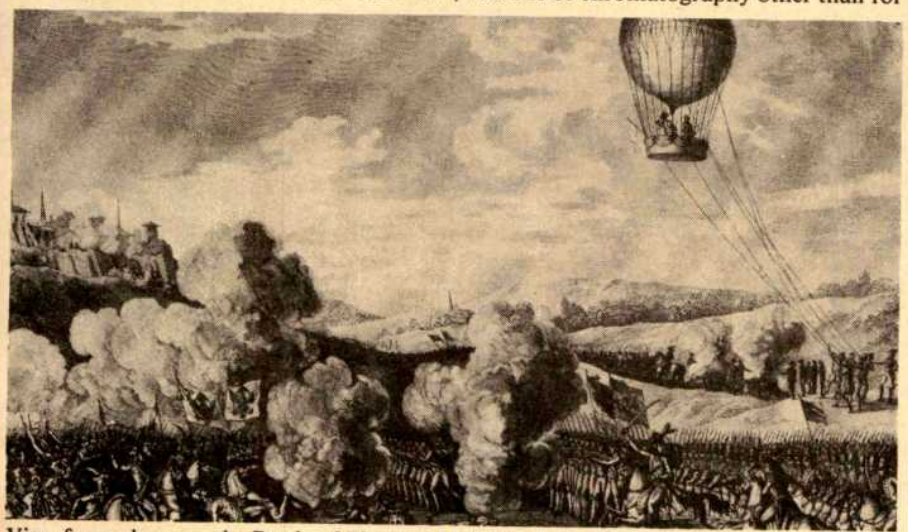
Around the world in eighty years

Harriet Guest

Voyage into Substance: Art, Science, Nature and the Illustrated Travel Account, 1760-1840.
By Barbara Maria Stafford.
MIT Press: 1984. Pp.645. $39.95, £41.75.



FROM its foundation in 1660 the Royal Society was aware of the capital value of the "*Philosophical* stock" accumulated by "Voyages into all parts of the World". Following the invention of a reliable marine chronometer, the later eighteenth century saw a proliferation of voyages (and land expeditions) from Europe, one of whose aims was the garnering of further philosophical stores. This aspect of exploration and travel accounts as investigations and surveys of nature forms the subject of Professor Stafford's *Voyage into Substance*.

The book is, as its title suggests, a journey into a considerable range of subject matter: Professor Stafford discusses and refers to a mass of accounts, and an almost overwhelming variety of locations, ranging from the Sahara to the Arctic, from the microscopic to the planetary, from the mine shaft to the balloon. Almost inevitably, however, this vast range poses problems of organization and method. The author argues that the diverse representations of nature that fall within the scope of her study are unified as expressions of the "scientific gaze". This gaze is achieved through a willed act of seeing, which somehow voluntarily denudes itself of cultural content or accretions, as "scientific scrutiny recaptured the innocent eye of the archetypal encounter with the earth". She claims that "scientific perspicacity... inaugurated a new visual habit of plainness or real transparency", and disclosed a nature which declared its own history and meaning. This innocent vision finds its expression in "a verbal (and pictorial) scientific style", of "masculine" plainness and accurate particularity, where "Art as scientific language, as limpid and democratic medium for the transcription of ipseity, does not self-expressively alter the pure presence of the properties it remands". It was evidently a style very different from Professor Stafford's.

The extent to which the procedures, at least, of the scientific enterprise were involved in and informed by its cultural contexts may be obscured by Professor Stafford's very selective notion of natural philosophy. The Royal Society, in its *Secret Instructions* to Cook, enjoined him to observe and collect a considerable variety of inanimate natural phenomena, but it also instructed him to "observe the Genius, Temper, Disposition and Number" of the native peoples he encountered. A large proportion of the 270 illustrations to this book carry out the same instruction: when, for example, William Hamilton illustrated the eruption of Vesuvius, he included in his aquatints some Neapolitan spectators of the event, and their expressive figures clearly invite us to see it as more than an object of scientific scrutiny. But Professor Stafford comments only on the "probing scrutiny" of the artist's gaze, and indeed almost never refers to the interpretative functions of human figures and compositional structures in landscapes. She quotes Georg Forster's intention "to throw more light upon the nature of the human mind, and to lift the soul into that exalted station, from whence the extensive view must justify the ways of God to man...", and its triple literary allusion to Pope, Johnson and Milton indicates that the aims of his account are not purely those of science as she has defined it, and that his language is neither plain nor transparent.

For Professor Stafford, science is the "recording of phenomena stripped of human history". This may have been the aim of some travellers and of most explorers, but it can hardly be said that they achieved it, unless, like Professor Stafford, we take the will for the deed. □

Separating out

C.S.G. Phillips

Contemporary Practice of Chromatography.
By Colin F. Poole and Sheila A. Schuette.
Elsevier: 1984. Pp.708. Dfl.159, $61.25.

THIS book is, in effect, a highly complex and competent review of the present state of the art in the techniques of gas chromatography, high-performance liquid chromatography and high-performance thin-layer chromatography. Little space is wasted on the history of chromatography, on the wide variety of chromatographic methods that have been devised but are now infrequently used, or on the applications of chromatography other than for analysis or preparative work. There is no reference to the various abstracting services available, or any general guide to the literature, while the wide use of computers with chromatographic instruments is only touched upon.

Where the book excels is in its attention to all the particular practical details of operating modern efficient chromatographic systems. It contains a mass of useful and critically considered information, backed by extensive bibliographies. There are two long, extremely helpful and illuminating chapters on the preparation of samples for chromatography and on "hypenated" methods (such as mass spectrometry, Fourier transform infrared and nuclear magnetic resonance) for the identification of components after they have been separated by the chromatographic column. *Contemporary Practice of Chromatography* will surely prove to be a most valued guide and source of reference for all practising chromatographers.

The beginner, however, will not find it an easy book to read; for all its many virtues, it will not serve as a general introduction to the subject. The reader is expected to know too much, technical terms are frequently used without explanation, and even when explanations are provided they are sometimes difficult to find and to follow (the index is quite inadequate). Further, the general introduction is not always convincing: for example, on page 31 alone I found four statements with which I would take issue. So although this book provides a mine of information, clearly it is one where some hard digging is required. □

C.S.G. Phillips is a Lecturer in the Department of Inorganic Chemistry, University of Oxford.

Chemical bondage

Geoffrey Wilkinson

Dictionary of Organometallic Compounds, Vols 1,2 and 3.
Executive editor J. Buckingham.
Chapman & Hall/Methuen: 1984.
Pp.3,000. £495, $990.

ALTHOUGH some organoarsenic compounds were known previously, organometallic chemistry, in which organic molecules or radicals are bound to metallic elements by metal–carbon bonds, really originated with two major discoveries in the nineteenth century. In 1827, in Copenhagen, Zeise discovered the salt $K[PtClC_1H_4]$ whose constitution as an ethylene complex, the first of the so-called "π complexes", was not fully established until the 1950s. Then in 1845, at a school in Hampshire, Frankland discovered the first true alkyl, diethylzinc. This discovery not only revealed a new area of chemistry but contributed substantially to the concept of valency. The later discovery of magnesium reagents by Grignard opened up even more possibilities as these were easier to handle as synthetic reagents than the flammable zinc compounds. The third major class is the carbon monoxide compounds, discovered by Schutzenberger and by Mond. Although "carbonyls" are not, by strict definition, organometallic, they have metal-to-carbon bonds and carbon monoxide chemistry is now so interlinked with that of the alkyls, aryls, olefins, acetylenes and related or derived compounds that it has become usual to include carbonyls under the general title.

Organometallic chemistry thus includes all manner of compounds, many of which are extremely unusual both in their structure and bonding. During the first half of this century the chemistry was dominated by organocompounds of the main elements — lithium, magnesium, mercury, silicon, phosphorus, arsenic and so on — and by utilization of magnesium and lithium alkyls and aryls in organic synthesis. Transition-metal organometallic chemistry developed only after about 1952. Carbonyl chemistry proceeded essentially independently, mostly in pre-war Germany through the work of Hieber and his school and of Fischer, Tropsch, Roelen, Reppe and others in industry where the use of transition metal compounds led to the development of new syntheses and to new industrial processes.

Over the past 35 years these two major streams have, to a large extent, merged, and organometallic chemistry today is a major field with its own journals, works of reference and textbooks. The number of papers and patents published annually has risen from a handful to thousands.

This *Dictionary* provides a list that comprises "those compounds which are in the opinion of the Specialist Editors, most typical, representative, interesting and useful or potentially useful and [presents] their properties and selected bibliography in an orderly and systematically indexed fashion". Quite a mouthful. The elements are treated in alphabetical order from silver (Ag) to zirconium. Each entry includes details of stoichiometry and molecular weight, and of some simple properties such as form, solubility, thermal and air stability, and toxicity, together with a few references to synthesis and spectra. The code-numbered compounds are also given their systematic name which many may find useful; for some of the more complicated compounds, trying to work out the name is often a substantial challenge and far more difficult than in organic chemistry. Structural diagrams are commonly provided and a useful feature is that these are repeated in the summary list at the beginning of each section. The index volume contains full names, molecular formulae and CAS registration numbers.

For workers in organometallic chemisty and catalysis, in both academic and industrial laboratories, this mammoth work will be very useful. It may be regarded as the Red Bible to supplement the now well-known Green Bible, otherwise the nine-volume *Comprehensive Organometallic Chemistry* published by Pergamon in 1982. The latter has discussions of various sorts in the descriptive text with copious data tables, while the *Dictionary* is designed to allow rapid access to limited synthetic and structural information. Readers may notice omissions; thus, out of the 145 manganese compounds no simple alkyl, such as $Mn(norbornyl)_4$ or $[Mn(CH_2SiMe_3)_2]_n$ is listed. Nevertheless, the editors' choice is pretty extensive and doubtless the promised annual supplements will fill in gaps as well as provide extensions. Expensive though it is, many institutions will have to acquire this work. □

Geoffrey Wilkinson is Sir Edward Frankland Professor of Inorganic Chemistry at Imperial College, University of London.

Starry night

Carole Stott

Maps of the Heavens.
By George Sergeant Snyder.
André Deutsch, London, Abbeville, New York: 1984. Pp.144. £19.95, $45.

THE game of joining the dots is not new. The Babylonians had such a pastime. They drew pictures by joining dots of light, or rather stars, in the sky. This ancient tradition was followed by Ptolemy whose *Almagest* (*circa* AD 150) lists over a thousand stars, grouped into 48 pictures or constellations. Today the sky is divided into an internationally accepted system of 88 constellations of which the Ptolemaic group forms the core. Many of the very earliest artistic representations are lost forever, and it is only from the advent of the printing press in the sixteenth century that we have examples in abundance. The first printed star maps were Dürer's, of 1516, and in the 300 years following, artists, mathematicians, cartographers and astronomers have all set down their own interpretations of the dots in the sky.

In *Maps of the Heavens*, George Snyder, who is in charge of maps and cartographic materials at Sotheby's New York office, looks at the evolution of the iconography of constellations in these more recent maps. The familiar 48 creatures and figures of mythology — Pegasus, Andromeda, Perseus, a lion, a dragon, dogs and bears and the rest, all of which Snyder lists — were joined by new figures. The observational work of astronomers such as Tycho Brahe, the revelations of the telescope and voyages to the Southern Hemisphere added new stars ready for forming into constellations. The stars became animals, religious figures, political symbols or tools of the sciences and arts. Some are still in use today; others, like La Lande's immortalization of his cat, Felis, or Schiller's replacement of the 12 signs of the zodiac by the 12 apostles, were short-lived.

Snyder's illustrations, which are predominantly from the sixteenth and seventeenth centuries, appear in almost chronological order. Many of them have been chosen for their beauty, not for their importance as stepping stones in the history of celestial cartography; the reader will search in vain for the influential Islamic constellations of Al Sufi, the popular and extensive *Uranographia* of Bode, and Piccolomini's star atlas of 1540 (which was not only the first printed star atlas but the first printed set of maps of the stars, as distinct from pictures of constellations). Rather, Snyder addresses himself to the colourful pageantry of celestial mapmaking.

Many of the maps betray their date or cultural and religious background through the artist's adoption of a certain artistic tradition. Here, however, the difference between the Eastern- and Western-style constellations is only hinted at as all but a handful of the 75 illustrations are from European countries. The joy of the book is the colourful and realistic photographic reproduction of the maps, which will appeal to a scientific as well as the intended, more popular audience. Each illustration is captivating in itself, while the complementary text, placed adjacent to the map, is reminiscent of an extended and authoritative catalogue entry. Consequently the book can be started and finished at a minimum of 75 different points. □

Carole Stott is Curator of Astronomy at the Old Royal Observatory at Greenwich, London, part of the National Maritime Museum.

BIOPHYSICAL AERODYNAMICS AND THE NATURAL ENVIRONMENT

by **A.J. Ward-Smith,** *Department of Mechanical Engineering, Brunel University, Uxbridge*

Encompasses a wide variety of topics within the context of the natural sciences, in which aerodynamic effects are of fundamental importance. Just as the miracle of bird flight was the original inspiration for powered flight by man, here Dr Ward-Smith, an aeronautical engineer, discusses how engineering concepts have shed new light on natural phenomena such as the range and variety of flight styles adopted by birds, the airborne dispersal of fruits and seeds, and the descent through the atmosphere of rain, hail and ice crystals. The book is intended as an introduction and is written in a general, non-technical style, avoiding the use of specialized scientific terms and advanced mathematical ideas, but is nevertheless an authoritative, integrated treatment of an expanding inter-disciplinary field.

CONTAMINANT EFFECTS ON FISHERIES

edited by **V.W. Cairns** and **P.V. Hodson,** *both of the Canada Centre for Inland Waters,* and **J.O. Nriagu,** *National Water Research Institute, Canada*

Deals comprehensively with the bioaccumulation, metabolism, and excretion of toxicants by fish. It addresses the tolerance of fish and fish populations to the stress of environmental alterations, and covers the changes in the biochemical and physiological systems associated with exposure to the common toxicants. Strategies for rehabilitating disturbed fisheries are also included.

ECOLOGY OF NATURAL RESOURCES

by **F. Ramade,** *Laboratoire de Zoologie et d'Ecologie, Université de Paris-Sud (Orsay)*

Discusses the application of ecological principles, tools and data to the conservation and management of the biosphere. This book provides an analysis of the ecological implications of man's use of his environment and an assessment of the strategies needed to conserve and optimise natural resources in the future. The fundamental ecological variables which influence the use and evaluation of natural resources are examined, as also are the ways in which both renewable and non-renewable resources are used. In-depth analyses are provided of rates of consumption, and potential and optimum sustainable yields.

MEMBRANES:
Endo- and Plasma Membranes of Plant Cells

by **D.G. Robinson,** *University of Gottingen, Germany*

This monograph treats the isolation, structure, function, biogenesis, and turnover of plant cell membranes, stressing the correlation of structure with function, with particular emphasis on biochemical investigation. It includes numerous electron micrographs.

Series: Cell Biology: A Series of Monographs, Volume 3

0471 86210 X 352pp January'85 £80.40

PROGRESS IN PESTICIDE BIOCHEMISTRY AND TOXICOLOGY, Volume 4

edited by **D.H. Hutson** and **T.R. Roberts,** *Shell Research Limited, Sittingbourne Research Centre, Sittingbourne*

Information on the biochemistry of pesticides is distributed widely throughout the literature and ranges from insect, plant and soil biochemistry through to mammalian toxicology. This series is one in which selected aspects are reviewed and, where possible interrelated by experts in the various fields. In selecting areas for review, account is taken of changes in the importance or use patterns of the Chemical classes of pesticides.

APHIDS ON THE WORLD'S CROPS:
An Identification Guide

by **R.L. Blackman** and **V.F. Eastop,** *Department of Entomology, British Museum (Natural History), London*

This book is the first publication to act both as an identification guide and an information source for a major group of agriculturally important insects on a world-wide basis. The primary aims of the book are, firstly, to enable non-specialist workers anywhere in the world to identify aphids found colonising crop plants, and secondly, to provide summaries of the available knowledge of each species, with reference to further information. The book includes and summary of techniques for studying aphids, a list of further information sources and a photographic guide to the 150 most economically-important species.

0471 90426 0 474pp November'84 £40.00

ECOLOGICAL ENTOMOLOGY

edited by **C.B. Huffaker,** *University of California, Berkeley;* and **R.L. Rabb,** *North Carolina State University at Raleigh*

Leading authorities comprehensively treat the ecological aspects of entomology — how insects affect and are affected by the ecosystems they live in; their adaptations; natural controls on population; their role in ecosystems; and the applications of this ecological data to insect population management or pest control.

0471 06493 9 860pp November'84 £95.00

WILDLIFE RESOURCES AND ECONOMIC DEVELOPMENT

by **S.K. Eltringham,** *Department of Applied Biology, University of Cambridge*

Considers the commercial value of the world's wildlife resources, both the biological potential and the problems involved in realising that potential. The ecological principles upon which wildlife exploitation must be based are described with particular attention paid to the theory of sustainable yield harvesting. Wildlife stocks considered include whales, seals and other marine mammals, terrestrial fur-bearers, ungulates, primates, rodents, birds, reptiles, amphibians, fish and invertebrates. Finally, the future of wildlife in a world of expanding human populations is considered.

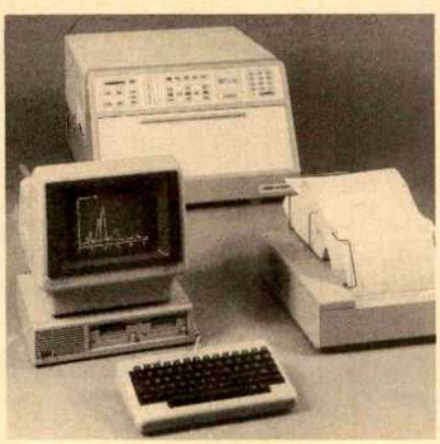
New gadgets for the lab

Recent additions to the range of instruments available for the biochemical laboratory include a sophisticated rotary mixer and an automation system.

● A new mixer from Coulter Electronics, the Rotary Coulter Mixer, will accommodate and mix up to 32 samples per tray, with the option of additional tray assemblies that can be pre-loaded. The mixer rotates samples at an angle of 45, 60 or 75 degrees, ensuring flexibility, whatever tube size is used. A mixing angle of 45 degrees is recommended for the commonly used 5 and 7 ml tube sizes; larger diameter containers may be more efficiently mixed using 60 or 75 degree end-over-end. The Coulter Mixer provides an efficient mixing process of end over-end inversion and accepts all standard tube types.
Circle No. 100 on Reader Service Card.

Automated pipetting by Drummond.

● Drummond Scientific Company has introduced an improved, inexpensive nosepiece modification kit for the Drummond Pipet-Aid. The kit incorporates a dual hydrophilic/hydrophobic filter which is designed to prevent over-pipetting and cross-contamination. The new Tissue Culture Failsafe Nosepiece is available as a retrofit kit and will also be available as an option for new Drummond Pipet-Aids. Each kit contains all necessary parts including four filters.
Circle No. 101 on Reader Service Card.



● A new storage box from Boehringer Mannheim provides a useful way of storing molecular biology enzymes. The strong plastic box is fitted with a polystyrene insert with space for 50 microcentrifuge tubes. The boxes provide a convenient means of storing enzyme stocks, buffers and DNAs at temperatures down to −80°C.
Circle No. 102 on Reader Service Card.

These notes are based on information provided by the manufacturers. For further details circle the appropriate numbers on the Reader Service Card bound inside the journal.

● The Z100A Zymate laboratory automation system, from Zymark Corporation, combines microprocessor-controlled laboratory robotics and work stations with dedicated engineering support. The Zymate system automates laboratory procedures involving steps such as weighing, liquid-handling, filtration, centrifugation, liquid-liquid and solid-phase extraction and sample conditioning (mixing, heating, cooling and evaporation). The system provides automated sample preparation for laboratories performing titrations, BOD measurements, XRF, ICP and AA, GC HPLC and NMR. It can be directly interfaced to these and other analytical instruments or can be used to fill racks or carousels with prepared samples.
Circle No. 103 on Reader Service Card.

● DNA synthesis support columns for Applied Biosystems Model 380A DNA synthesizers are now available from American BioNuclear. Endcaps and columns are precision machined from inert plastic to give leak-free performance, and retaining filters are constructed from Teflon mesh allowing maximum flow rate without loss of support. Aluminium crimp seals are secured by hand and each column is inspected before shipment. The column packing material is derivatized long-chain alkylamine controlled pore glass (LCAA-CPG), prepared to a loading of 20-30μmol per gram.
Circle No. 104 on Reader Service Card.

● The CAMAG automatic computer controlled Scanner II + HP9816 set-up is a TLC evaluation tool featuring automatic scanning track location with optimization of each sample zone, automatic evaluation via peak height area, floppy disk storage of all raw data, dual wavelength scanning and video screen integration. For every assignment, the system gives a printout of a complete analysis report.

Dispensing syringes from Hamilton.

● Hamilton Company's new line of Terasaki/Microtitration dispensers delivers six equal liquid volumes simultaneously and repeatably, from 0.5 μl to 10.0 μl. Dispensers are available with needle spacings of 6.35 mm for Terasaki/HLA plates, or 9 mm for standard microtitration plates. Each dispenser consists of six identical Hamilton Gastight/Microliter syringes, mounted in a special clamping system. When the lever is depressed, all six syringes are advanced simultaneously, dispensing 1/50th of the syringe volumes. This way, aliquots can be dispensed 50 times without refilling.
Circle No. 107 on Reader Service Card.

● Philips' latest microprocessor-controlled ion-selective analyser, the compact PW 9415 ion-selective meter, offers direct measurement of mV, *p*H, *P*X, degrees centigrade and concentration, together with the incremental methods of standard addition and subtraction, and sample addition and subtraction. A special low-level concentration mode helps the operator to obtain results even when the electrode has a nonlinear response. The operator is taken through the measurement sequence with an easily recognized series of prompts. Results are shown on the display and may be reprocessed on a printer or computer if required. Other standard features of the PW

9415 include an anti-spill membrane keyboard, analogue output for a recorder and a self-check diagnostic capability.

Automated chromatography—the new LKB Ultrochrom.

● LKB's UltroChrom GTi system offers multimode separation of macromolecules, through a system combining the best features of LPLC, HPLC and FPLC. Designed for the biochemist working with proteins, peptides, nucleic acids and even carbohydrates, GTi provides fast separation, high resolution and increased bioactivity. The biological activity of proteins after purification is generally between 91% and 99%. By using gel filtration (GFC), ion exchange (IEC) and hydrophobic reaction chromatography (HIC) in one system, UltroChrom GTi makes it simple to select the most appropriate chromatography for any problem. The system offers true HPLC, so can be used for mainstream reversed phase chromatography, including microbore and LC.

Nucleolink™: inexpensive alternative to high-priced DNA synthesis

Pierce presents an alternative to expensive automated DNA synthesis or costly custom oligonucleotide synthesis services. A complete set of reagents are provided and the procedure has been thoroughly researched so virtually anyone can synthesize oligonucleotides in their own laboratory at a sensible price.

Easy-to-use, our Nucleolink DNA Synthesis Kit employs a modified phosphotriester approach, resulting in short cycle times and high yields. Our Nucleolink DNA Synthesis Kit offers you:

- **Lost cost per base;** the economically priced Nucleolink DNA Synthesis Kit offers repetitive yields of 95% or greater and sufficient reagents to sythesize up to four 20-mers at a fraction of the cost for custom DNA synthesis.
- **Short cycle time;** a coupling time of 2 minutes, for a total cycle time of 15 minutes.
- **Easy-to-use instructions;** step-by-step-protocols enable anyone to successfully synthesize oligonucleotides; (includes post-synthesis work-up and purification procedures).
- **Stable reagents;** chemical improvements allow longer storage of phosphotriester reagents not possible with other oligonucleotide synthetic methods.

● Delivery systems in which up to four solvents may be blended can be used in the analysis of a wider range of samples than two or three solvent systems. This versatility is characteristic of Perkin-Elmer's four-solvent delivery systems for higher performance liquid chromatography, the proven Series 4 and the new Series 400. The new system can be used for all types of HPLC — microbore, analytical, high-speed and semi-preparative, and dedicated single-function command keys simplify operation. Each 'method' consists of up to ten programming steps and nine user-defined methods can be stored. Low conversion volumes allow solvent compositions to be changed in seconds, so that changing from one method is simple to another. The Series 400 pump can be programmed for isocratic or gradient analysis with up to four solvents. Simultaneous solvent and flow programming is standard.

● A new system from Forma Scientific helps to increase anchorage dependent cell yields in microcarrier applications. Micro-Stir magnetic stirrers with Magna-Flex flasks gently mix microcarrier beads at slow speeds, so that anchorage-dependent cells are protected, helping to increase product yields. The four-position stirrer features adjustable speed control plus stirring and delay timers for precise, repeatable cycles. A single-position unit with speed control only is also available. Both units easily fit into Forma incubators for culturing under controlled conditions. Flasks in 500 and 1,000 ml are available.

● Hi-Tech Scientific's QF-10 preparative quencher is microprocessor controlled and facilitates the chemical and/or freeze quenching of a fast chemical reaction after a known ageing time. This makes it possible for a fast reaction to be studied by an intrinsically slow technique such as gas-liquid chromatography, or radio isotope counting. The ageing period is continuously variable from 5ms to 10.3s.

● The Thermex-IBM thermometer interface, available from Columbus Instuments, converts popular IBM-PC or XT computers into a 16-channel printing thermometer with disk data storage capacity. Thermex provides 16 individual channels for 16 thermocouple probes with cold junction compensation provided for each individual probe. Columbus provides a complete hardware/software package plus a variety of temperature probes calibrated in the range 0 to 50°C with accuracy of 0.1°C. Thermex can be used in any other temperature range with a special probe calibration program. Biological temperature measuring probes are available from Columbus for rectal, intravenous and implantable applications.

New plant tissue culture collection

THE American Type Culture Collection has recently established a plant tissue culture bank. The collection will accept well-documented plant tissue cultures with properties useful in research, teaching, or industry. These cultures will be made available to the scientific community for a fee to cover expenses. Cultures are also accepted for patent application purposes. At its opening last December there were 62 cultures in the bank including alfalfa, blueberry, birdsfoot trefoil, carrot, celery, corn, datura, lily, rice, soybean, sugar cane, tobacco, tomato, walnut, wheat, and tumour cell lines of sunflower and grapes induced by *Agrobacterium tumefaciens* carrying Ti plasmids.

NATURE VOL. 314 28 MARCH 1985

Contrast in budget styles

India and Britain last week published taxation budgets for the year ahead. The underlying objectives are closely similar. But the Indian budget is much more imaginative.

ONE of the legacies of British rule in India is that the country's financial year begins (as in Britain) on 1 April (but there are plans to change that). So it is not simply a coincidence that the governments of both India and the United Kingdom should last week have published their plans for raising revenue during the year ahead and, in India's case, for spending it as well. (The pattern of spending in Britain has already been determined.) Curiously, the two governments have been forced by circumstances into similar strategies. Both are anxious that more should be done to make industry, and especially technically advanced industry, more prosperous. For different reasons, each government is anxious to shift the burden of raising revenue from direct taxation (of incomes and corporate profits) to indirect taxes. Each government is convinced that a well-designed budget is a means by which its domestic economy can be made productive and competitive. But this year, there can be no dispute that the government of India has made a more imaginative assault on the problems facing it that has the British government. The British government, and its Chancellor of the Exchequer, Mr Nigel Lawson, have been widely criticized for cowardliness. It seems not to have been noticed that by comparison, the government of India and its finance minister, Mr V.P. Singh, have produced a dazzling performance.

India's budget for the year ahead is the most dramatic consequence yet of Mr Rajiv Gandhi's succession as Prime Minister and of his expressed determination to make India modern. As such, his first budget should be regarded not merely as a fiscal instrument but as a strategy by means of which developing countries elsewhere might seek to drag themselves by their bootstraps into the twentieth century. For India, like many other developing countries, has nourished since independence in 1947 the notion that the development of the economy can be planned from the centre. It is not intended, even now, that this goal should be abandoned. What the new government appears, however, to have recognized is that there is a distinction between the process of channelling resources in socially desirable directions (such as the improvement of education or relief of poverty) and the attempt to control in detail the economic behaviour of the people who must be the instruments of change.

Spending

On the spending side, the Indian government plans to follow the course that has been charted in the past five years. Briefly, it will persist with the encouragement of science and technology through its technical agencies, with functions as different as the sponsorship of space research and the provision of grants for research at universities. Those similarly dependent on the British budget for research funds will be envious of the real increase planned for the coming year in India, which uniformly exceeds 10 per cent. The central government's budget will not help solve the huge problems of India's universities, most of which are the concern of state governments, but there is always a chance that the new government's good example will bring about more general enlightenment. But perhaps the most important spending decision is negative, the announcement as part of the budget package last week that government revenues will no longer be used on such a vast scale to subsidize the Indian railways. Attempts in Bengal to organize a protest boycott by railway passengers, always destined to be self-defeating, seem nevertheless to have passed off without trouble. Economic realism seems to have a logic of its own.

The revenue side of the Indian budget is more daring. But how can it matter, for the development of a technological economy, that a government should raise the funds it plans to spend in one way rather than in another? This is where Indian and the British analysts come close to agreement, believing that the burden of taxation can be an important determinant of the way in which funds are invested in innovation. That is why both governments have come to believe that it would be economically beneficial if incomes where less heavily taxed, and if the burden were shifted to what people spend. It reality, the Indian government has a further incentive to follow such a policy, for it is generally agreed that the incidence of personal taxation (which takes away roughly half the income of a person earning roughly $12,000 a year) is so sharp that it can only encourage the growth of the black economy, that based on the transfer of huge sums of cash and gold between private individuals and even corporations so as to avoid the tax net altogether. The Gandhi/Singh remedy is a substantial reduction of personal taxation, counterbalanced by increased revenue-raising from other sources, among which the largest single item so far is the increase of railway fares. The result may be to tempt back to legality some of those who at present manage to avoid paying taxes by simple dishonesty.

Realism

The government of India has taken several further steps in the direction of economic realism, which is nothing but a calculation that people should be allowed as far as possible to do what their inclinations suggest, by reducing (but not yet abolishing) the mechanism by which the government decides whether private or even partly public companies should be allowed to embark on some novel manufacturing enterprise. Ironically, even after the budget had been published at the weekend, last week's newspapers in India still carried statutorily required advertisements by Indian companies declaring their ambitions to branch out in new directions, and asking for objectors to declare themselves. The rationale for these regulations is straightforward; economic resources should not be diverted into activities that do not serve the general purpose. The problem on which India has repeatedly broken its ambitions in the past forty years is that civil servants are not much good at deciding what directions the development of industry should follow but are certainly slower than industrialists to make up their minds. And the system of industrial licensing has become one of the most flagrant foci for the corruption that has become endemic. By this attempt at letting people decide for themselves, the new Indian government may be following the present British government, but it may claim credit for having taken a gigantic step in one.

So what can be wrong with such a brave assault on convention? The snag is that the Indian government, following that of the United States, is planning deliberately to overspend its resources in the year ahead by about ten per cent, in round numbers the equivalent in rupees of $3,000 million, or between one and two per cent of President Reagan's budget deficit. Even so, such modest profligacy is a gamble. The experience of recent years has shown that the states usually manage to end up overdrawn with their bank, the central government, and that budget

deficits usually double between one April and the next. This time the government must hope that economic freedom will abate this tendency. If not, there will be inflation, the poor will feel even more poor and the momentum of development will be interrupted. Even the government acknowledges that it is betting on a favourable monsoon. We should all keep our fingers crossed.

Mr Nigel Lawson will quickly plead that a British finance minister could not dream of taking such risks; for one thing, what with the developed luxury of a welfare system, his government's spending is a much larger proportion of the national wealth. Yet Mr Lawson's problem for the past year has been very much like Mr V.P. Singh's: how to create a climate in which such wealth as there may be is directed towards productive investment, preferably in innovation. The pre-budget calculation seems to have been that a replacement of direct by indirect taxation would give saving an edge, and that it would be beneficial if the favourite media for personal savings (mortgages and pensions) could be put on an equal footing with investments in risky ventures. In the event, the British government found it lacked the courage to give such offence to its electors. Nor could it go along with the entreaties of its political opponents (not to mention a substantial section of its own political party) that the annual deficit should be deliberately increased so as to stimulate demand. (Relatively credit-worthy Britain's deficit will nevertheless be twice India's.) So Mr Lawson emerges as a piteous character, "boxed in" as he describes himself. No doubt he will be laughing if India comes a cropper, perhaps because the monsoon fails in June. But will he not be furious with himself, perhaps even as furious as his taxpayers will be with him, if India's gamble comes off when he can boast only that he did not think it the right time to make a risky budget? □

New star wars row

The private dispute at Geneva over star wars may yet be drowned by rows between allies.

MR Richard Perle, Assistant Secretary of Defense at the Pentagon, is one of the US administration's hard men, and was probably hired for that attribute, not for his skill as a diplomatist. But even so, his performance in London last week inevitably raises the question whether his operating licence should be amended.

The circumstances are very odd. Two weeks ago, Sir Geoffrey Howe, the British Foreign Secretary, had made a speech in which he made quite clear his support for research under the umbrella of the Strategic Defense Initiative and then went on to muse about the problems that would arise if ever the time came to deploy an effective defence against ballistic missiles. There would have to be negotiations with the Soviet Union about the scale and manner in which this would be done. And even when agreement had been reached, there would remain difficulties about the true measure of security an apparently leak-tight umbrella could provide, if only because the present familiarity of strategic doctrines, bizarre though they may seem, would be undermined. Sir Geoffrey went on to reflect that the difficulties he foresaw might never arise because the research programme might demonstrate that the goal is unattainable. None of this conflicts with what is understood to be the objective of the research now under way, at least since the British prime minister's pre-Christmas visit to Washington last December.

So why should Mr Perle promptly launch an attack on Sir Geoffrey at a conference held in Britain just a few days afterwards? The most charitable explanation is that he read only a bowdlerized version of Sir Geoffrey's speech, or that he was himself misquoted, or quoted out of context. Yet another explanation, so mundane that it must seem an insult to such a person as Mr Perle, is that he was jet-lagged. Yet people in his trade do not usually set about supposedly friendly statesmen with such vigour, and in public, so that some kind of explanation is essential. Otherwise, as Mr Perle must by now recognize, there is a danger that listeners will think there must be more to star wars, even now, than mere research. □

Illegality proliferates

The US administration should be more diligent in preventing nuclear proliferation

FOR an administration that has been concerned — some would say obsessed — with halting the flow of US technology to the East, the Reagan Administration has been curiously apathetic about nuclear non-proliferation. So it comes as no surprise that its apathy should set the tone for the government's law-enforcement officials responsible for federal statutes designed to prevent sensitive nuclear-weapons technology from reaching non-weapons states. There is no other explanation for the strange case of a Pakistan national arrested last year when he attempted to ship home 50 high-speed switches that just happen to be of a kind needed for building an atomic bomb. Nazir Ahmed Vaid was allowed to plead guilty to one count of violating US export laws; he received a suspended sentence and was quickly deported. Although the original indictment had made clear that the switches were sensitive nuclear technology and suggested that Vaid was working on behalf of the Pakistan government, all such references were dropped in the plea bargain. The judge who approved the plea bargain said there was no evidence that Vaid was a foreign agent; he was merely a businessman "expediting what he thought was a business deal". The federal prosecutors agreed.

An investigation by the *New York Times* has now uncovered a very different story. In fact, the government had in its hands proof that Vaid was acting directly as an agent for one S.A. Butt, who happens to be the director of supply and procurement for the Pakistan Atomic Energy Commission. Telexes from Vaid to Butt make it clear that Vaid knew it was illegal to export the switches without a licence, that he was working on "alternate ways to buy these products" after a direct approach to the sole manufacturer failed and asking what he should say the "ultimate consumer" of the products was. Butt cabled back that he should say the ultimate consumer was the research and development department of Islamabad University. The prosecutors told the *Times* reporter that they had not appreciated the significance of these telexes because they had not been able to find out who Butt was. (He had no record in the US Department of Treasury crime computer, they said.) Butt is in fact well known in arms control circles as the man who successfully procured reprocessing and enrichment technology for Pakistan from Europe in the 1970s. Had these facts come out at a trial, Vaid could have been sentenced to as much as 20 years' imprisonment for violating the Atomic Energy Act.

Precisely what Pakistan is about is anybody's guess. Since the Indian explosion in May 1974, Pakistan has encouraged speculation that it is on the way to making some kind of bomb. Most probably it has been doing its best, with help from where it could be had, people like Vaid included. On present form, dependent as it is on the United States for delivery systems, Pakistan could not realistically hope to be an independent nuclear power, but it could reasonably hope to be able to make trouble. For the past five years, the United States has been ambivalent, reckoning Pakistan an ally on Afghanistan. Until recently and perhaps still, it has fudged the nuclear issue.

It is not necessary to subscribe to conspiracy theories to see a connection between the administration's laxity on nuclear non-proliferation and the laxity of a federal prosecutor in Houston in pursuing this case vigorously. Prosecutors have a limited amount of time to devote to too many cases; they are not going to knock themselves out on cases that will not win them approval at a higher level. The administration has unmistakenly set the tone, a blend of laxity and of contempt for the law, or at least for the spirit of President Carter's Nuclear Non-Proliferation Act. The act may rashly have offended governments which believed that their obligations under the Non-Proliferation Treaty (NPT) were sufficient and may unwisely have overridden legal contracts, but is there any reason why it should not apply to countries which have scorned the NPT and which have no other claims on the United States? □

British research

Research council offers hope for astronomers

THE worst fears of the British astronomical community, that Britain might abandon observation in the Southern Hemisphere, may have been allayed by last week's meeting of the Science and Engineering Research Council (SERC). Some consider that the council was favourably disposed to the submission of its Astronomy, Space and Radio (ASR) Board for funds over the next five years, at a time when a combination of exchange rate fluctuations and pressure on the council's budget from other areas of science and from engineering have never been so acute. But the forward-look process has revealed differing perceptions of priority within the council's committees. Moreover, the long-term outlook is not yet certain, as the Advisory Board for the Research Councils (ABRC) has yet to consider the council's proposals, and some of the options involve international agreements.

By all accounts, the January meeting of the ASR board was an emotionally charged affair. Faced with the task of producing a list of priorities for the council, the board's subcommittees had thought the unthinkable and ordered their respective research programmes on strictly scientific grounds. It was the ASR's board's task to co-ordinate these shopping lists into a package for presentation to the council. In the event, there was a heated debate over proposals for ground-based optical astronomy.

Two of the most important telescopes currently at the disposal of British astronomers are the Anglo-Australian Telescope (AAT) and the UK Schmidt telescope, both in Australia. Both have proved highly successful and are generally agreed to be capable of producing world class results for several years yet. In the next few years, however, two new telescopes on La Palma in the Canary Islands — the 2.5m Isaac Newton and the 4.2m William Herschel — are due jointly to provide a first-class facility in the Northern Hemisphere.

At the January meeting of the ASR board, a certain polarization developed between those who favoured the retention of Southern Hemisphere activity those who felt that it would be better to concentrate resources at a variety of wavelengths in the Northern Hemisphere. This option would allow more collaboration, for example, between optical, infrared and radio astronomers, all of whom are strongly represented in Britain.

The prevailing view was that the Northern Hemisphere option would be the easier to sell to backers, chiefly on the grounds that it would be more easily managed. The final package that went to the council was broadly split into three. The worst-case, or lower guideline option, included studentships and grants, data processing, support for approved space projects such as the X-ray satellite ROSAT and the Comet Halley explorer Giotto, the current subscription to ESA, the European Space Agency (the 5 per cent increase recently agreed will not be paid by SERC), and the Northern Hemisphere telescopes and radars. This package would represent a 10 per cent cut in current plans.

The centre guideline option, representing the current spending level, would add support for ESA's future space programme as spelt out in its "Horizon 2000" report. The third component of the ASR board's list, and relatively low in its priorities, includes Solar System space research and Southern Hemisphere facilities.

At last week's meeting, however, the council stopped short of recommending a withdrawal from the Southern Hemisphere observatories, partly as a result of the strength of the scientific case and partly because of the international implications. Broadly speaking, the council favoured rather more than the central guideline package. One option being investigated for several of SERC's major facilities is that working time should be sold abroad to recoup costs. And, in a move that will bring weary shrugs of resignation from the staffs of the two British observatories in Sussex and at Edinburgh, yet another committee is to be set up to decide their future. This time, however, its committee is apparently to be chaired by SERC's chairman, Sir John Kingman, who is said to want this resolved before he leaves later this year.

Philip Campbell

Acid rain

US/Canada stand-off (contd)

Washington

LAST week's agreement between the United States and Canada on acid rain appears to represent no shift in the Reagan administration's policy: research, yes; controls, no. Canada, meanwhile, is accelerating its unilateral efforts to reduce emissions sources responsible for acid deposition without waiting for reciprocal action from the United States.

What last week's agreement does is to create two "special envoys" who will "examine" the acid rain issue and report within a year. The Canadians hope they will become negotiators; but the announcement suggests their role will be limited to consultation. For months, the Canadian government had made clear that acid rain would be at the top of the summit agenda. And while Canadian officials say the agreement is a hopeful sign, environmentalists have already dismissed it as a contrivance that allows Prime Minister Brian Mulroney, under considerable domestic pressure to achieve results on the acid rain problem, to claim that he did not come away completely empty-handed.

Earlier this month, however, the Canadian government was able to take credit for some more tangible steps towards acid-rain control. The federal government agreed to allocate $150 million to aid the smelting industry, Canada's major contributor to acid deposition, to reduce sulphur dioxide emissions. The provincial governments and industry will provide the remaining portion of the estimated $1,500-2,000 million. And, although it is only a minor source of the problem, Canada will as of September 1987 require NO_x emissions from cars and light trucks to match the stricter US standards; this is seen more as a political move to remove US objections that Canada was demanding US action while refusing to clean up its own house.

The Canadian government says that these steps will enable the country to reach its earlier-stated goal of reducing wet sulphur deposition to 20 kg per hectare per year in the sensitive eastern provinces — but only if the United States takes "compatible" action. Canada's reduction plans, which will cut total sulphur dioxide emissions by approximately one-half, will be completed by 1994.

Although US officials do not challenge the Canadian assertion that at least 50 per cent of acid deposition in eastern Canada is the result of emissions from US power plants (while only 10 per cent of acid deposition in the northeastern United States originates in Canada), the Reagan administration insists that more research must be done before the expense of new sulphur controls can be justified. The US argument is that not enough is known about the linearity of the atmospheric response or about how quickly lakes subjected to acid deposition actually acidify. If the lakes respond very quickly, they argue, then it is possible that virtually all susceptible lakes are already acidified, and new emission controls will make no difference.

Canada has been pressing for a 50 per cent reduction in US sulphur emissions from appropriate regions. A plan proposed by former Environmental Protection Agency administrator William Ruckelshaus but rejected by the Office of Management and Budget would have cut emissions from midwestern power plants by some 3-5 million tons, which Canada says would have been sufficient. **Stephen Budiansky**

Exhaust emissions

Europe's fiercest battle yet?

Brussels

THE political agreement to clean up car pollution in Europe reached by European governments in the long night of 20/21 March may yet be regarded as one of Europe's fiercest battles. The upshot is that there will be obligatory lead-free motor fuel throughout the Community by 1 October 1989 and, the calculation goes, a 60 per cent reduction of exhaust emissions against the yardstick of 1985. The surprise is that this solution, very much a compromise, was reached without loss of face for any member government.

The need for an agreement of some kind stems from the determination of West Germany to reduce exhaust emissions quickly, and in particular from the West German threat (uttered last year) of a unilateral introduction this July of lead-free motor fuel. In the event, West Germany went along with a package of proposals that will allow different categories of cars (classified by engine capacity) to be dealt with differently. The United Kingdom seems especially proud of having won this concession and, in particular, agreement that engines of medium capacity (between 1.4 and 2 litres) may be dealt with not by catalytic converters but by the application of novel technology as represented by "lean-burn" engines (see below).

The new standards will first make their impact generally in 1988, when new models of cars with engines above 2 litres capacity will have to conform with the new emissions standards. By 1 October of the following year, all new cars sold will have to conform. In the intermediate range, new emissions standards will apply to new models from 1 October 1991 and to new cars appearing on the roads from 1 October 1993. For smaller cars, with a capacity of less than 1.4 litres, the emissions standards are to be introduced in two stages, with a provisional standard coming into force in 1990 (for new models) and a more rigorous standard three or four years later.

Part of the uncertainty remaining about emissions standards arises because of the difficulty in defining the permissible limits of exhaust emissions from engines of different sizes. The intention, however, is that the European testing procedures will progressively be made to conform with US standards within the next few years.

One reason why last week's negotiation was successful is that West Germany eventually won the blessing of its partners for its scheme to offer financial incentives to owners of vehicles conforming with improved emissions standards. These incentives will apply from 1 July this year, but it has now been agreed that, to qualify, the exhaust emissions of small cars must be at least 15 per cent less than the transitional standards set for 1990. Moreover, the financial incentive must not exceed DM750 over a three-year period rather than the DM1,700 originally proposed by West Germany.

The underlying issue here, to which the French environment minister Huguette Bouchardeau paid most attention at last week's meeting, is that financial compensation should be "significantly less" than the cost of clean technology if it is not to contravene the Community's rules on the provision of direct subsidies for manufactured products, not to mention the environmental doctrine of "polluter pays".

The financial incentives to be offered by West Germany will include a DM0.04 per litre subsidy on lead-free motor fuel, to be introduced next week and a ten-year exemption from road-fund tax for drivers equipped for clean driving from 1 July. Friedrich Zimmermann, West German minister for the interior, admitted after the negotiating session last week that "going it alone would have meant chaos".

The United Kingdom, at the outset one of the strongest opponents of the West German initiative, also seemed content with the outcome. For cars above 2 litres engine capacity, British manufacturers seem already to have accepted that catalytic converters will be necessary. Indeed, most car models in this range depend for their economic success on export sales, for which purpose catalytic converters may already be fitted. But the United Kingdom is also pleased with the concession that lean-burn engines may be fitted to smaller vehicles as an alternative to catalytic converters.

The Community's agreement on vehicle emissions will be promulgated by means of a directive from the Commission, due to be agreed on 30 June. For the time being, diesel- powered engines and vehicles weighing more than 3.7 tonnes are not covered by emission standards, but proposals are expected by the end of the year.

Anna Lubinska

Catalytic converters or lean-burn?

Brussels

THE British arguments against catalytic converters for smaller engines are both economic and technical. It has been estimated that a catalytic converter would cost £500 at the outset, and would involve a maintenance outlay of £90 with possible replacement after four years costing £150. Allowing for fuel penalty, the cost at Community level would be 15,000 million ECU a year if catalytic converters were the only means of conforming with emissions standards.

The United Kingdom argues that a universal requirement of catalytic converters would further open up the European market to the Japanese, whose products already conform with US standards. The investment needed for the two production lines would be a burden on ailing European car industries, while the cost of catalytic converters would depress demand.

Rather than forcing the car industry down this cul de sac, the British have been arguing for time in which to develop lean-burn engines, working on the principle of altering the fuel/air ratio, thus provoking earlier combustion. The result is a fuel saving of about 15 per cent as opposed to the 5 per cent fuel penalty with catalytic converters. A prototype by Ford UK is to be demonstrated in June and could be on sale in September. The added cost to the consumer of the lean-burn engine is estimated at between £50 and £70.

The high air/fuel ratio of the lean-burn engine lowers both carbon monoxide and nitrous oxide emissions, but increases hydrocarbon emissions, for which reason an oxidation catalyst costing up to £50 would still have to be fitted.

Anna Lubinska

CERN collision

ONE of the first events taken in a streamer chamber at the European Organisation for Nuclear Research, CERN, last week, showing a proton colliding with an antiproton at 900 GeV in the centre of mass, the highest energy for such controlled collisions yet observed. Despite the complicated manoeuvres required to reach such

energies, the collider is working well, with beam lifetimes of seven hours, double what was expected, and luminosities of 3×10^{26} $cm^{-2}s^{-1}$. The plans were to introduce a gamma-ray converter around the beam pipe on Friday, to seek high multiplicity events without gamma ray production, first detected in cosmic ray observations — the Centauro events (see *Nature* 21 March, p.221).

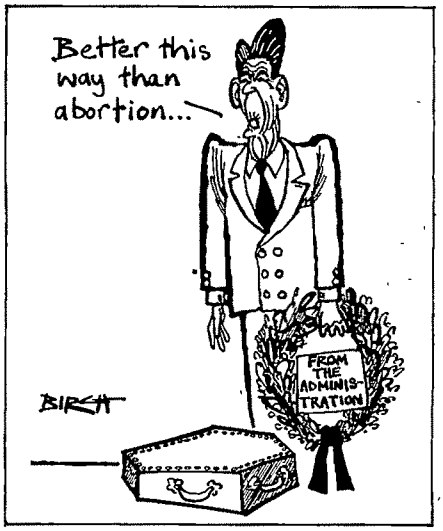
Infant mortality

US improvement halted



Washington

A SUDDEN halt in the improvement of US infant mortality statistics after two decades of dramatic progress is turning into a political issue for the Reagan administration as critics charge that cuts in social programmes are to blame.

From 1965 to 1981, infant deaths declined from 24.7 per 1,000 live births to 11.9. But in 1982 and 1983, the rate of improvement began to level off, to 10.9 per 1,000 in 1983, the latest year for which complete stastistics are available. Preliminary data suggest that there was virtually no improvement in 1984. And public health researchers say that the death rate has actually increased in about 10 states in the past few years.

After first suggesting that the slow-down was merely a statistical fluctuation, Dr Edward Brandt, just before leaving his position as Assistant Secretary for Health last December, acknowledged in a letter to state health officials that the problem was "worrisome". The administration has refused to comment directly on accusations that cuts in medical and food assistance programmes to the poor are to blame.

A study released last month by the Institute of Medicine (IOM) of the National Academy of Sciences lends credence to the critics' charges. It found a substantial link between inadequate prenatal health care and low birth-weight, the single greatest

risk factor in infant deaths. And the number of women visiting a physician in the first three months of pregnancy decreased in 1982 after increasing steadily during the 1970s. (The decrease was greater among black women than white women. The infant mortality rate for blacks remains twice that for whites in the United States, as it was in 1965. Black women are also about twice as likely as white women to give birth to low-weight babies.).

Those who draw a connection between the infant mortality trends and social programmes point out that the dramatic drop that began in 1965 coincided with the start of the "War on Poverty" programmes, such as federally-funded neighbourhood health centres. And according to Dr Julius Richards, who was assistant secretary of health during the Carter administration, 725,000 people have lost services at community health centres as a result of Reagan administration budget cuts. A study in Boston found that the infant mortality rate in areas of the city served by five such centres that suffered budget cuts increased by 46 per cent in 1982 over the previous years.

The group pointed to another clue for the slowdown: while mortality rates for infants less than one month old continue to fall, the rate for infants between one month and one year old may actually be increasing. Neonatal intensive care units are allowing more low-birth-weight infants to make it through the first 30 days, but more of these high-risk infants still die within the first year of life.

The experience of other countries suggests, however, that the United States can still make considerable progress — but it will take something other than advanced medical technology and intensive care units. The United States has one of the higher infant mortality rates among the industrialized nations; much of the difference, according to the IOM study, can be explained by the difference in incidence of low birth-weights. And, perhaps, more to the point, the rate of decline in infant mortality rates in the United States (until the recent slow-down) was in line with the rate of decline in other countries with substantially lower rates, according to Dr Sam Shapiro of Johns Hopkins University, which suggests that rapid progress remains a reasonable goal.

The Public Health Service is for the time being limiting its response to assisting the states in planning studies of infant deaths and identifying possible corrective steps. With the incorporation of federal service programmes into block grants to the states under the Reagan administration, it is up to the states to take those steps.

Stephen Budiansky

European synchrotron source

More horse-trading on sites

MONEY, finally, will probably decide where and when the long-awaited European Synchrotron Radiation Source (ESRS) is built. Denmark's representatives, at the latest meeting of the "Levaux committee", established by the European Science Foundation to select the ESRS site, offered 30 per cent of the capital cost if the source went to Risø, Denmark's national nuclear laboratory. Italy's delegation offered 50 per cent if it went to Trieste, a lost corner of Italy that the government dearly wishes to develop. But the French and West Germans together proposed Grenoble, near the French Alps, and offered 68 per cent (39 per cent from France and 29 per cent from West Germany). The British could have had the casting vote (preferring Grenoble), but could offer no money. And Austria and Switzerland also professed a cashless interest in the Franco-German proposal.

Meanwhile, however, the third most important figure in the French government, socialist Louis Mermaz, president of the French national assembly, has lost his seat in Grenoble as the president of the regional assembly. It was widely supposed that it was to protect Mermaz that, at the last moment, France switched its allegiance from Strasbourg (near the German border) to Grenoble. So will the French choice now revert to Strasbourg (which Germany always preferred)? "No. I don't think so. It's decided", said a French research ministry spokesman on Monday.

According to the French ministry, the Levaux committee heard site reports on Risø, Trieste and Grenoble which showed them indistinguishable on all technical counts, including vibrations and geology — whereas the handful of Grenoble sites had been in question as being close to an autoroute and the Alps. "The most dangerous vibrations come from the life of the machine itself", the French ministry claims. Thus the only distinguishing factor was money, and here France and Germany are ahead.

Nevertheless, even the Grenoble proposal comes 32 per cent short of the capital required, and France and Germany will be seeking new (paying) partners. But they will make entry as easy as possible. Thus in June, France and Germany will set up a steering committee ("provisional administrative council") to which all nations are invited "even if they can't say the exact amount they will pay". Nations that admit they cannot pay will be invited as non-voting observers.

During this year, the council will nominate a director-general, set up a scientific council and seek the cash to begin construction. If the money is found, construction will begin in the summer of 1986. Could ESRS go ahead as a purely Franco-German project (as the high-flux neutron facility, the Institut Laue-Langevin, began)? Robert Comès, whom the ministry has nominated as preliminary representatives of the Centre National de la Recherche Scientifique on ESRS, says the facility "should be European", and as French political thinking is at present strongly in favour of European initiatives and research, a Franco-German breakaway seems unlikely.

Robert Walgate

French applied science

Researchers help but stay put

FRENCH scientists are making an effort to link up with industry — but are not prepared to quit their laboratories for a year or two to work with an industrial partner. That is the picture painted by Jean-Jacques Duby, the director for applications at the Centre National de la Recherche Scientifique (CNRS), the principal French research council for basic science, at the end of his first two years in the job.

According to Duby, his new Directorate (the Direction de la Valorisation et des Applications de la Recherche, DVAR) has helped CNRS nearly double the number of new patent applications each year by CNRS groups from 71 in 1982 to 134 in 1984, while contracts with industry have tripled in value from FF 10 million (£1 million) in 1982 to FF 31 million (£3 million) last year.

Other indicators of the application of CNRS science also show improvements, such as a doubling in consultancies (to 157). But Duby's *bête noire* is lack of mobility — with only 41 CNRS staff out of a total of over 6,000 making even a temporary move to industry in 1984, a negligible improvement on the 37 in 1982. A new contract of employment for CNRS researchers, which came into effect last year, was intended to increase mobility, by giving staff civil servant status (thus guaranteeing employment and pension rights whatever moves a person might make), but clearly it has had little effect so far.

Moves in the other direction, out of industry and into research, are also rare. Duby launched a new scheme last year to grant "associate directorships of research" to industrialists wishing to spend time in CNRS laboratories. Just six such positions are about to be announced. The French, whose economy is still more agricultural and land-based than most in Europe, like to stick to their territory.

Nevertheless, there has been at least a psychological change in the relationship between French scientists and industry. The year before Duby came to CNRS, a survey of decision-makers showed that the CNRS profile had fallen "very low". But "now we even get phone calls from the big companies", says Duby. This is a "drastic improvement" on the past. But the smaller companies are still largely unaware of CNRS, and even the big companies are very wary "at risk point", when they must decide whether to invest money with CNRS in a project. "We lack venture or any other capital in France", says Duby. Another problem is that French law centres on institutions rather than contracts, so new ventures tend to require new institutions.

Despite these obstacles, Duby's DVAR has been trying every possible method of making a profit out of CNRS science, often with success. Some FF 2.8 million (£280,000) was redistributed to 54 CNRS laboratories last year from profits from patents alone. And the organization has created companies — under its new constitution, it is free to invest and make profits — such as MIDIROBOTS, a robotics company in the south of France.

Interest from industry is as great in fundamental physics as in the engineering sciences, Duby says. Organic chemistry and pharmaceuticals (where the companies have money to spend) lead the field, followed by materials science. Interest in electronics, data processing and mathematics has been "disappointing", although Duby had expected demand for work on systems and modelling.

CNRS is also putting a lot of effort into biotechnology, although this faces two major problems: on the research side, groups are often controlled by an old guard of fundamentalists, little interested in application; while on the industrial side, the big companies such as Rhône-Poulenc have rigid, seven-year research programmes into which, paradoxically, it is difficult to fit new ideas.

Duby and his DVAR are also working hard with:

- LABINFO, a database on French research and researchers, now covering 5,500 laboratories in CNRS, universities and other research councils, through which industry can trace who is working on what.
- The CNRS industrial relations committee (CRIN), whose twenty working groups discuss industrial problems and research solutions, and make proposals for research to CNRS.
- Framework contracts with companies, which cover matters such as potential patents rights, exchange of staff and payments, forming an "umbrella" under which CNRS laboratories can more rapidly reach agreement with the company on a detailed project. These contracts are being increasingly "regionalized", being signed and managed by local branches of CNRS management.
- Publicity: CNRS has been holding "industrial days" in the regions, such as one on lasers in Grenoble and one on biotechnology in Paris, and has even established an information centre at Orly airport south of Paris.
- Co-financing of applied research with the national association for the application of research, ANVAR, which works mostly with small and medium industry: this brought CNRS laboratories an extra FF 25 million (£2.5 million) in 1984.

But Duby, ever energetic, says CNRS has much more to do. The figures for CNRS/industry cooperation are simultaneously "optimistic and derisory". They are optimistic in that they are growing; derisory in that they remain too small.

Two thirds of CNRS laboratories still have no link at all with industry, and those links are with only 1,000 out of 50,000 French businesses. ANVAR, by contrast, has 5,000 such links. It is a target Duby will be aiming for.

Robert Walgate

UK higher education

Modest extra for high-tech

AN injection of £43 million into selected British universities over the next three years was announced last week by Sir Keith Joseph, Secretary of State for Education and Science (see *Nature* 7 March, p.3). The intention is that the extra money will help to bridge the expected shortfall of graduates available to the high-technology and engineering industries, particularly those involved in information technology, electronics and software. The sum to be disposed by the University Grants Committee (UGC) will be £11 million in 1985-86 and £16 million in each of the next two years.

This injection may be described as a "third time lucky" attempt by Sir Keith to fulfil an election promise to increase spending on such training. Originally, it was intended that funds would be switched within the budget of the Department of Education and Science (DES) from the arts and humanities to science and engineering. It was realized, however, that this would penalize the arts disproportionately, given the difference in unit costs between a science and an arts graduate. A second attempt to find the money was partially successful but ended in the debacle last autumn when Sir Keith was forced by a backbench revolt embarrassedly to retract a proposal that better-off parents should pay towards the tuition fees of their offspring. This diminished the extra funds for universities from £48 million to £38 million over three years.

The third attempt was supported by the Prime Minister, Mrs Margaret Thatcher, whose involvement was made necessary because the scheme requires contributions from various government departments. Those who forked out were the Welsh and Scottish Offices, and the Departments of Energy and of Trade and Industry.

UGC is already considering bids from universities for 1985-86 funds. In subsequent years, polytechnics will also be able to compete, which would represent further encouragement after the announcement earlier this year of an allocation of £2.5 million for 1985-86 for science and technology research. Mrs Thatcher has now written to some of the industrialists whose concern over future skilled manpower shortages helped to stimulate the new funds to ask for their views on the allocation of the money available and on the prospects for more direct support for university research.

Philip Campbell

Soviet academy

Winds of change discerned

THE general meeting of the Soviet Academy of Sciences, which opened only three days after the accession of Mr Mikhail Gorbachev, was quick to respond to the tone of the new regime. In his opening speech, the president of the academy, Anatolii P. Aleksandrov, put special emphasis on Mr Gorbachev's remarks at the Central Committee plenum urging all Soviet scientists to "more active involvement in the solution of important economic, public health and cultural tasks".

Such exhortations are not, of course, new. For the past two decades, every party directive on science has urged closer ties between research and production. This time, however, there was a note of urgency not always apparent at academy meetings. In a rare moment of self-criticism (relayed, incidentally, by Moscow radio), Aleksandrov noted that since the 26th Party Congress in 1981, "many scientific developments which seemed to be economically productive, important and accessible to our industry, were made use of only after a long delay".

The lag in implementing research results in Soviet production is a well-established fact of Soviet life and seems to be endemic in the central planning system, which makes no provision for the non-productive weeks or months necessary for modernizing plants or installing new equipment. The traditional scapegoat, however, is the planner or the factory manager; for scientists to accept at least part of the responsibility is, to say the least, unusual.

Whatever the explanations, Aleksandrov went on to say, Soviet scientists must now apply their efforts to finalizing the plans for the coming five years. Although the "basic directions" have already been decided by the academy and the State Committee for Science and Technology, "certain revisions are required".

What these "revisions" will entail is not too difficult to guess. This year, Konstantin Frolov, a specialist in mechanical engineering, has been elected as an additional vice-president. Each academy vice-president is responsible for a major field of research within the academy institutes; Petr Fedoseev for social sciences, Yurii Ovchinnikov for chemical and biological sciences, Evgenii Velikhov for physical and mathematical sciences, Aleksandr Yanshin for Earth sciences and so on. Although all these sectors have their applied and technological aspects, the election of Frolov to the vice-presidency suggests a policy change that would restore to the academy the technology institutes of which it was shorn in the reforms of the early 1960s.

Another field not often stressed at academy meetings is that of military research but, at a special session devoted to the 40th anniversary of the end of the Second World War in Europe, the contribution of Soviet scientists to the allied war effort was much lauded. Then, Aleksandrov continued, the level of development of Soviet science still directly influences the country's defence potential, countering "the military superiority of the forces of imperialism". The academy went on to adopt a resolution calling on "scientists of the world" to ensure that atomic research is directed towards peaceful purposes only and that space technology is used not for "star wars but to support the cause of peace and progress".

For the most part, however, the academy meeting ran true to form. Reports were presented, foreign contacts noted (28,500 Soviet scientists posted to socialist countries during the past five years) and the "complexities" of relationships with the United States over the past five years deplored. A few major innovations were mentioned almost in passing, in particular the establishment of a centre for public opinion research at the Institute of Sociological Research. Some difficulties were glossed over. Academic secretary Georgii Skryabin correctly reported the "successful research" into computer software but said nothing of the difficulties in training computer engineers recently noted in *Izvestiya* by Vyacheslav Elutin, the All-Union Minister of Higher and Secondary Specialized Education.

Perhaps, however, the most significant tribute to the new Gorbachev era came in the TASS announcement that, as expected, Aleksandrov had been re-elected president of the academy. Leading Soviet scientists are, in general, as remote from the public as are political leaders and, at 82 and in failing health, Aleksandrov has been more remote than most. Almost ten years after his first election to the post, TASS has nevertheless decided to give him something more of a public image, Aleksandrov's career was "a flurry of brilliant ideas and decisions". "He is cheerful and sociable", TASS went on, "likes a good joke and a hearty laugh. But he is furious when he sees injustice".

Vera Rich

Soviet geneticist

Smuggling charge dropped

DR David Goldfarb, the Moscow Jewish molecular geneticist, who last year was accused of trying to smuggle Soviet "national security material" — bacteriological strains — to the West, has been informed by the KGB that the smuggling charge against him has been dropped. He is now threatened, however, with prosecution for advocating a Western boycott on his behalf.

Dr Goldfarb, whose emigration visa for Israel was apparently obtained by supporters in the Academy of Sciences bypassing the normal emigration and security channels, had that visa rescinded last April, a few days before he was due to leave. His research notes, personal papers and strains were confiscated and he was informed that the strains were the property of the Soviet Union. In fact, all the strains involved had originally been obtained from laboratories in the United Kingdom or the United States, either directly or through the good offices of Wladyslaw Kunicki-Goldfinger, or of the Polish Academy of Sciences.

Recently a group of biologists from the United States and Europe proposed a moratorium on the sending of strains to the Soviet Union until Dr Goldfarb's materials were returned to him and he was issued a new exit visa. During his recent conversation with KGB officer Gusev, Dr Goldfarb was confronted with a copy of a letter he had written to Professor Elie Wollman of the Institut Pasteur in Paris, supporting the idea of the moratorium. Gusev said that the letter might constitute a case of "anti-Soviet propaganda" and made Dr Goldfarb sign a document to that effect. The document, together with the letter, will be forwarded to the prosecutor's office, in order to determine whether any further action is necessary. When Dr Goldfarb asked how Gusev had got hold of the letter, he was told that "someone picked it up in the street". Gusev added that, in any case, the moratorium would not be effective, since the Academy of Sciences said that only a few letters of protest had been received from the West".

Gusev then returned to Dr Goldfarb all the confiscated written materials (but not the strains), and said that the smuggling charges had been dropped. According to a representative of the New York-based Helsinki Watch Committee, this is the first known incident of the KGB returning confiscated material, or informing a suspect that the charges against him had been dropped.

In a telephone conversation with his son in New York, Dr Goldfarb said that so far it is unclear whether the return of the material indicates that he will be allowed to emigrate, or whether it merely marks a change in tactics by the KGB in response to Western reaction to the "strains affair". The Goldfarb case was raised during the negotiations last January about the possible resumption of the bilateral exchange agreement between the Soviet Academy of Science and the US National Academy of Sciences. According to Professor Alex Rich, a member of the United States team, Dr Yurii Ovchinnikov, a vice-president of the Soviet Academy said: "Of course this strain thing is not serious and we are trying to clear it up. But there is not much that we can do as it is in the hands of the KGB".

Vera Rich

UK–Japan exchange

Go East young man

Tokyo

GIVEN the near-impossibility of finding any kind of academic post, most young UK scientists would find it hard to believe there is a source of extraordinarily generous post-doctoral fellowships that never attracts enough applicants. But, according to new figures from the fellowship scheme operated by the Japanese Society for the Promotion of Science and the Royal Society of London, this is exactly the case.

The fellowships are available to support study in Japan's universities, many of which now boast enviable facilities, and would enable a foreigner to live in comparative luxury. A generous tax-free monthly stipend of nearly £1,000 (Y270,000) is provided, along with a monthly housing allowance of up to £350 (Y100,000) which would cover most of the rent of a reasonably spacious apartment in Tokyo, and to add icing on the cake there is an annual allowance of a further £350 (Y100,000). All of this is topped off with a round-trip airfare from Britain to Japan. But despite these incentives, only 32 of the 60 awards, which are for one or two years, have been taken up in the first six years of operation of the scheme: scarcely 50 per cent of the posts have been filled.

So what has gone wrong? Britain's figures make a poor showing when compared with identical schemes operated in West Germany and France. In these countries, all but one of the available fellowships have been taken up, and in 1983, for example, there were 35 qualified applicants for the eight fellowships open to French scientists.

Royal Society officials say the lack of applicants is due to the extremely tight situation for academic posts in Britain — few young scientists are willing to risk leaving Britain for the Far East for one or two years; they prefer to be on the spot for any "new blood" openings that might come up. But the employment situation is surely no better in West Germany and France.

Part of the problem may lie in fear of the unknown — language barriers and apprehension about the state of scientific research in Japan may deter potential applicants. It is true that any foreign scientist coming to Japan must accept that he or she does so as a "guest". On the plus side this means that a visiting scientist need not follow the gruelling work schedule of his Japanese counterparts, although some attempt to conform is expected — young Japanese scientists typically work 12 hours a day six or seven days a week. On the negative side, permanent posts in Japanese universities are virtually closed to foreigners; in 1982, government regulations were changed to allow the appointment of foreign nationals to university staffs in spite of their status as civil servants, but only two foreigners have so far been appointed as permanent members of staff in Japanese national universities. But British scientists who have ventured to come to Japan under the fellowship scheme have not regretted the move, according to John Richards, science officer of the British Council in Tokyo.

Maybe the real problem is that information about the scheme has not been widely enough disseminated in Britain. In France and West Germany, several organizations are involved in the selection procedure. In France, for example, many scientific organizations (such as CNRS and INSERM) and two ministries have representatives on the selection committee, and perhaps this more broadly based involvement of scientific and government bodies helps to draw in more applicants.

Those who criticize Japan for putting up barriers should recognize that here is a situation in which Japan has opened its doors to foreigners but few are taking the opportunity to walk in.

David Swinbanks

Asbestos

Claims centre in sight

Boston

IN the face of mounting legal costs and jammed court dockets, a group of asbestos manufacturers and insurance companies is setting up an out-of-court processing centre to handle the claims of the thousands of workers who claim to have been injured by exposure to asbestos.

After two years of negotiations, the Asbestos Claims Facility, to be based in Boston with a branch in San Francisco, will be born officially on 29 May. So far, 33 manufacturers — including the Manville Corporation, which filed bankruptcy three years ago in anticipation of financially-crippling liability judgements — and 22 insurance companies have agreed to participate.

More than 23,000 cases are now pending in state and federal courts, with about 500 new suits filed each month. A Rand Corporation study estimates that manufacturers and their insurers have already spent $1,000 million to settle asbestos-injury claims over the past ten years, with the companies' and plantiffs' legal expenses consuming 61 per cent of that total; legal expenses were threatening to escalate even further as the manufacturers and insurers began suing each other to determine who was responsible for paying off the successful plaintiffs. In joining the Asbestos Claims Facility, the companies have agreed to drop those battles. The insurance companies will provide the first several hundred million dollars (the exact amount is not yet certain) to pay off claims; if the insurance funds are exhausted, the manufacturers will shoulder the remaining financial burden.

Workers who choose to bring their claims to the facility will have to submit certain standard information, including employment and medical records. They will have to establish that they have suffered asbestos-related injury, such as asbestosis, and that they were exposed to asbestos-containing products made by at least one of the participating manufacturers. Facility staff will then try to negotiate a settlement. Failing that, the next step will be an offer to enter into mediation — binding or nonbinding — with a neutral third party. If an agreement still cannot be reached, the worker will be free to take the case to court. The facility will provide legal defence on behalf of all the companies in those cases.

Claimants, who were consulted by the companies in planning the facility, stand to gain by having their cases heard much more quickly than is now the case and by lower legal costs.

Thomas Henderson, a Pittsburgh lawyer whose firm represents 500 plaintiffs, says he is cautiously optimistic.

The Reagan Administration, which has resisted calls for government intervention in asbestos cases, has been more lavish with its praise. The establishment of the facility, says Office of Management and Budget general counsel Michael Horowitz, "demonstrates the ability of the private sector to resolve serious national problems without reliance on the government to dictate and enforce its own agenda".

Tom Burroughs

Universities clouded

THE most gloomy statement yet of the prospects for British universities was uttered last Friday by the person best qualified to judge, the chairman of the University Grants Committee (UGC), Sir Peter Swinnerton-Dyer. In a statement to a joint meeting of UGC with the Committee of Vice-Chancellors and Principals, he said that the failure of Sir Keith Joseph to refer to UGC's advice on higher education last November in a recent open letter "must be a bad sign" and a proof that the advice had been rejected.

In money terms, Swinnerton-Dyer said, the British government was expecting the universities to accommodate budget erosion of 0.5 per cent a year while asking them "to do new things". But, he guessed, the new system of cash limits would amount to a cut of 2 per cent a year. At this rate, he said, it would be necessary either that university departments or that whole universities should be closed. □

Whales

UN scientist takes a hand

WHALES and other marine mammals have found a new (objective) champion — the Yugoslav marine scientist Stjepan Keckes, for long director of the United Nations' "regional seas" programme. That programme, one of the most effective of the United Nations Environment Programme (UNEP), is now to extend its work from environmental protection to a study of fisheries and marine mammals.

Thus earlier this month, Keckes convened a meeting in Geneva of all agencies supporting marine mammal research, and had armed himself with a list of 36 research projects already mounted at a cost of $6 million and of 30 new projects, potential claimants on UNEP, which has $390,000 to spend on marine mammals this year. The environmentalist group Greenpeace proposed a project to clean up an island fouled by nets where the rare Hawaiian monk seal breeds, but most proposals were for research.

Research is sorely needed, according to British fisheries scientist Sydney Holt, who represents the Indian Ocean islands of the Seychelles on the scientific committee of the International Whaling Commission (IWC). IWC, which is a group of whaling nations and of others opposed to whaling, has proposed a ban on whaling from next year. Holt supports the ban, but says that IWC whale population models, on which catch quotas are based, are "not worth the computer tape they are stored on". In the UNEP regional seas magazine, *Siren*, he says that the survival rate of juvenile whales is a key factor in calculations but that it cannot yet be measured. Thus the models simply assume a figure, which remains constant as a function of population and population density. "In other words, we ignore it ... all our calculations are based on models in which we ignore changes in nearly every important factor."

Holt claims, for example, that there is no certainty that right whales are increasing in the Southern Ocean, as has been claimed. And humpbacks seemed to be increasing rapidly in the North-West Atlantic only because a lot of them were seen on the coast and in fishermen's nets. "But the whales were coming inshore for food because the offshore fisheries were depleted."

Keckes believes his research programme will breathe life into the floundering "global action plan" for marine mammals which has been planned over seven years by UNEP and the Food and Agriculture Organization. One objective is to help coordinate the work of bodies such as the World Wildlife Fund and the International Union for the Conservation of Nature. Governments are to meet on the issue in Nairobi next month. **Robert Walgate**

European telecommunications

Commission plans ahead

Brussels

THE European Commission has announced plans for the preparatory phase of a major research and development programme to modernize European telecommunications. Known as Research in Advanced Communications in Europe (RACE), the programme will be considered by Community research ministers at their meeting on 4 June.

Over the years, research in telecommunications has been a central part of the Community's industrial strategy. In the late 1960s, for example, a commission under Dr Pierre Aigrain singled out telecommunications as a fruitful field for collaboration but was unable to devise a workable programme. More recently, however, the Commission has been able to develop common specifications for equipment, plans for the coordination of licensing procedures and, last October, partial liberalization of European markets for equipment (see *Nature* **311**, 697; 1984).

The new programme has been put together by the Commission with the advice of national experts drawn from industry and academic life. The first objective of the preparatory phase will be to pave the way for the infrastructure needed both to support existing services and to develop new services for voice, data and video transmission. The Commission intends that there should be close collaboration between the RACE project and the Community's advanced information technology research programme, known as Esprit.

Between 1986 and 1991, work under the new programme will concentrate on integrated broad-band communications systems, when there will be some precompetitive development of equipment and services. The Commission also intends continuing the development of international standards in telecommunications.

If the first phase of the programme is agreed, the Commission would push on with a second phase between 1991 and 1996 and would then expect to invest at least 150,000 million European Currency Units (ECU) in advanced telecommunications equipment including colour telecopiers, newspaper transmission, voice-driven telecopiers and mobile videophones.

Large though this estimate may be, the Commission points out that it is small compared with the size of the telecommunications market, which is expected to amount to $500 million a year by the turn of the century. Europe is estimated to invest 20 per cent of total expenditure on telecommunications equipment, but the Commission hopes that its programme will help Europe to break into foreign markets on a substantial scale by the next century.

Meanwhile, the Commission is planning to hold a second demonstration of videoconferencing techniques in Europe in June this year and hopes that by May it will have developed a single standard for second-generation mobile telephones to replace the three standards now in use.

Anna Lubinska

European biotechnology

Brussels

THE governments of the European Community have now given the formal go-ahead for a four-year programme of research and training in biotechnology. As in other fields, the Community hopes to encourage transnational cooperation between academics and industrial interests in the ten member states.

Belatedly, 55 million European Currency Units (ECU) has been allocated for the period between 1985 and 1989, of which 9.5 million ECU are specifically earmarked for research in the collection of information, the modernization of databanks and the provision of access to existing facilities. As part of this effort, the Community hopes to improve existing collections of biological material and to develop better methods of storage and recovery.

Although the scale of support for the four-year programme falls one-third short of the sum originally sought by the Commission, the new programme is broader in scope than the first proposals, which concentrated on biomolecular engineering. While research in genetic engineering will still be supported, the new programme will also involve research on protein design as in the construction of artificial enzymes and the potential industrial applications of gene transfer. Applied research will include the development of reactors for converting waste lignocellulose into ethanol, from which the research directorate of the Commission has hitherto fought shy because of the uncompetitive prices of raw materials in Europe.

The underlying objective of the programme, according to the Commission, is to create a series of interlocking biotechnology research centres across Europe. But the cut in the research budget means that fewer contracts can be awarded, while it has been necessary to drop the study of the genetics of higher plants and the application of cell biology to the prevention of human disease, although work on the development of vaccines will continue.

Although the application of biotechnology in public health is an important aspect of the new programme, the chief focus of the research to be supported will be the use of agricultural products for industrial purposes, not for eating. The hope here is to find a solution to the problem of food surpluses in the Community.

Better safe than sorry

SIR — I accept that if Enoch Powell's Unborn Children (Protection) Bill, for which I voted, becomes law it will obstruct and divert the course of research on the physiology of fertilization and implantation. But neither the Warnock committee, nor the Royal Society evidence to it, nor the Medical Research Council comments on its report, seemed to me to take sufficient account of the pace of current research in mammalian embryology and molecular genetics. Here most of the work is done on the mouse and other animals, with much of the most important fundamental work on the control of the structure of the embryo being done on the fruit fly. Many processes of development are similar across a wide range of species.

It seems unlikely that the fruits of such research will be a sharp distinction between a well-defined range of severe genetically based abnormalities such as Down's syndrome and a "normal" genetic make-up. There seems more likely to be a continuous distribution of manifold genetic variations with structural and functional consequences with varying social acceptability.

Shall we then reject an embryo which seems likely, say, to have a tendency towards schizophrenia, without our being able to tell whether there may be a genetic association with some less detectable tendency such as intelligence or aesthetic sensitivity? Would we wish to allow individuals, or the Secretary of State, or a medical panel such choices? Yet no sooner do we have the technique of *in vitro* fertilization available than the most pressing arguments are being put forward for developments in clinical research and practice to help with many clinical and humanitarian problems by refinements in the technique and its mode of use. Within the next few years, which will be the life of the Powell bill, the problems apparently susceptible to such treatment may well extend over wide areas of human formation and behavioural tendencies, affecting most people and most of life.

Is it not wise to explore much more thoroughly the mechanisms of genetic selection and manipulation before rushing in to apply them prematurely in ill-understood ways to human embryos? Is it not wise then to allow society time to think through the legal, social, moral and religious questions raised? That is certainly the overwhelming view of the lay public to whom we are answerable in the House of Commons. Those who want a greater freedom to experiment, for entirely understandable reasons, are playing directly into the hands of forces hostile to science.

There is a danger of building up a public backlash against science as a whole that will be more damaging, even within embryology and developmental biology, than any such restrictions as those of the Powell bill. Within a fortnight of the vote on the bill, at the annual lunch of the Parliamentary and Scientific Society, Sir Keith Joseph, Secretary of State for Education and Science, was using it to take the heat off criticisms of his slaughtering of British science, sententiously lecturing the assembled scientists about their need to take moral considerations into account in their research. It is not morality that the scientists lack, but political guile.

Yellow rain

SIR — In their detailed letter on the yellow rain controversy, Rosen *et al.*[1] confound their own case for chemical warfare in South-East Asia. Contending that "people indigenous to the area collected and turned in anything that was yellow, in spite of the fact that yellow rain attacks were rare by mid-1982", the authors discredit the principal source of eyewitness testimony and of environmental samples, including those in which they have reported the presence of tricothecene mycotoxins. One must be suspicious of the assertion that Hmong refugees once provided authentic samples and testimony from chemical warfare attacks and at some arbitrary time ceased to do so. If we hold Rosen *et al.* to their statement, native witnesses might well have dissembled in their accounts of chemical warfare and turned in unauthentic samples at any point from 1978 to the present.

The Hmong interviews on yellow rain, which Rosen *et al.* have obviously not consulted, offer numerous accounts of chemical attacks both before and after mid-1982. These interviews, conducted from 1979 to 1983 by a variety of agencies (refs 2-4 and R. Haruff, personal communication), show a persistent pattern: the warfare scenarios, including the repercussions of illness and death, vary considerably in content and scope, while the purported chemical warfare agent seen on the ground is invariably described as yellow and matches bee faeces[5]. While the interviews by no means offer unequivocal proof of chemical warfare, they do represent the combat experience of Hmong guerrillas in Laos.

Further, the interviews suggest Hmong refugee accommodation to their US patrons' interest in building a case against Soviet influence in South-East Asia. As the bee faeces theory implies, the transformation of Laotian attacks on the Hmong into the metaphor of yellow rain may have occurred early in the post-Vietnam War phase of US–Hmong relations[5], leading refugees to procure descriptively appropriate samples whose aetiology was as much a mystery to them as to Western investigators.

The complex political vulnerability of the Hmong, both in their flight from Laos and their dependence on US officials, is an integral part of the yellow rain story. If the controversy is ever to be resolved, it will require a more studious appreciation of Hmong perspective than evidenced by Rosen *et al.* in their facile repudiation of native testimony.

Australian databank

SIR — A computer-based system (MBIS, the Molecular Biological Information Service) for use by molecular biologists within Australia, has been put on-line by the Division of Molecular Biology of the Commonwealth Scientific, Industrial and Research Organization (CSIRO). The system can be used free of charge by authorized individuals who are either directly linked to CSIRONET (CSIRO's computing network) or through a dial-up service. Dial-up Access is charged as a local call and transmission speed can be either 300 or 1,200 bytes per second.

The system is menu driven, allowing simple access to the services available. At present, nucleotide sequence databases from GenBank, the European Molecular Biology Organization and National Biomedical Research Foundation (NBRF) are on-line as well as the NBRF protein database and are updated as soon as new versions are made available.

Bibliographic information (GenBank) is also on-line. The software library can be used to retrieve, compare and/or analyse sequence data. The uploading or downloading of information is easily accomplished. Apart from programmes written at the division, software has been made available by R. Staden and M. Kanehisa.

An electronic Notice Board and separate electronic Mail System are available which we hope will aid better communications among molecular biologists in Australia.

A new type of forest decline in Germany

from L.W. Blank

There is much concern about the state of West Germany's large forests which are threatened by an unprecedented decline. Research into its causes no longer focuses on acid rain, but on a possible interaction of increased ozone concentrations, acid mist and climatic factors.

IN the past few years a severe and rapidly increasing decline of forests has been observed in the Federal Republic of Germany (FRG). It is now estimated that half of the total forest area is damaged to a varying extent[1]. This 'new type' forest decline, as it is called, is unprecedented in severity and geographical extent. Unlike most previous localized dieback events it cannot be attributed to a known cause.

Forest decline is now widely considered to be the most important environmental problem in the FRG, attracting considerable scientific as well as public attention. Here I present a brief account of the history of the decline, its present extent and severity, and the discussion of its potential causes.

History

First reports of damage in the early 1970s did not attract much attention or cause any serious alarm. Damage was then confined to a single species (silver fir; *Abies alba*), which accounts for only 2% of the total forest area (Table 1). Furthermore, silver fir decline is not an uncommon phenomenon in Central Europe, where localized dieback events have been well documented during the last two centuries[2,3]. However, the recent fir decline occurred almost simultaneously at various locations in the south of the country including the Black Forest and the Bavarian Forest[4-6] (Fig. 1). Similar fir damage has also been observed in Italy, Switzerland, Poland and in Czechoslovakia[7-10].

Silver fir decline in the FRG increased dramatically during the hot and dry summer of 1976 and is now affecting nearly all stands. Main damage symptoms are: gradual discolouration and subsequent loss of needles, from the base to the top and from inner to outer branches; premature growth reduction and formation of a 'stork's nest' crown; branch dieback in the lower crown and formation of epicormic shoots; extention of normal wet heartwood into the sapwood at the base of the tree ('wet core'); damage to the fine root system.

Since the late 1970s damage has also been noticed on other tree species. Norway spruce (*Picea abies*), Scots pine (*Pinus sylvestris*), and common beech (*Fagus sylvatica*), which together account for 77% of the total forest area (Table 1), have started to show signs of damage. Symptoms are similar but not identical to those reported for fir; a comprehensive list of symptoms is given by VDI[7]. Damage to Norway spruce, the dominant species in German forests where it forms 40% of forest plantations, is of particular importance, not the least because of its considerable economic value. Monitoring plots in severely affected areas of Baden-Württemberg showed a rapid increase in damage to spruce from 6% in 1981 to 94% in 1983[11]. Similar plots do not exist for other parts of the country, and reliable data on the increase of damage are thus rare.

Damage was initially restricted to higher altitudes (above 500 metres), affecting older trees more severely than younger ones. Although there still appear to be patterns of damage due to altitude and age the variability between individual trees is so great that severely affected trees can be found next to apparently healthy ones at most sites.

Present severity

To obtain a clear picture of the extent and severity of damage the Federal Minister of Food, Agriculture and Forestry initiated forest damage inventories which were carried out by the individual federal states in the summer of 1982, 1983 and 1984. Forests were assessed using a set of criteria detailing damage symptoms for all relevant species[12]. This verbal description has since 1983 been complemented by a set of colour

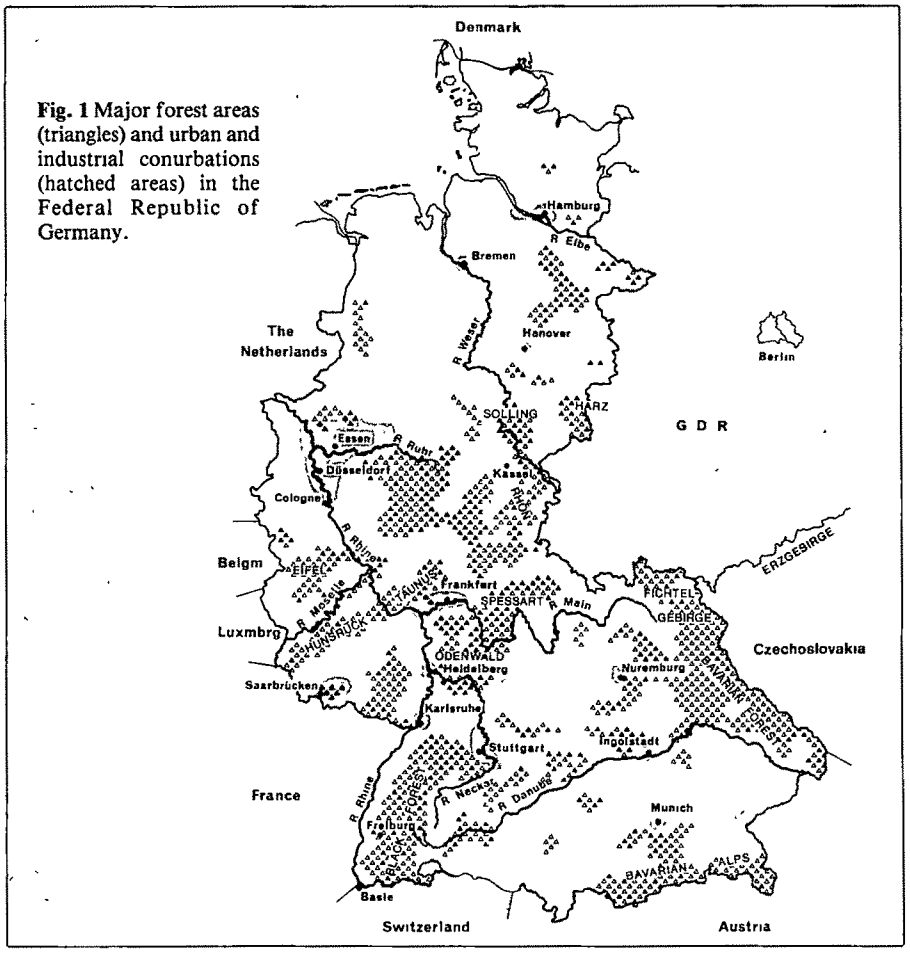

Fig. 1 Major forest areas (triangles) and urban and industrial conurbations (hatched areas) in the Federal Republic of Germany.

photographs[13]. Extent and severity of damage were classified using a system of damage categories. The initial system of three categories (category I, slightly damaged; category II, damaged; category III, severly damaged) as used in 1982 and 1983 was extended in 1984 by adding a category 0: 'without damage symptoms' and category 4: 'dead'. The main criterion for damage classification was the percentage of needle loss, which was related to damage categories. Trees with a loss of up to 10% were considered unaffected (category 0), 10-25% loss indicated slight damage (category I), 26-60% medium damage (category 2), and more than 60% loss severe damage (category 3). A second important criterion for damage classification was the discolouration of the foliage.

Before comparing the results of the three successive inventories, it is important to note that there are marked differences in their methodology and consequently in the accuracy of their damage assessment. The first survey in 1982 was largely an estimate, covering only parts of the country. The following survey in 1983, which covered the whole of the Federal Republic, used more detailed assessment criteria, and three federal states based their survey on spot-checks at assessment areas. This system was adopted on a national basis for the 1984 inventory, with a 4 by 4 km grid system determining test areas. The results obtained in these areas were extrapolated and presented as percentage damage to each tree species, to certain forest areas or to the total forest area.

Table 1 Area and species composition of forests in the FRG

Species	Area (ha × 10^6)	Proportion of total forest area (%)
Spruce	2.951	40
Pine	1.464	20
Fir	0.176	2
Beech	1.250	17
Oak	0.615	8
Others	0.950	13
Total	7.406	100

The total area of the FRG is 244,000 km^2; approximately 30% of this area is covered by forests.

Perhaps the most striking impression gained from a comparison of the three inventories is the drastic increase in the total damage forest area from 8% in 1982 to 34% in 1983 and 50% in 1984 (Table 2)[1,14]. This is mainly due to an increase in damage category I (slight damage) from 6% to 25% and now 33%, and an increase in category II (damaged) from 1.5% to 9%, and now 16%. The percentage of severely damaged and dead trees has risen only slightly from 0.5% in 1982 to 1.5% in 1984. Coniferous trees are generally more affected than deciduous species, but damage to beech and oak has risen sharply since 1983 (Table 3). Although damage can now be found all over the country, the southern states of Bavaria and Baden-Württemberg still appear to suffer most.

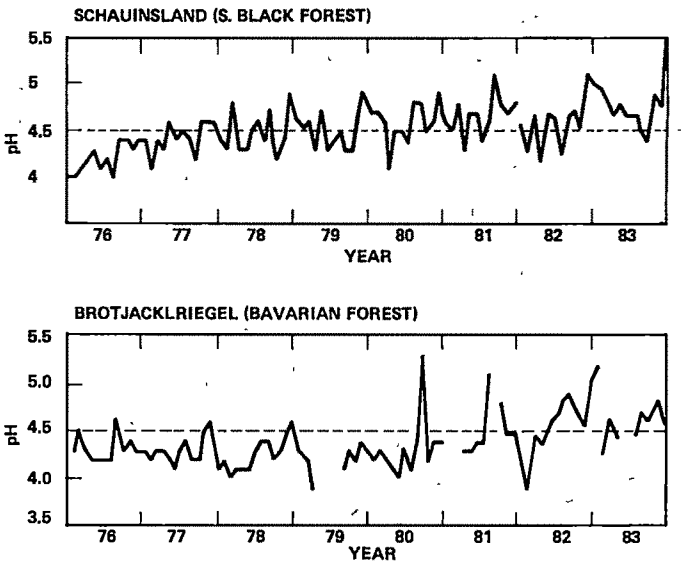

Fig. 2 Acidity of wet deposition (monthly means) in the Black Forest (Schauinsland) and the Bavarian Forest (Brotjackriegel)[19].

Disputed results

The official damage data based on the inventories are, however, not undisputed. In particular, the methods of damage assessment have been heavily criticized[15,16]. The criteria used for damage classification are unspecific but damage was, at least in 1983, ascribed to air pollution as a 'major or contributing cause'. There is now also a debate as to whether needle loss is a suitable criterion for damage classification. It has been suggested that needle loss up to 20% or 25%, currently resulting in a classification as 'slightly damaged', may in fact still be within the natural variation of healthy forests. The 1984 Swedish forest damage inventory, which is based on the German surveys, takes this into account, considering a needle loss of up to 20% as normal; the results of this survey are due to be published later this year.

Despite this controversy about assessment methods, the reliability of presented data and the comparability of the three inventories it is, however, undisputed that the decline has again increased and can now probably be seen as the major environmental problem in Germany.

Potential causes

This widespread disease, now affecting a variety of species in stands with different characteristics could not be attributed to a known cause of previous dieback events. Factors such as extreme climatic conditions (such as frost, sudden changes in temperature, drought), insect or pathogen attack, unsuitable silvicultural practices (for example, selection of the wrong species or provenance), or local sources of pollution can not explain the geographical extent of damage and its sudden increase within a few years. The discussion of the potential cause or causes very soon centred around air pollutants, which are now widely believed to play a major role in the decline. 'Acid rain', a term which at the beginning of the 1980s was becoming increasingly popular in Germany (and which was often used as a synonym for air pollution in general), was initially blamed by the media[17], and it was suggested, that SO_2 emissions in particular were the cause. This generalizing hypothesis has, however, in recent years given way to a more detailed discussion in which a number of potential causes have been suggested. It is now widely believed that the decline may be a complex disease, involving a number

Table 2 "New type" forest decline in 1983 and 1984 according to damage categories

	1983		1984	
Damage category	Area (ha × 10^6)	Forest area (%)	Area (ha × 10^6)	Forest area (%)
I	1.830	24.7	2.424	32.9
II	0.647	8.7	1.163	15.8
III + IV	0.076	1.0	0.111	1.5
I + II + III + IV	2.545	34.4	3.698	50.2

Categories defined as: I, slightly damaged; II, damaged; III, severely damaged; IV, dead. Total forest area, 7.4 × 10^6 hectares.

of factors, and there is also the possibility that the widespread decline is a number of concurrent regional events with a common trigger.

Direct effect of acid

Direct effects of sulphuric and nitric acid are, at least within the scientific community, not generally considered to be primarily responsible for the damage. The rain in affected areas is not sufficiently acid to cause damage even to sensitive plants[18], and there has been no increase in rain acidity in recent years in the Southern Black Forest or in the Bavarian forest, both areas severely affected by the decline (Fig. 2)[19].

Soil acidification

The most widely accepted initial hypothesis was based on a suggestion that wet and dry acid deposition affects the soil by destroying its buffering system. This would lead to leaching of nutrients (for example Ca, Mg, K) and mobilization of toxic aluminium ions, which would damage the fine root system of the tree, eventually resulting in its death[20]. The theory proposed that soil acidification is a natural process, but has in recent years been accelerated by increased acid input due to air pollutants. This ecosystem-orientated hypothesis of a soil-mediated effect is based on a comprehensive study of nutrient cycling in the Solling Mountains[21] (North Germany; see Fig. 1), and the results were extrapolated to other areas. It has been extensively criticized[22], mainly on grounds that damage occurs to trees on a variety of soils including those in calcareous areas with characteristics markedly-different to those found in the Solling Mountains. The hypothesis cannot explain both the temporal and geographical development of the recent decline.

SO_2 and NO_x

High concentrations of SO_2 are known to cause damage to most plants including trees[23,24]. Severe and large-scale damage to forests is reported from Poland and particularly Czechoslovakia (Erzgebirge, Riesengebirge), areas under the direct influence of high SO_2 concentrations from lignite combustion.

Only a comparatively small area in the FRG next to the East German and Czech borders (Fichtelgebirge) is exposed to similarly high SO_2 levels, with mean annual concentrations between 50 and 60 $\mu g\ m^{-3}$ and episodes of much higher concentrations (up to 1,500 $\mu g\ m^{-3}$)[25]. Damage in this area has been attributed to the direct action of pollutants, and is similar to that observed in the Erzgebirge area in Czechoslavia.

Direct effects of SO_2 and NO_2 have not been proposed as the cause of damage for the majority of sites in the FRG. SO_2 levels are generally well below the limits suggested by the International Union of Forestry Research Organizations (IUFRO). They recommend a limit of 25 $\mu g\ m^{-3}$ (annual mean), 50 $\mu g\ m^{-3}$ (average over 24 hours), and 75 $\mu g\ m^{-3}$ (97.5 percentile of 30-min values during the period of growth) in higher regions of mountains and in forests at extreme sites[26]. The Schauinsland (Southern Black Forest) and the Brotjacklriegel (Bavarian Forest) sites with forest damage, are both classified as 'clean air monitoring stations' by the German environmental protection agency (UBA). Annual mean SO_2 concentrations at the two sites during 1972-1983 were between 10 and 15 $\mu g\ m^{-3}$ (Bavarian Forest) and between 4 and 8 $\mu g\ m^{-3}$ (Black Forest), and annual mean NO_2 concentrations were below 8 $\mu g\ m^{-3}$ (Bavarian Forest) and 6 $\mu g\ m^{-3}$ (Black Forest) (Fig.4)[19,27]. A first indicator that SO_2 alone was unlikely to be the primary cause of damage was the prolific growth of lichens even in severely damaged forests.

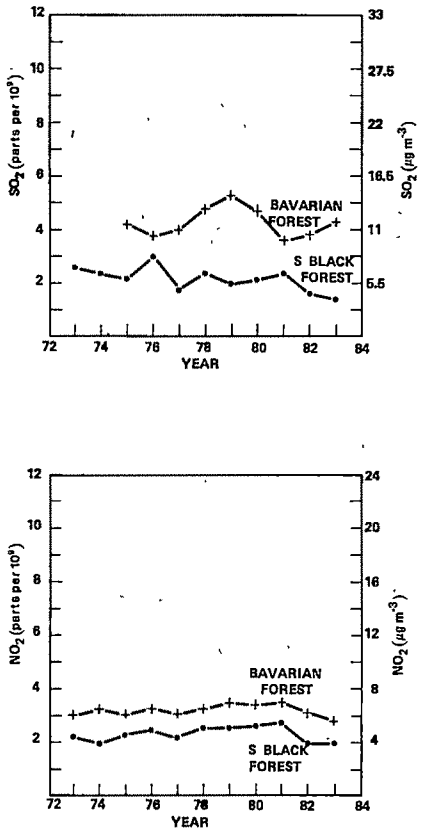

Fig. 3 Mean annual concentrations of SO_2 and NO_2 in the Black Forest (Schauinsland) and the Bavarian Forest (Brotjackriegel)[19].

Ozone

It was recently suggested that ozone (and possibly other photooxidants) may be involved in the decline[28], and the following mode of action was proposed[29]: Exposure to elevated ozone levels damages cell membranes, resulting in an increased leaching of ions by acid fog and acid rain. Ozone also causes damage to chlorophyll, and thus reduction in carbohydrate production and root growth. This reduces the ability to compensate for leached nutrients by increased uptake. A similar hypothesis includes frost as another important factor[30,31].

Ozone levels in damaged forests in the FRG are often remarkably high[29,32,33] and sometimes comparable to parts of the United States where ozone is known to have caused injury to trees[32]. Recent measurements show that daily mean ozone levels in 'clean air areas' of the Southern Black Forest (Schauinsland) and the Bavarian Forest (Brotjacklriegel) are often above 100 $\mu g\ m^{-3}$ (refs 19,29) with annual mean concentration of the order of 80-110 $\mu g\ m^{-3}$ (Black Forest) and 60-90 $\mu g\ m^{-3}$ (Bavarian Forest).

There is, however, still a paucity of data, particularly from areas with extensive forest damage. There is also a shortage of data on long-term trends in ozone concentrations — only one data set gives a clear idea of the trend in natural background ozone concentrations in Central Europe over the past 20 years. Ozone levels at Arkona on the isle of Rügen in the Baltic Sea off the German Democratic Republic, an area not affected by local air pollution, increased by 60% between 1956 and 1977 (Fig. 4)[34]. A similar trend has been reported for two other stations in forest areas of the German Democratic Republic[34], and it can be assumed for forest sites in the FRG and other neighbouring countries as well. This coincides with the steady increase of NO_x and hydrocarbon emissions from motor vehicles, which react with sunlight to produce ozone during transport over long

Table 3 Extent of 'new type' forest decline according to tree species

Species	Total area (ha × 10^6)	Affected area (%) 1983	1984
Spruce	2.950	41	51
Fir	0.178	44	59
Pine	1.463	75	87
Beech	1.262	26	50
Oak	0.612	15	43
Others	0.940	17	31

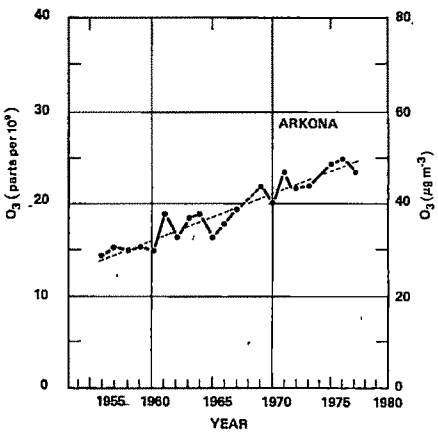

Fig. 4 Trend in mean annual ozone concentration at an unpolluted site in the German Democratic Republic (Rugen). Ozone was measured by bubbling air through KI solutions, so the data represent total oxidant. A filter was added in 1972 to remove interference from reducing gases such as SO_2 (redrawn from ref. 34).

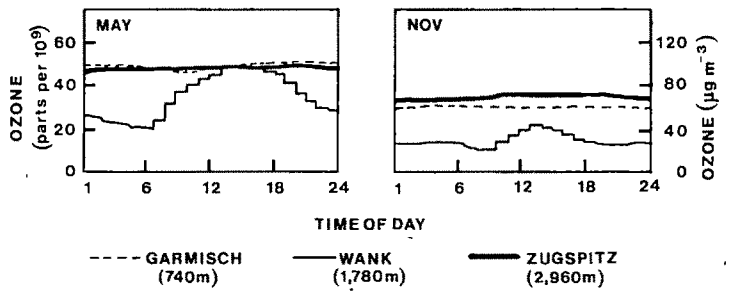

Fig. 5 Diurnal trends in ozone concentrations (1977-82) at three altitudes in the Garmisch-Partenkirchen Valley in the Bavarian Alps (Garmisch 740 m; Wank 1,780 m; Zugspitze 2,960 m). The site at Wank is close to the tree line (redrawn from ref. 35).

distances from urban areas. It has been suggested that the ozone would then affect remote areas, particularly at high altitudes, which are not under the influence of high levels of the 'classic' pollutants SO_2 and NO_x. Data from the Bavarian Alps (Garmisch-Partenkirchen) show low and steady ozone concentrations between 1977 and 1982 in a valley, and higher concentrations with a trend towards an increase at higher altitudes nearby[35]. It was at higher altitudes of remote forest areas that damage was first noticed. What is perhaps most important, in this context, is the lack of the diurnal pattern, characteristic for urban areas, at higher altitudes where concentrations appear to remain remarkably steady for long periods (Fig.5)[35].

Besides the involvement of ozone a second major factor has been suggested to interact with the oxidant; acid mist. A high incidence of fog is characteristic for higher altitudes in some damaged mountain areas in the FRG, with an annual mean of up to 226 days with periods of fog reported for a station in the Bavarian Forest[36]. Data on the frequency, the duration, and the ion-concentration of fog collected in damage areas, however, are rare.

The photo-oxidant hypothesis is at present the most widely accepted explanation for the new-type forest decline. It is, however, still largely based on circumstantial evidence and needs further supporting data from forest areas as well as experimental verification. Experimental work using or exceeding concentrations of ozone believed to be common at areas with a high incidence of damage have so far failed to produce the chlorosis which is so characteristic of the decline in Norway spruce[29,37]. There is also little known on the relative suscepability of the species concerned, and conifers, which are thought to be more resistant than deciduous species, appear to be affected first[38]. Another open question is the possibility of the quality of received radiation being involved. It cannot be ruled out that the higher proportion of ultraviolet radiation received by trees at higher altitudes could be involved in the degradation of chlorophyll in damaged needles. It will also be necessary to re-examine existing data on ambient air quality and to expand the network of air quality monitoring stations and monitored pollutants, preferably by including sites in damaged areas.

Climate

Although there appears to be a consensus amongst scientists that air pollutants play a major and probably the key role in the decline, it has also been suggested that climatic factors may be involved. The series of dry and hot years experienced during the last decade has certainly affected tree vitality and resistance to pollutants and pathogen attack. Hot summers in the continental climate have often been followed by harsh winters, with temperatures below −15°C not an uncommon event. Drastic and sudden changes in temperature as on New Years Eve of 1978 when the temperature dropped by almost 20°C within hours may be equally important.

Pathogens

As the number of trees affected by fungal infections has markedly increased over the past few years, it has been suggested that pathogens play an important role, probably as a secondary cause of decline following a lowering of the resistance by pollution or climatic factors. Rehfuess and Rodenkirchen[39] report a comparatively high incidence of fungal infection (*Lophodermium* and other fungal pathogens) from forests in Southern Germany in recent years.

There are also suggestions that the decline is an epidemiological rather than a pollutant-induced phenomenon[40]. This theory suggests, that pathogens (probably mycoplasms or rickettsia-like organisms) may be the cause of decline. This would explain the rather patchy occurrence of damage but this hypothesis is not yet supported by field or laboratory evidence.

Conclusions

The new-type decline is no longer confined to Germany. Damage has recently been reported from Switzerland (deciduous trees)[10] and Sweden (spruce)[41]. Reports in the media suggest that similar damage can also be found in Italy, Austria and the Netherlands. The situation in Eastern European countries, where large-scale direct SO_2 injury is known to occur, is difficult to assess, as there are hardly any reports on the present state of the forests.

The alarming reports on the state of Germany's forests have aroused considerable and understandable emotion, sometimes overshadowing a realistic and critical discussion of the true extent and severity of the decline, of proposed causes and potential remedial measures. There is now, however, also an increased number of research projects under way. One would hope, that laboratory as well as field work will help to unravel the causes of the decline, as all proposed explanatory hypotheses, including the currently much favoured ozone-hypotheses, are still largely based on circumstantial evidence, requiring verification under realistic conditions. It would at present certainly be premature to conclude that a conclusive explanation for this apparently complex environmental problem is available. □

Recalculating interatomic forces

The van der Waals force between atoms and molecules is generally taken to be inversely proportional to the inverse sixth power of the distance, but positronium atoms may interact differently.

ALTHOUGH the van der Waals force has been part of classical physics for the best part of a century, since the recognition that the departure of the behaviour of real gases from the perfect gas laws points to a short-range attractive force between atoms and molecules, there is no classical explanation of the effect. Provided that the interacting species have no permanent dipole moment (when the van der Waals force is negligible), the best that can be done is to suppose that atoms and molecules are attracted to each other as a consequence of their polarizability; each becomes a little dipole under the influence of the other.

Classically, it is easy to see that this force has a short range in the sense that it will be proportional to a large power of the reciprocal distance R between the interacting entities (for the force due to an induced dipole is already proportional to $1/R^3$), but two interacting atoms which mutually induce a symmetrical pair of dipoles will be found to have a mutual energy greater than they began with, corresponding to repulsion, and which classically will not happen. That is why the van der Waals force has been regarded as essentially a quantum phenomenon at least since F. London's successful account of it half a century ago. Now, even that has been refined by means of an elegant calculation due to J.R. Manson and R.H. Ritchie (*Phys. Rev. Lett.* **54**, 785; 1985). The outcome could be interesting.

The simplest way of calculating the van der Waals force gives a reasonable result, but is now shown to be subtly too simple. For definiteness, suppose that the two interacting atoms are two hydrogen-like atoms whose nulcei are separated by a distance R. To a first approximation, the single electrons of each of them are described by a set of hydrogen-like wavefunctions centred on points separated by a distance R. The more realistic next approximation then consists in the addition to the total energy of the system of the terms representing the interaction between the pair of nuclei and the pair of electrons (both positive, denoting repulsion) and between each nucleus and the other electron (negative, for attraction).

Practitioners of wave mechanics will take this kind of problem in their stride. The extra interaction energy is supposed small compared with the interaction between each nucleus and its "own" electron, so textbook perturbation theory applies. The complete set of wavefunctions of each atom enters into some linear combination of the wavefunctions corresponding to all of its quantum states. London remarked that geometrical symmetry ensures that the first-order perturbation calculation is zero. But second-order perturbation theory yields a plausible result: an attractive force between atoms proportional to $1/R^6$.

At its simplest, perturbation theory is a way of calculating the energy of a system that differs to only a small extent from one that can be solved exactly. For the calculation of van der Waals force between two hydrogen-like atoms, for example, the behaviour of each electron under the influence of its own nucleus is exactly calculable, and the result is the familiar infinite set of discrete energy levels converging on the ionization energy of the atom. The energy of the combined system of two atoms close together is then approximately calculable from the terms representing the interaction between the atoms and the wavefunctions corresponding to the original unperturbed system, the product of two one-electron wavefunctions centred on the positions of the two nuclei separated by a specific distance.

Second-order calculations give a familiar result. The energy of the interacting system differs from that in which the interaction is ignored by an amount expressed as an infinite series in which each term represents the square of the probability that the interaction energy will induce a transition from the original state to another but weighted by the reciprocal of the energy difference between the states. Straightforward calculation along these lines recovers the London result that the energy of the combined system is decreased by an amount proportional to $1/R^6$, entirely appropriate for the short-range van der Waals force.

But the argument is incomplete. Implicit in the calculation is the assumption that the pair of interacting atoms is static, with the two nuclei fixed in space. Yet the calculation itself suggests that the interaction is responsible for an attractive force between the pair of atoms which in the absence of specified constraints, should be sufficient to make the configuration of the system time-dependent.

The circumstances resemble those familiar in the calculation of the properties of molecules, where it is customary to calculate electronic states on the assumption that the atomic nuclei are fixed in space, and then separately to calculate such things as the vibrational frequencies of the molecule, which entails allowing that the nuclei can move. The justification of this is the Born-Oppenheimer approximation, which is usually sustained by the observation that the characteristic frequencies of electronic motions are much greater than those with which atomic nuclei move. One day some lucky graduate student will find a supervisor to back sober up-to-date investigation of the circumstances under which the approximation does not apply.

Meanwhile, Manson and Ritchie have provided an intriguing example with which to begin, the van der Waals interaction between two positronium atoms, the metastable atoms consisting of a positron and an electron, the least massive of all hydrogen-like atoms. The starting-point for the calculation is a description of the unperturbed state of the system which allows that each of the interacting atoms may be in motion (so the wavefunctions are products of two atomic wavefunctions and two momentum wavefunctions, or plane waves). What Manson and Ritchie have done is to calculate the van der Waals force between two atoms whose initial states are described in this way.

First, there is a matter of interpretation, which goes back to London. The terms in the series representing the second-order perturbation energy, which are products of the probability that the interaction energy will cause transitions between electonic states, may be regarded as representing processes in which a virtual photon is allowed to excite the system in a defined way and then be emitted again, to be absorbed where it began. But, in such a process, there must be not merely a transfer of energy but of momentum — the atoms concerned must recoil. Manson and Ritchie have allowed for recoil in the calculation of the forces between positronium atoms. So the $1/R^6$ behaviour of the van der Waals force is modified, by the effects of recoil, to one that tends to $1/R^4$ at small separations between the atoms.

The chief interest in this work will be the neatness of the calculation. For the interaction between positronium atoms, the departure from $1/R^6$ behaviour should be recognizable out to a distance of four atomic units, and may thus be measurable. So should be departures from London's result for the interaction between positronium and other atoms. Meanwhile, the calculation is a telling reminder that even the best-tried algorithms should be constantly reassessed. **John Maddox**

Synthetic fuels

From lignin to coal in a year

from John Larsen

SEVERAL million years and a minor imperfection in the carbon cycle have given us coal, yet Winans and his colleagues at Argonne National Laboratory have taken less than one year to prepare a thoroughly characterized synthetic coal[1]. The material they produce is indistinguishable from the real thing by all the techniques so far applied to it and its synthesis raises many interesting questions in coal chemistry.

Coals are extraordinarily complex mixtures, which Neaval has likened to fruitcakes[2], with the various components originating from different parts of the plants from which the coals are formed. Coal's organic constituents, which range in size from methane to macromolecular gels of effectively infinite molecular weight, are mixed throughout with a variety of inorganic materials, principally clays. Determining the structure of coal has been difficult because the normal techniques of organic chemistry are not well suited to complex macromolecular mixtures.

As is usually the case, instrumental advances have been responsible for much of the recent progress in understanding coal structures. The resurgence, in semi-quantitative form, of the concept of coal as a three-dimensionally cross-linked macromolecular structure — originally developed by van Krevelen[3] — came just in time to support new and improved spectroscopic techniques[4]; the switch from grating IR instruments to Fourier-transform IR spectrometers not only added the kind of sensitivity that is so valuable with opaque samples, but also enabled spectra to be subtracted from one another, an enormous aid when working with complex mixtures. The recent availability of high-resolution nuclear magnetic resonance (NMR) spectra of solids is also being vigorously exploited and has greatly extended our ability to follow structural changes. This technique is still troubled by the 'invisibility' to NMR of many of the carbon atoms in coal, but all the indications are that visible carbon atoms are representative of the whole sample. New chemical methods, mostly better oxidative[5] and reductive[6] degradation techniques, are also contributing to structural information on coal. But these contributions have added little to our understanding of the process by which coal is formed. It is in this respect that the Argonne group's description of a convenient preparation of man-made coal is likely to be most important; already it has raised the possibility that natural coal production is a catalytic process.

The synthetic coal is produced by warming lignins (highly aromatic molecular components of woody tissue) at 150° C for a few months in the presence of twice as much montmorillonite clay, which seems to serve an acid-catalytic role. Fourier-transform IR, NMR, electron-spin resonance, gas chromatography, mass spectrometry and oxidative degredation were used to analyse the product. The changes that were observed are similar to those that occur in natural coal production. Lignin heated without clay did not produce coal, and heating cellulose (the other portion of woody tissue), with or without clay, also failed to produce coal, perhaps settling the controversy over the role of cellulose in coal formation. More surprisingly, the clays cause fatty acids to form a coal component called alginite, which is thought to derive naturally from the remains of algae that contain fatty acids, as an important lipid constituent.

The most thorough previous attempt to produce coal artificially was a thirty-year experiment initiated at the US Bureau of Mines by R.A. Friedel[7,8]. This experiment, which outlived the laboratory that started it, consisted of pyrolysis at 200°C of several possible coal precursors, including pine wood and lignite, a very young brown coal with high oxygen content. As judged by NMR, electron-spin resonance, IR spectra and elemental analysis, in only eleven years lignite was altered to a material similar to a much older coal and the pine wood formed material similar to a subbituminous coal. Interestingly, pyrolysis of pine wood at 300°C for one hour produced coal-like materials, which contrasts with Winan's observation using lignin as a starting material. According to H. Retcofsky, who is completing a study of the Bureau of Mines's samples, pyrolysis for eleven years at 200°C is roughly equivalent to one hour at 290°C.

The Argonne work raises many questions, particularly concerning the relevance of acid catalysis using large amounts of clay. Real coals often contain only a few per cent of coal clays. Is their production catalysed by clays? What is the mechanism by which acid catalysis is extended into the solid from the clay surface? Is this mixture of solids mobile? If so, will time alone allow the few per cent of clay in natural coal to convert the entire mass? What is the *p*H dependence of this acid-catalysed process? These questions will surely be addressed. The production of artificial coal will open a new era of the study of coal formation by allowing the direct experimental test of hypotheses. The preparation of isotopically-labelled coals for spectroscopic and other studies, is already underway and will be welcomed by those trying to unravel coal reactions. □

Early mathematical wheelwork

Byzantine calendrical gearing

from Francis Maddison

FOUR fragments of a sundial incorporating a geared calendar (Fig. 1), inscribed in Greek and probably dating from the late fifth or the early sixth century of our era, document a gap in the history of precision gearing as yet unfilled by literary evidence. The fragments are extensively described and discussed by J.V. Field and M.T. Wright in a forthcoming paper[1]; and at an exhibition* that opens today in London's Science Museum, the fragments are set in historical relationship to the very few surviving devices with precision gearing from the last century BC to the beginning of the fourteenth century.

It may still commonly be thought that gears with precisely determined numbers of teeth were first used in mediaeval clocks, but an early discovery of underwater archaeology disproved that view. In 1901, the cargo of a ship which sank around 80 BC near the island of Antikythera in the Aegean was found to contain a corroded mass of bronze gear-wheels and fragments of bronze plates with Greek inscriptions. The late Derek de Solla Price showed that these remains had formed part of a complex calendrical computing device, a fact which fitted uneasily into the traditional view of a Hellenistic society little interested in technology[2]. The main input into the box containing the mechanism was by a crank which rotated a contrate wheel to turn a main wheel, one revolution of which represented a solar year. Outputs seem to have included a function of the Metonic cycle (using a differential), the relative positions of the Sun and Moon, and the risings and settings of certain stars throughout

*'Early Gearing' Geared Mechanisms in the Ancient and Medieval World', from 28 March 1985. Exhibition catalogue from Science Museum, London SW7 2DD, UK

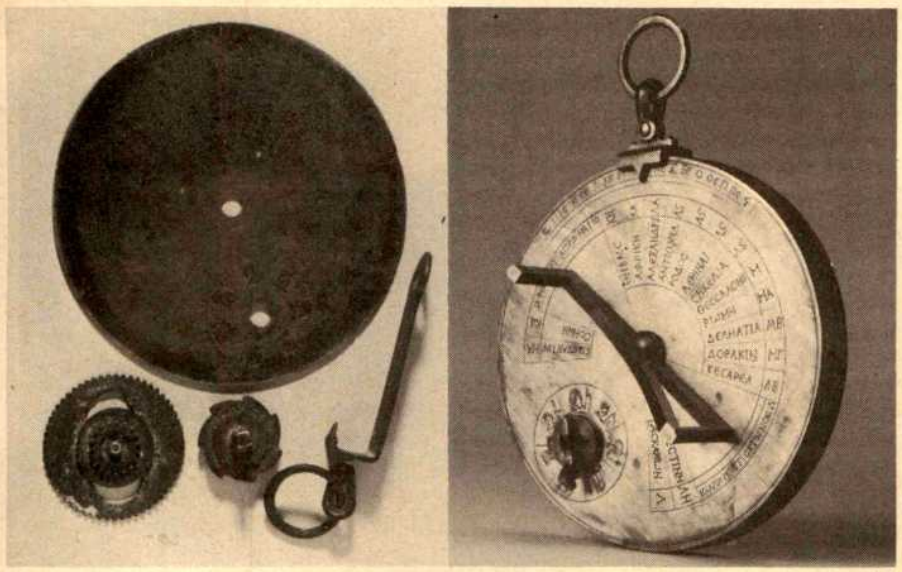

Fig. 1 The four fragments (left) and a reconstruction (right) of a Byzantine sundial-calendar with Greek inscriptions and probably made in AD 479-565. The large disk has a diameter of 135 mm. Reconstruction by M.T. Wright. (Courtesy Trustees of the Science Museum).

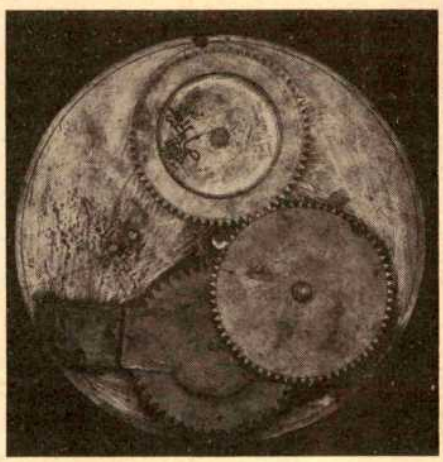
the year. The Science Museum exhibition includes a model of the Antikythera machine (lent by the Smithsonian Institution, Washington).

Price related the triangular-toothed gearwheels of this mechanism to a Hellenistic tradition of automata and mechanical toys, applied to an astronomical water-clock tradition, as recorded by Vitruvius around 25 BC. He pursued the tradition further, by way of Islamic interest in automata and water-clocks with opening windows, spherical weights falling into gongs, and moving human figures, to the mediaeval European astronomical clocks, with their mathematical modelling of the motions of the celestial bodies (as on the planetary clock of Giovanni de' Dondi, completed in 1364) and astrolabe dials and jacks (like the clock of 1410 on the Old Town Hall in Prague)[3-5]. This is an involved and complicated story, fascinating in its implications for motivation and cross-cultural transmission, but the gaps in the sequence are wide and the pursuit of detail a difficult task.

Chronologically, the history of mathematical gearing has been devoid of surviving artefacts or literary description from the Antikythera mechanism until about AD 1000, when the eminent Islamic scientist al-Bîrûnî wrote a treatise on the different types of astrolabe, and included an account of a geared calendar. The Science Museum exhibition includes a reproduction of al-Bîrûnî's text and an astrolabe (made in AD 1221-2 by Muhammad the son of Abû Bakr, the needle-maker of Isfahân, and borrowed from the Museum of the History of Science, Oxford) which includes just such a geared calendar (Fig. 2), though with slightly different gear-ratios. On the back-plate are apertures showing (in the Arabic alphabet, used numerically) the age of the Moon, and its phase by the rotation of a silvered and blackened disc; furthermore, the relative positions of the Sun and Moon are indicated by inlaid gold and silver points on concentric rings within a scale of the signs of the zodiac. A gear-train links the manually-turned discs giving the data, confirming al-Bîrûnî's remark, two hundred years earlier, that the wheels in his calendar were like those fitted to the backs of astrolabes.



The fragments acquired by the Science Museum, regrettably without any provenance beyond the vendor's statement that they were bought in the Lebanon, fall chronologically midway between the Antikythera mechanism and the al-Bîrûnî calendar. A detailed metallurgical, technological and historical study of the fragments[1], together with a new translation and commentary on al-Bîrûnî's description of the geared calendar[6], show that the fragments were part of a geared calendar, the gear-ratios of which correspond exactly with those given by al-Bîrûnî, associated in this case not with an astrolabe but with a portable vertical disk sundial of a type well-known from late antiquity. The Greek inscriptions and the date of manufacture attributed to the fragments — before AD 650, probably AD 479-565 — indicate a source for the al-Bîrûnî calendar, and push back its origins by at least 500 years. Among the fragments is the front plate which bears a scale for adjustment to the latitude of the sundial, scales of solar declination for adjusting the gnomon (missing) which bore the hour-lines, and a table of the latitudes of various places (including Constantinople, Alexandria, Athens, Sicily, and Rome). It also has a circular scale of the days of the week (indicated by pictorial representations of the 'rulers' of the day), over which moved a pointer linked to the calendar. The back plate and some wheelwork are missing, but a ratchet survives, suggesting that the calendar mechanism might have been 'clicked on' each day, to provide the date for setting the gnomon. Field and Wright discuss the possible use of the calendrical mechanism to convert sundial readings by moonlight to solar time, and to predict eclipses. Remarkably, geared calendars of this type were still in use at the end of the sixteenth century.

Because of their age, the new fragments impose a revaluation of commonly held views of Byzantine science and technology. The exhibition of which they form a part covers an important and exciting theme — fourteen centuries of precision mathematical gearing for computation before the end of the European mediaeval period.□

Immunogenetics

Lymphocyte development genes and immunodeficiency disease

from S. Darling and P. Goodfellow

UNLIKE AIDS, some human immunodeficiency diseases are inherited rather than acquired. Several of these genetic diseases are linked to X-chromosome loci and are responsible for catastrophic illness[1,2]. As neither the immunoglobulin genes[3] nor the T-cell receptor genes are themselves sex linked[4-6], it has been suggested that the X-linked disease loci might include regulatory genes responsible for lymphocyte development. This hypothesis is supported by two papers in this issue[7,8], which report the isolation of an X-linked sequence that is developmentally expressed in lymphocytes and is aberrantly expressed in a mouse model for X-linked immune deficiency.

CBA/N mice have an X-linked mutation, *xid* (reviewed in ref.9), which renders them incapable of producing antibodies to soluble polysaccharides. Their immunodeficiency is caused by a B-cell defect and the mice seem to lack a specific subpopulation of mature B cells. In humans, a similar defect in antibody production is present in the X-linked Wiskott-Aldrich syndrome[10], which, unlike the mouse disease, is accompanied by defects in T-cell and platelet function. Arguing that the mouse *xid* genes affected in X-linked immune deficiencies would be expressed in lymphocytes[7], Cohen *et al.* sought *xid*-related messenger RNA by the 'subtraction' cloning technology developed for isolating the T-cell receptor genes[11,12]. Of the 15 lymphocyte-specific cDNA clones thus prepared, one clone, which is apparently T-cell specific, recognized an X-linked gene family that might contain as many as 15-20 members. These genes have been named *XLR* (X-linked, lymphocyte-regulated)[7].

Two lines of circumstantial evidence suggest that the *XLR* genes are directly related to the *xid* locus. First, genetic studies with congenic strains of mice show there to be very close linkage between the *xid* locus and the *XLR* locus. Second, detailed expression studies detect *XLR*-derived mRNA not only in T cells but also in plasma cells and other B cells at late stages of differentiation. Unlike plasmacytomas derived from normal mice, plasmacytomas from *xid* mutant mice do not contain *XLR* transcripts[8]. Independent evidence has implicated mature B cells as the target tissue for the *xid* locus[9]. So, either the *xid* locus is regulating the *XLR* locus or the two loci are identical. Final proof of identity will require demonstration of an alteration in an expressed *XLR* gene that is the result of the *xid* mutation.

The X-chromosome of eutherian mammals has been conserved during evolution[13] and the presence of an *XLR* locus in humans can be predicted confidently. It will be of obvious interest to study *XLR* expression in Wiskott-Aldrich syndrome and in the other human X-linked, immunodeficiency syndromes. Even if mutation at the *XLR* locus is not directly responsible for disease, this gene family is certain to be studied in detail. With a developmentally-regulated expression that is apparently restricted to lymphocytes, and with the possibility that different members of the gene family are transcribed at different times, the *XLR* genes may well be responsible for regulating lymphocyte development and are therefore bound to be extensively examined in the coming months □

Molecular biology

Coordination of sequence data

from Arthur M. Lesk

MANY challenges are presented by the very rapid growth of DNA and protein sequence information, the opportunities arising from advances in computer data-base management facilities, and the variety and importance of the applications of this knowledge. Not least is the challenge of coordinating the various data-banking projects.

The main archives of nucleic acid sequences, at the European Molecular Biology Laboratory Library and GenBank (a collaborative effort between Los Alamos National Laboratory and Bolt, Beranek and Newman), now contain approximately 3×10^6 bases, about half of the total of published sequences. It is estimated that another 5×10^5 bases are currently being published every six months, and the process is still accelerating.

The major archive of amino-acid sequences of proteins (now often derived from gene sequences) is the Protein Information Resource, based at the National Biomedical Research Foundation in Georgetown, Virginia, now under the direction of W.C. Barker. It contains over 3,000 entries, comprising over 6×10^5 amino-acid residues. R.F. Doolittle of the University of California at San Diego, and S. Sakakibara of the Protein Reseach Foundation, Osaka, Japan, also maintain protein-sequence data banks. In addition, numerous specialized collections exist, such as the 'Sequences of Proteins of Immunological Interest', published by the US National Institutes of Health, and the International Haemoglobin Information Center, which is directed by R.N. Wrightstone of the Medical College of Georgia.

The Protein Structure Data Bank at Brookhaven National Laboratory, directed by T.F. Koetzle, contains, in its latest release, 253 sets of atomic coordinates of proteins and nucleic acids, almost all derived from X-ray crystallography.

Current activities fall into four categories. First, there is data acquisition by an archive. The basic chain of events at present is: publication; surveillance of the literature and extraction of published data by the archiving project; quality control; editing, formating and addition to data base. Second, the archived information is distributed on magnetic tape or, if only small amounts of information are involved, over computer networks. Third, there is information retrieval, dependent on the development of computer program systems as interfaces between archived information and research projects. Finally, there are applications — for example, the search of a data base for sequences similar to the one that has been newly determined.

Those of us whose activities primarily involve applications depend, ever more crucially, on the quality, completeness and accessibility of the archives. Despite the stake of the scientific community at large in these resources, individual projects have so far borne the responsibility for collecting, maintaining and distributing the data. In contrast, many groups all over the world are developing software for information retrieval and research applications in molecular biology. To the extent that the computer programs are well described and readily distributed, they are subject to ordinary processes of natural selection from which, one may presume, the most effective will ultimately emerge in common use.

How can new generations of molecular biologists and new generations of com-

puters interact most effectively? Certain algorithms and computer programs are already mature and applicable directly to the data bases that are increasing so fast in scope. The introduction of very large, fast computers and the design of special-purpose chips will have several effects. Certain tasks, for which computational power is the limiting resource, will for the first time become feasible. The prediction of protein structures from sequences may fall into this category, although there is considerable pessimism about the adequacy of the models on which such calculations have so far been based. Faster computers will also enable some tasks, now possible but slow, to be performed interactively. This will stimulate changes in the design of algorithms and user interfaces.

The intimate combination of graphical and numerical approaches to computational molecular biology will continue to be essential. A scientist analysing a protein or nucleic acid structure will want to ask a variety of questions. The computer's response may take the form of a picture, or text, or both. When possible, the program will respond at conversational speed, to establish a dialogue between user and program. Which tasks are interactive and which must be 'spun off' into batch queues must depend on the hardware configuration.

Until now, many programs have been designed to answer descriptive questions about protein sequences or structures. To design systems that address more complicated questions, such as "What if...?" or "What is the relationship between...?", the user must be able to perform computational experiments that modify the structures. Such questions will require more powerful interactive and manipulative tools, and are likely to involve the development of expert systems.

A major problem in creating programs for a worldwide community of users is the design of supple software, adaptable to the needs of different users. A very general concept suggested some time ago may provide a useful approach. This is the 'virtual data base' — an information-access system that is self-modifiable, under user control. Each session of each user will produce an 'active state' in which certain working files of structures have been created, identified and linked, and certain groupings of elementary operations defined to create a working set of higher-level commands and procedures. It will be useful to be able to save, restore and manipulate the 'active state of the data base', or to define a 'start-up procedure' to establish, at the beginning of any session, a state tailored to the individual investigator or even to the particular project.

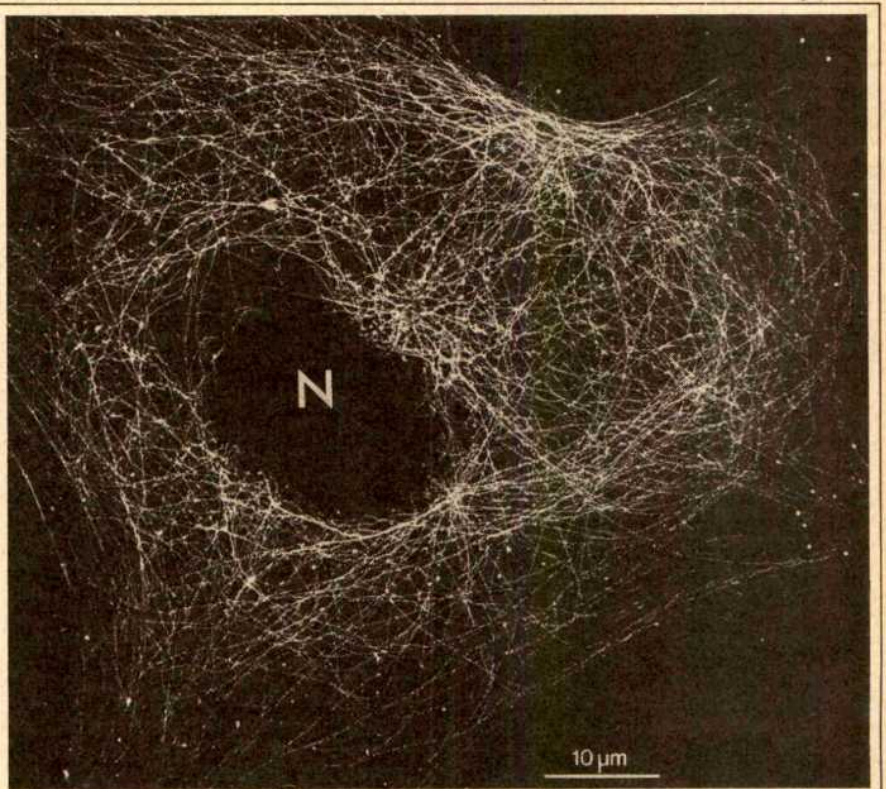
The need to establish a mechanism for coordination stems not from any dissatisfaction with the operation of information management projects currently in existence, but from the fear that Malthusian growth will saturate the channels of data acquisition, distribution, and utilization. To meet the need, CODATA (the Committee on Data of the International Congress of Scientific Unions) has established a Task Group on coordination among data banks. This group, chaired by Professor B. Keil of the Institut Pasteur, and comprising representatives from Europe, North America and Japan, has been charged with enhancing international cooperation in archiving, distribution and utilization of information related to protein sequences.

General problems that the CODATA task group plan to address include:

(1) Maintaining directories of protein sequence data bases* — including the special features of their contents or support facilities, addresses of their directors, and availability — and of computer programs for data retrieval and applications.

(2) Encouraging the establishment of guidelines and use of standardized nomenclature, and the development and general acceptance of common formats for data exchange.

(3) Establishing links between protein sequence data banks and data banks containing related information, such as nucleic acid sequences or protein structures.



(4) Fostering coordination of efforts to avoid duplication and to maximize the effectiveness of the work of different groups in different countries; for example, by identifying gaps in current programs and encouraging the development of specialized data bases when appropriate.

(5) Guiding the design of distributed material to enhance the general utility of the data banks, taking into account the needs of scientists without sophisticated familiarity with computer programming or those with access to limited computer resources. This may include the development of introductory tutorial documents for new users, or sponsoring training courses as satellite sessions of scientific meetings.

The effective coordination of the efforts of one scientist and one computer working together on a single project is primarily a technical one. The effective coordination of the efforts of many scientists, working separately on different projects, requires the personal touch as well. It is hoped that the CODATA Task Group will be able to pay due attention to both sorts of problems, and thus be able to channel the force of the information explosion in molecular biology into even more productive directions. □

*The committee would be grateful if individuals who have assembled such data banks would write to the chairman, so that the catalogue may be as complete as possible.

Arthur M. Lesk is at the Medical Research Council Laboratory of Molecular Biology, Hills Road, Cambridge, CB2 2QH, UK and is a member of the CODATA Task Group.

Microtubule network of an epithelial cell visualized by immunophotoelectron microscopy. N is the nucleus. The technique combines photoelectron imaging with immunofluorescence. For this example, the cell was first treated with a monoclonal antibody to microtubules, then with a fluorescently-labelled antibody to the first antibody, and finally with a colloidal gold-labelled antibody to the second antibody. The second stage was used to enable the technique to be compared with immunofluorescence microscopy, which has a resolution of 200 nm, whereas the resolution of immunophotoelectron microscopy is 10-20 nm. Astronomy

Supernovae and the distance scale

from Sidney van den Bergh

IN SPITE of fifty years of observational effort, the Hubble constant, which measures the size (and somewhat less directly the age) of the Universe, remains poorly determined. That is so because galaxies are extremely distant and so the 'standard candles' within them are exceedingly faint. The most luminous known standard candles are supernovae of type I (SNI) at maximum light. On page 337 of this issue, W.D. Arnett, D. Branch and J.C. Wheeler suggest that it may be possible to calibrate the maximum luminosity of SNI directly from nuclear physics. This approach bypasses the traditional and error-prone 'distance ladder' technique for the determination of the extra-galactic distance scale.

It is now generally believed that the precursors of SNI are mass-accreting carbon/oxygen white dwarfs in close binary systems. The C-O nuclear fuel in these objects will ignite if mass transfer from a binary companion pushes the total mass of the white dwarf above about 1.4 solar masses (the Chandrasekhar limit). Nuclear incineration of C-O to radioactive ^{56}Ni in an exploding white dwarf will produce 1.4×10^{51} erg per solar mass. Most of this energy ends up as kinetic energy of matter ejected during the supernova explosion.

The optical luminosity of SNI is believed to result from the trapping and thermalization of the γ rays and positrons emitted by the decay of ^{56}Ni through ^{56}Co to ^{56}Fe. Detailed hydrodynamical calculations have indicated that a C-O white dwarf that is pushed over the Chandrasekhar limit will produce 0.4 - 1.4 solar masses of ^{56}Ni. Based on these calculations and other evidence, the best estimate of Arnett *et al.* is that a SNI will produce 0.6 solar masses of ^{56}Ni and that the decay of one solar mass of ^{56}Ni would produce a maximum supernova luminosity of $(2.2 \pm 0.2) \times 10^{43}$ erg s^{-1}. They then deduce, from knowledge of supernova spectra, that the decay of 0.6 solar masses of ^{56}Ni will produce a supernova with a maximum blue magnitude, M_B(max), of -19.5, with limits of -20.4 and -19.1, corresponding to 1.4 and 0.4 solar masses of ^{56}Ni.

For SNI that have been observed to occur in elliptical and lenticular galaxies (which are generally dust-free) with redshifts larger than 3,000 km s^{-1} (for which random motions of individual galaxies can be neglected), Arnett *et al.* find that $M_B(\max) = -18.4 + 5 \log (H/100)$. Substitution of their calculated value of M_B(max) into this relation yields $H = 59$ km s^{-1} Mpc^{-1}, with upper and lower limits of 73 and 39 km s^{-1} Mpc^{-1}.

This result places Arnett *et al.* firmly on the side of those who find that the Hubble constant is small enough to accommodate the age of the Universe derived from evolutionary age models of globular cluster stars — about 1.8×10^{10} years. Those who favour larger values of the Hubble constant and smaller ages of the Universe will, no doubt, bring forward four arguments. First, incineration of a carbon/oxygen white dwarf might, in fact, produce less than 0.4 solar masses of nickel. Second, calculation of the maximum optical luminosity of SNI involves rather complex radiative transfer calculations in a supernova shell in which physical conditions are not yet perfectly understood. Third, more photoelectric observations of supernovae are required to support the assumption that all SNI have the same luminosity at maximum light. And, fourth, it is not yet entirely certain that SNI at maximum light are well represented by spherical black bodies with a temperature of 20,000 K.

As long as such uncertainties remain, the search will continue for additional calibration techniques for the extra-galactic distance scale. New urgency has been given to this search by the recent work of A.R. Walker (*Mon. Not. R. astr. Soc.* **212**, 343; 1985) which suggests that the calibration of the Cepheid distance scale may be in error by as much as 0.2 - 0.3 mag. Promising new methods for the calibration of the extra-galactic distance scale, which have not yet been fully exploited, involve observation of the light curves of distant novae (two of which have recently been discovered in the Virgo cluster galaxy M87) and comparison of the luminosity functions of distant globular systems with those of M31 and the Galaxy. Such determinations are now possible by detecting the maxima of the luminosity functions for the distant globular cluster systems surrounding NGC3379 and M87. The ultimate solution to the distance-scale problem may have to await the Space Telescope. □

Palaeontology

Scottish window on terrestrial life in the Lower Carboniferous

from Andrew R. Milner

ONE of the areas of the world that has the greatest potential for filling some of the gaps in our knowledge of the land fauna before the middle stage of the Upper Carboniferous — the Westphalian (316–296 Myr) — is the Scottish Midland Valley around and between Edinburgh and Glasgow. This area is covered by sequences of freshwater, estuarine and marine beds and there are many coal-mines and surface workings cutting through the appropriate horizons. Over the last decade, the palaeontological community has benefited greatly from sustained prospecting in that area by Mr Stanley Wood. Amongst other new sites, he has revealed an early Upper Carboniferous lake-bed assemblage of aquatic amphibians and fishes at Cowdenbeath[1,2]; an early Upper Carboniferous coastal assemblage of fishes and crustaceans at Bearsden[3]; and, as reported on page 355 of this issue, the first Lower Carboniferous assemblage of terrestrial amphibians, arthropods and plants at East Kirkton[4].

The origin and early diversification of terrestrial animal life is a vast palaeontological and evolutionary jigsaw of which we still have only a handful of pieces. The first certain terrestrial arthropods — from the Rhynie Chert and the Old Red Sandstone — are of Lower Devonian age (410 - 400 Myr), whilst the earliest known amphibians are Upper Devonian (around 360 Myr) and already show few relictual fish-like characteristics. To cover the intervening time span, some half-dozen localities have produced only fragments of information about terrestrial arthropods, although the recently reported Middle Devonian locality at Gilboa, New York State[5] shows great promise. The record has until now been little better for the early Carboniferous and it is not until the Westphalian that palaeobiologists can study comprehensive assemblages of myriapods, arachnids, insects, molluscs and vertebrates. Many groups of terrestrial animals make their first appearance as fossils in the Upper Carboniferous, in particular the winged insects and reptiles, but their very structural diversity at this time speaks for a long previous history. By the time we can see what is happening on land, many of the most interesting events have already taken place.

This, then is the significance of the East Kirkton assemblage, which is quite unlike any previously described association of Lower Carboniferous/Mississippian animals. It seems to be in a spherulite-bearing freshwater limestone laid down in shallow pools associated with hot springs[6]. No fish or benthic invertebrates are present, suggesting that the pools were generally uninhabitable. To my knowledge, only two Palaeozoic sites, both younger, show environmental similarity

to that at East Kirkton. One is an algal limestone from Hamilton in Kansas, which appears to be a very similar matrix but without the spherulites, and is of late Pennsylvanian or early Permian age. It has produced a similar association of temnospondyls, arthropods and plants[7] but differs in the presence of at least one genus of fish being present in abundance[8]. A Lower Permian freshwater limestone of rather different character from Niederhässlich, near Dresden, also has a large fauna of small amphibians and reptiles without fish[9]. A comparative study of these sites might ultimately permit us to identify common geological factors and so to predict further such localities.

The predominant amphibian in the East Kirkton assemblage bears a close resemblance to *Dendrerpeton*, a temnospondyl amphibian from the early Westphalian of Nova Scotia and Ireland[10,11]. The Nova Scotia material was found in accumulations inside hollow lycopod stumps, suggesting preservation under terrestrial conditions[12], and it is generally believed that *Dendrerpeton* was a terrestrial animal. The East Kirkton amphibian is the earliest certain temnospondyl, showing the definitive large tympanic notch and the huge openings in the palate that characterize the amphibian order Temnospondyli and its descendants — the frogs.

The few months of collecting at East Kirkton have produced intact amphibians, millipedes, eurypterids, scorpions, the earliest harvestman and much plant material, some of it three-dimensionally preserved in chert. If collecting can be extended, the material should establish whether the Euramerican Lower Carboniferous continental fauna was significantly more primitive than its Upper Carboniferous equivalent. If they were similar, the problems of early terrestrial evolution and diversification are pushed back into the Devonian.

As one of the earliest sites to produce most of the components of a terrestrial ecosystem, East Kirkton deserves comprehensive investigation. But there are difficulties in attracting funds for such projects, which makes it increasingly necessary for palaeontologists to adopt a higher public profile. Following the successful dinosaur exhibition put on by York Museum with the cooperation of the British Museum (Natural History), the Hunterian Museum of the University of Glasgow is preparing an exhibition based on Stanley Wood's remarkable collections, to include some of the East Kirkton material and the spectacular Bearsden fishes. It will travel around museums in Scotland and visit the British Museum (Natural History) in London during 1986. □

Cytoskeleton

Myosin filaments in cytoplasm

from Thomas D. Pollard

EVERY so often a quiet and contented field of research is awakened by a technical advance that at once changes the conventional wisdom and opens up new avenues for experiments. The paper by Yumura and Fukui in the 14 March issue of Nature[1] should have this impact on investigation of myosin filaments in non-muscle cells.

Myosin is best known as a filamentous protein of muscle, in which, together with actin, it plays a major role in the process of contraction by the sliding-filament mechanism. Much less is known of the function of myosin in non-muscle cells and its presence in filamentous form has been in doubt. Yumura and Fukui have shown for the first time, in either the light or electron microscope, both the extent of polymerization of myosin and the distribution of its filaments inside a non-muscle cell. Yumura and Fukui devised a simple method to visualize the filaments. The trick involves flattening live cells with an agar overlay[1] to create a more or less two-dimensional cell, in which fine details are not obscured by superimposition, and individual myosin filaments, stained with a fluorescent antibody, can be resolved in the light microscope[2]. Although only demonstrated for the cellular slime mould *Dictyostelium discoideum*, the technique should be widely applicable.

Previous work with fluorescent antibody staining of vertebrate cells in culture has established that myosin is associated with actin-containing stress fibres[3,4] and the cleavage furrow during cell division[4]. The staining was often reported to be punctate, but it has not been possible to resolve individual filaments. It has also been difficult convincingly to demonstrate myosin filaments in non-muscle cells by electron microscopy, even using antibodies[5-7]. The general view has been that myosin filaments are present, but too small to visualize by light microscopy and so few in number that they are lost to view in electron micrographs among the abundant actin filaments.

The new technique makes it possible to identify individual rod-shaped particles in cells that are stained with a fluorescent antibody to myosin. Although there is no direct proof that these particles are myosin filaments, it is very likely so, because they are the same size and shape as the filaments prepared from purified myosin.

Yumura and Fukui are able to make several important points on the basis of their observations. First, the bulk of the myosin is polymerized into filaments in the cell. Second, they confirm that myosin is concentrated in the cleavage furrow of dividing cells but add that the filaments are oriented parallel to the band of actin filaments that encircles the equator of the cell. This is the alignment expected if the myosin interacts with actin filaments in a sliding-filament mechanism to produce the force required for division. This observation strengthens arguments for such a model[4,9,10]. Third, they show that cyclic AMP, the chemoattractant for *Dictyostelium*, causes a striking transient redistribution of the myosin filaments in the cell. This change may very well be a primary step in the chemotactic response of the cell to cyclic AMP and we can look forward to learning whether it is caused by phosphorylation of the myosin[11] or some other mechanism. Finally, evidence is provided that the myosin filaments are destroyed by treatment with osmium. If this is true for myosin in other cells, it may well explain previous difficulties in demonstrating myosin filaments by electron microscopy □

Plasma physics

Fusion in magnetized plasmas

from A.C. Riviere

FUSION of light nuclei under controlled conditions promises to be a source of energy for electricity generation in the future. The latest acheivements in plasma physics and controlled nuclear fusion, many of which were reported at a recent conference*, make it clear that considerable progress has been made towards the conditions needed for 'ignition', when energy lost from the plasma is matched by energy gained from alpha particles produced by fusion reactions. In a plasma that is half deuterium and half tritium, this requires the product of nuclear density (N) and energy confinement time τ_E to exceed about 2×10^{20} m^{-3}s with the temperature above 10 KeV (10^8 K).

The main approach to fusion has been to use a magnetic field to isolate the hot plasma from the vacuum vessel wall, and the most successful magnetic field geometry is that of the 'tokamak' which combines a strong toroidal field with the field due to a toroidal current flowing in the plasma. A record value of 0.8×10^{20} m^{-3}s for $N\tau_E$ at 1.5 KeV has been achieved in the Alcator C tokamak at MIT (M. Greenwald) by injecting solid hydrogen pellets into the ohmically heated plasma. This method of refuelling raises N without causing a reduction in τ_E. In a much larger tokamak, Doublet III at San Diego, a value of 0.14×10^{20} m^{-3}s for $N\tau_E$ at 6 KeV has been achieved by combined neutral-beam heating and hydrogen-pellet refuelling in a divertor configuration. In the latter variant of the tokamak, magnetic field lines are arranged to connect the plasma edge to a remote collector rather than have the plasma edge defined by a local solid surface. This allows some control over the flow of impurity ions into the plasma and thereby a reduction in radiation losses. Experiments at ASDEX, Max Planck Institut, Garching and PDX, Princeton, also show improved performance with a divertor, particularly in allowing the maintenance of a second plasma state, called the H-mode, the τ_E of which is about a factor of 2 better than that of the more usual state. In the H-mode a steep rise in temperature occurs at the plasma edge but whether the divertor configuration is essential for this to be formed is not yet clear.

Although plasma densities and temperatures close to those required for ignition have been achieved separately at various times, it remains difficult to reach the necessary energy confinement time. Energy is lost from the plasmas in fusion experiments at an anomalously high rate compared with that expected from the effect of electron-ion collisions. Until recently the scaling of τ_E with size for tokamaks was though to vary as the square of the scale size — in particular, $\tau_E \propto a^2$, where a is the minor radius of the plasma — so larger and larger machines have been built. With results now available from a wide range of machines it is, instead, found that τ_E increases as the cube of the scale size, probably as $\tau_E \propto aR^2$, where R is the major radius of the torus (P.C. Efthimion, TFTR, Princeton). The Joint European Torus (JET), the largest tokamak built so far with $R = 2.96$ m and $a = 1.25$ m, started operating about a year ago and its performance is at least as good as was originally hoped — with τ_E about 0.8 s — and confirms the scaling with aR^2 (P. Rebut and J.G. Cordey). Plasma currents approaching 4 MA have been achieved in JET and 25 MW of additional plasma heating power is soon to be installed. This is expected to drive the plasma density and temperature up to the conditions where the power deposited by the α-particles from thermonuclear reactions will play a major role (P. Rebut).

Many new experiments have been successful in improving energy confinement. For example, injection of deuterium instead of hydrogen beams into deuterium plasmas at Doublet III and ASDEX, refuelling with pellets rather than feeding gas at the plasma boundary at Alcator C and Doublet III, addition of low Z impurity ions at ISX-B, Oak Ridge, and the use of magnetic divertors at ASDEX, Doublet III and PDX. An explanation for all these effects did not emerge at the meeting, although careful construction of the relative shape of temperature and density profiles may be one factor in minimizing the cross-field energy flow to the walls.

A clear answer is, however, emerging on the maximum value of the ratio (β) of plasma to magnetic-field pressure that can be supported by tokamaks with present techniques. Many experiments have found a β limit, independent of the form of heating, given by $\beta = \text{const} \times I/(aB)\%$, where I is the plasma current and B the value of the toroidal field at the plasma centre. The maximum value of the constant achieved in experiments at Doublet III, ASDEX, PDX, and both CLEO and TOSCA (Culham), is about 3.5, which is in quite good agreement with theoretical calculations by several groups. Beyond this value of β, the τ_E decreases rapidly or the plasma completely breaks up ('disrupts') and the plasma energy is lost. The currently observed limit to β is rather restrictive for present thermonuclear reactor designs based on the tokamak, because their values of I/aB are too small. Some re-thinking of typical reactor parameters is now needed. It should be recalled that there is a limit (the Kruskal/Shafranov limit) above which the plasma current of a tokamak cannot be increased; at higher currents the plasma usually disrupts and terminates the discharge.

The ability to contain a higher value of β is expected for the reversed field pinch (RFP) — a toroidal magnetic system in which the toroidal field is reduced relative to that of a tokamak and is comparable with the poloidal field. An RFP achieves gross stability by reversing the toroidal field in the outer plasma layers, thereby providing a region where the field-line pitch changes rapidly with radius (high shear). Although the development of RFPs is somewhat behind that of the tokamak, D.A. Baker (Los Alamos National Laboratory) reported that an electron temperature of 0.5 KeV has been achieved in the ZT-40M experiment with a plasma current of 0.4 MA; the discharge duration had been improved from a few ms to 27 ms at lower currents. Similar progress was described by P.G. Carolan (Culham) from the performance of the HBTX1A experiment. These parameters move the RFP performance towards that of tokamaks of the

*10th international conference on 'Plasma Physics and Controlled Nuclear Fusion', Imperial College, London 12-19 September 1984.

100 years ago

THE PEABODY MUSEUM AT NEW HAVEN, U.S.

THE Peabody Museum, Mr. Ingersoll informs us, stands on the corner of Elm and High Street, just without the *campus* of Yale College. The building is due to the liberality of George Peabody, who gave a sum of money, in 1866, to erect a house for the collections. Thanks to the financial prosperity of Massachusetts, the bonds for a hundred and fifty thousand dollars had greatly increased, and those set aside for the first wing of the building had become worth a hundred and seventy-five thousands dollars when the trustees began to build. With that sum they have erected one of the finest buildings, for its purpose, in the United States—a lofty and ornamental structure of red brick and cream-coloured stone, whose broad and numerous windows expresss the desire of the investigators within for all the light they can get.

The glory of the Yale Museum is its palæontological treasures, brought together wholly by Prof. O. C. Marsh. The few representatives of this collection visible in the second-floor and in the hall-ways are alone sufficient to stamp the museum as pre-eminent of this line; but they are merely an advertisement of what cellar and attic contain. It is not too much to say that, in respect to vertebrate palæontology (outside of fishes), this museum is not surpassed in the world. Where other collections own fragments or single skeletons, Prof. Marsh boasts scores or hundreds of individuals.

From *Nature* **31** 510, 2 April 1885.

same size and, according to one theoretical model, the performance of an RFP at the reactor level could exceed that of the tokamak (J.B. Taylor, Culham).

Another approach to maintaining a stable discharge at high values of plasma current is to apply a helical field of the correct helicity from outside. OHTE was built to test this hypothesis and T. Tamano (San Diego) reported that a plasma current of 0.5 MA had been maintained in OHTE for several milliseconds, giving electron temperatures of 0.5 KeV, although the desired field configuration may not have been completely established. The β values achieved by the RFPs and OHTE are around five per cent and so comparable with those from well-maintained tokamaks, but are obtained at the cost of very high power input, indicating a very short τ_E. Thus, to make their use in power stations more economically attractive, tokamaks will need higher β values, whereas the RFP and OHTE devices will need to achieve very much larger values of τ_E.

The spheromak type of configuration has affinity with the RFP but the plasma is formed as a free toroid that generates its own field so that a central conductor through the hole in the plasma doughnut is not required. M. Yamada (Princeton) reported successful generation and control of such plasmas in the S1 spheromak for a period of one millisecond at a plasma current of 0.35 MA, but with an electron temperature of only ~ 50 eV. The CTX (Los Alamos) and CCTC-I (Osaka) experiments have also generated such plasmas. Although at an early stage of development, these intriguing devices should tell us a lot about the ability of magnetized plasmas to regulate themselves by automatically relaxing and maintaining a preferred magnetic geometry.

Stellarators are an important class of field configurations which require no plasma current and entirely confine the plasma by the use of externally-generated helical fields. Heliotron E is stellarator with a highly-sheared magnetic field. It can achieve a β value of 2 per cent (K.Uo, Kyoto) and more power may take the value yet higher. Theoretical limits to β in stellarators, discussed by B.A. Carreras (Oak Ridge) and J. Johnson (Princeton), are comparable to those for the tokamak. Wendelstein VII A (Garching) is a weak shear $\lambda = 2$ stellarator in which, like Heliotron E, the plasma is heated both with neutral beams and with absorption of microwaves at the electron cyclotron resonance. In this machine, τ_E shows a strong sensitivity to the rotational transform with large dips in τ_E at rational values (H. Renner, Garching). The weak shear in this case probably allows large regions of the plasma to be interconnected because of the effect of small resonant perturbations. Overall, however, stellarators are now improving on the performance of tokamaks of comparable size, and producing τ_E values closer to the classical values expected due to collisions alone. Their value of τ_E can therefore be expected to increase as B^2, a feature not observed in tokamaks; this should be confirmed in the new devices now being constructed at Garching (WVIIAS) and at Oak Ridge (ATF). As stellarators do not require a plasma current they can be operated continuously without plasma disruption. The complex coil system required to establish the helical field is a serious drawback to stellarators but simpler coil designs, which would avoid most of the engineering problems, have been proposed.

The mirror machines, with their essentially linear geometry, are the most studied non-toroidal systems. Many of these devices, some quite large, are in operation. Very ingenious techniques are used to prevent electrons, ions and energy being lost too rapidly along the field lines. In TMX-U (Livermore) and Gamma 10 (Tsukuba), the formation of potential barriers and improved energy confinement have been demonstrated. However the plasma parameters in the centre ($N = 6 \times 10^{18}$ m^{-3}, $T = 0.2$ KeV and $\tau_E = 5$ ms) are still modest compared with toroidal systems.

The heating of plasmas above that provided by the plasma current is technically difficult and has, until recently, relied on injection of fast particle beams. Heating by the absorption of radio-frequency waves has now advanced to the point where MWs of power can be delivered to the plasma. In particular, at the electron cyclotron resonance, radiation with wavelengths of 3.6 and 5 mm and a power level of 1 MW has been used very effectively both in the Doublet III tokamak (K.H. Burrell) and in the T10 tokamak in Moscow (V.V. Alikaev). The local nature of the power deposition with this form of heating has been used to study energy transport and instability control.

There is no doubt that exciting progress in fusion research has been made in many directions, although extensive development work will be needed for economic power generation from fusion. The next significant step in fusion research is going to be the achievement of ignition and many now believe this can be done. □

New constraint on biomedical research?

THE recent prosecution of the Royal College of Surgeons, Parliamentary moves to replace the Cruelty to Animals Act (1876) and the search for *in vitro* alternatives to animal experimentation may have far-reaching effects on research in Britain. A further step in this often acrimonious debate was taken at the inaugural meeting of a new pressure group in Oxford last week.

The conference was opened by the ecologist, Dr J.H.C. Finch. He pointed out that we are, of neccessity, closely linked with all the living organisms with which we share the planet, and that we ignore this at our peril. The wholesale destruction of ecosystems, nuclear proliferation and unethical experimentation were all part of the same anti-life attitude.

Citing electrophysiological evidence that even plants, although they lack a demonstrable nervous system, are capable of responding to painful stimuli, Dr Finch said, "We should respect and revere all the organic world". In the following discussion, several participants pointed out that large and effective organizations already exist for animal rights and suggested the formation of a parallel group to protect plant life. One delegate suggested the term 'chlorophyll based organisms' or CBOs, because they felt the word 'vegetable' can carry derogatory connotations. However, after debate, the name Vegetable Liberation Front was accepted for the new organization.

On the question of agriculture, it was agreed to demand that the government support a major research initiative to develop methods for the *de novo* molecular synthesis of foodstuffs. Until this was achieved, the spraying of crops with local anaesthetic before to reaping was recommended. No agreement was reached on the ethics of genetic engineering of bacteria for mass production of nutritional protein. One faction insisted that transfection is a violation of genetic integrity, and that this constitutes a subtle form of oppression. "Even bacteria have rights", said one speaker.

There was a strong feeling expressed by many that the movement could only develop, like the Animal Liberation Front, through direct action. Tactics for harvest sabotage, ranging from the immobilization of tractors (but not by stuffing potatoes in their exhaust pipes) to the occupation of grain silos were discussed. Attacks on herbicide factories were rejected because "they could serve a useful role in culling the human predator." The international nature of the struggle was stressed by a fraternal delegate from Holland. He proposed simultaneous demonstrations throughout the EEC outside offices of Interflora, a multinational corporation accused of cruelty to flowers.

Given the urgency of the problems raised, the question of a constitution was deferred until a subsequent meeting. However, a manifesto was drawn up and agreed by the overwhelming majority of delegates. The document was engraved on tablets of stone, since the manufacture of paper was held to entail the suffering of trees, and a copy was posted through windows of the editorial offices of this and other journals.

R.A. Tatouille, University of Brussels.

Amazonian Indians and the forest environment

SIR — The statement in a recent *News and Views* article by May[1] that Amazonian Indians possess a much greater knowledge of their environment than has been commonly believed prompts me to communicate some data gathered recently that further support this contention.

The Institute of Economic Botany of The New York Botanical Garden (supported by E. J. Noble Foundation) is engaged in a four-year comparative ethnobotanical study on the question "How important is the forest to Amazonian Indians?" Much has been written on the significance of the forest to Amazonian Indians[2], but rarely has the degree of importance been quantified, and then only on a very small scale[3]. A primary goal of the project is to quantify forest utilization for 1 hectare of forest with each tribe studied.

The Chacobo Indians of Bolivia were the first to be studied[4]. Just 30 years ago, the tribe numbered only about 135 individuals who essentially lived outside the Bolivian cash economy by hunting, fishing, and subsistence agriculture in isolated forest locations along the Ríos Ivon, Benicito, Geneshuaya and Yata in the northeastern Bolivian department of Beni[5-7]. In 1955, modern missionary work with the Chacobo began and in the ensuing years a number of aspects of their culture, including their ceremonies, traditional mode of dress, and supernatural beliefs have been lost. Other aspects, including their botanical knowledge, are to a greater degree intact, at least among the elders. Although their numbers have increased to about 400, their culture is on the verge of extinction. The majority of the tribe (some 280 individuals) live today on 43,000 hectares of forested land along the Río Ivon, and on this reserve make their capital village, Alto Ivon (11°45'S, 66°02'W). The vegetation around Alto Ivon is Tropical Moist, terra firme forest. The elevation is about 200 m and the topography is level. The inventory, which was carried out in January and February 1984, was made on a strip of undisturbed forest 10 × 1,000 m. Every tree with a DBH (diameter at breast height) of 10 cm or more was marked and collected. Indigenous names and use information were obtained from Chacoba informants.

The inventory showed that 91 species, represented by 649 individual trees, occurred in the hectare. Of these, the Chacobo had uses for 75 species (82% of the total), or 619 individual trees (95% of the total). The species were grouped into five classes of utilization: food, fuel, crafts and construction, medicinal, and commercial. Some species, especially the palms, had uses in more than one category. There was only one commercially exploited species, wild rubber (*Hevea brasiliensis*), and 5 individuals of that species were found. Fourteen species (163 individuals) were used specifically as a fuel for cooking, smoking rubber, or both. Thirty-three species of trees (264 individuals) provided edible wild fruits. Twenty-three species (225 individuals) were collected that were used in crafts and construction. Finally, 23 species of trees (271 individuals) were found in the sample hectare that were used by the Chacobo for medicinal purposes.

The demonstration that the Chacoba utilize 82% of the tree species in their environment has significant implications not only for the thesis that such tribes have a profound knowlege of their forest, but also for those individuals concerned with the protection of indigenous cultures in Amazonia. For example, by combining this sort of ethnoecological information with the data being obtained from the Minimal Critical Size of Ecosystems Project (cosponsored by the Brazilian National Institute for Amazon Research and the World Wildlife Fund-US)[8], it should be possible to make more intelligent recommendations as to how much forested land must be allocated for self-sustaining Indian reserves.

Every ethnobotanical study done in Amazonia reaffirms the view that indigenous peoples are scientifically interesting, legitimate and invaluable sources of knowledge about the forest. Since one tribe differs from another in important ways, and since these people are so rapidly losing their traditional knowledge, many more studies are urgently needed. It is clear that botanical inventory involving indigenous cultures, especially in the tropics, can quite justifiably be considered the most worthwhile expenditure of time and effort for this generation of field botanists.

Electrical aspects of the snowflake crystal

SIR — The discussion "No pattern yet for snowflakes"[1] laments the inability of Vicsek's calculations[2] to reproduce the long-range symmetry observed in snowflakes. In the closing lines it is suggested that adding lattice vibrations to the calculations may be helpful. Because snowflakes are polycrystalline conglomerates there would seem to be little chance that these very short wavelength vibrations could be the mediating phenomenon for symmetry patterns that are many millimetres in size. Long wavelength vibrations have been proposed by McLachlan[3] and later by Tolansky[4]. An inherent drawback in any vibrational theory is that the details of the observed structure must be matched by a spectrum of vibrations with equivalent complexity in amplitude, frequency, and phase. In addition, a mechanism for the generation, transmission, and maintenance of these vibrations must be found.

A simpler, more direct mechanism is desirable to explain the generation of the observed cooperative behaviour in dendrite growth. I have proposed a mechanism that will provide the long-range symmetry observed based on phenomena known to be present during the snowflake development[5]. The fact that snowflakes carry an electric charge has been observed by many workers in the field. The influence of electrical fields on ice crystal growth has been observed by Zawidzki and Papée[6], as well as by Muchnik and Rud'ko in the Soviet Union. The mechanism of symmetry induction is the accretion of water vapour at those sites on the crystall that lead to the lowest potential-energy state. There are twelve symmetry axes to the common snowflake. The axis of each dendrite and the bisector of the angle between dendrites serve as reflection planes to sequentially propagate the pattern to all dendrites. Pohl has described the behaviour of dielectric materials in divergent fields and its commerical application[7].

It is interesting to note that this symmetry-inducing mechanism operates regardless of the sign of the charge of the snowflake, which may change during the growth period, or whether the snowflake is increasing or diminishing in size. It is also independent of the number of dendrites, or their length or configuration.

An examination of a collection of photographs of snowflakes, such as that of Nakaya[8], leaves one impressed by the varieties of type and detail of the symmetry achieved in snowflakes.

It would be most interesting if future calculational models of snowflake growth would include the influence of their external electrical field. Crystal growth from the liquid phase will not show phenomena dependent on an external electrical field and thus cannot duplicate the symmetry found in snowflakes. It is interesting to note that this restriction would not necessarily apply if vibrational processes were the source of symmetry.

Source of Precambrian chemical and clastic sediments

R. G. Miller & R. K. O'Nions

Department of Earth Sciences, University of Cambridge, Downing Street, Cambridge CB2 3EQ, UK

The Nd isotope composition of chemical and clastic sediments surviving from the Archaean provides no evidence for the existence of pre-4,000-Myr continental crust. Either the amounts of such crust were trivial or it was destroyed substantially by 3,800 Myr ago. Nd in major Precambrian banded iron formations was supplied largely by continental weathering, and in this respect the water masses in which they formed were analogous to the modern oceans.

THE oldest surviving vestiges of undisputed continental crust are no older than 3,800 Myr. If a substantial amount of continental crust existed before then, it must have been destroyed and essentially lost from the record. Materials eroded from such an early crust, however, might have contributed to later Archaean sedimentary systems.

Clastic and chemical sediments deposited throughout the Phanerozoic differ from those deposited earlier in Earth history in several important respects. One of the most pronounced differences concerns the apparent absence of banded iron formation (BIF) in the Phanerozoic and its abundance in the Archaean and early Proterozoic[1-3]. In the present-day weathering environment, Fe(II) is readily oxidized to Fe(III), which, because of its low solubility in normal *p*H ranges, suffers little transport. As a consequence, the concentration of Fe in sea water is far too low ($\sim 3\times10^{-6}$ g l^{-1})[4] to produce extensive Fe-rich sediments, such as those once deposited in the Hamersley Basin ($\sim 2\times10^{10}$ kg Fe annually)[5]. At the time of BIF deposition, substantially higher concentrations of Fe may have developed in sea water, possibly in response to more reducing conditions in the oceans[6].

Important changes may have occurred also in the clastic sedimentary record. For example, Taylor and colleagues[7-9] have shown that many Archaean sediments are characterized by relatively low abundances of Th and U and the absence of a Eu anomaly, whereas Proterozoic fine-grained clastic sediments possess both higher Th and U abundances and a pronounced Eu anomaly. These differences have been interpreted to reflect a fundamental change in the character of the exposed continental crust. It remains to be demonstrated, however, whether or not the Archaean clastic sediments that have surived to the present (now found largely in greenstone belts) are representative of the entire sedimentary mass as it existed at those times. If the inferred changes in the chemical character of the continents are indeed real, and not an artefact of selective sampling or sediment preservation, then their implications for the changing nature of continental differentiation are profound.

The question of the provenance of Precambrian chemical and clastic sediments and their implications for the development of the exposed continental crust are investigated here by the measurement of ^{143}Nd abundances in Precambrian sediments. The use of the ^{143}Nd natural radiogenic tracer (α-decay product of ^{147}Sm; $t_{1/2}=1.06\times10^{11}$ yr) derives from the ~40% lower Sm/Nd ratio of the continents compared with the mantle. The uniform Sm/Nd ratio of fine-grained clastic sediments, together with a complementary evolution of ^{143}Nd in the continents and the mantle, renders sediments from old and juvenile crustal sources readily distinguishable, even when these sources have been reworked and recycled in the crust[10-16]. The relationship allows an estimate to be made of the average residence time of the Sm and Nd components in the continents rather than the mantle ($=t_{CR}$, or model crustal residence age)[12]. It is well established[17-20] that the isotope composition of modern seawater Nd reflects a major input from continental sources and that this signature is acquired by chemical sediments presently forming in the ocean basins. On this basis, Precambrian BIFs are expected to acquire their Nd from the water bodies from whch they were precipitated and thereby provide information on the nature of the sources involved.

Sm–Nd isotope data are reported here for Archaean fine-grained clastic sediments from Canada and South Africa and for samples of some classic banded iron formations in Africa, Australia, North America and Greenland. Samples from a late Proterozoic (~450–800-Myr-old) BIF in Brazil have also been analysed because they seem to have all the essential features of the older and better-known examples.

Sample selection and techniques

Fine-grained clastic sediments either temporally or spatially associated with BIF occurrences have been selected both to compare the provenance of coeval chemical and clastic sediments and, together with published data, to investigate the sources of Archaean sediments in general (Tables 1, 2). Specifically included are samples from the ~3,450-Myr-old Fig Tree and Moodies Groups of the Swaziland Supergroup[21-25], the somewhat younger Pongola Supergroup (~2,950 Myr) located south of the Swaziland Supergroup[21,25,26] and the ~2,700-Myr Yellowknife Supergroup of the Canadian Northwest Territories[27-30].

Samples of oxide (±silicate, carbonate) facies banded iron formation have been selected from a number of classic BIFs deposited in the interval ~3,800–600 Myr (Table 3). The oldest samples are from the highly deformed and metamorphosed Isua supracrustal belt in south-west Greenland, formed ~3,750 Myr ago[31-38]. Typically, the iron formation at Isua consists of quartz–magnetite–amphibole–carbonate assemblages[38-40]. Other samples have been selected from the Animikie Basin of Lake Superior (the Biwabik and Negaunee BIFs, deposited ~2,000-Myr ago[41-44]), the Australian Hamersley Basin (~2,400 Myr)[45-47] and the Fig Tree/Moodies Groups[21,48] of the southern African Swaziland Supergroup (~3,450 Myr)[21,49-51]. Samples have also been included from the much younger (800–500 Myr) and less well-known BIF in the Jacadigo Series of Morro do Urucum, Brazil[2,52]. Although this deposit is about an order of magnitude smaller than, for example, the Lake Superior BIF, it seems to be typical of banded iron formations in terms of its mode of occurrence, lithological associations and mineralogy.

Samples of banded iron formation were either sawn into Fe- and quartz-rich bands and analysed separately, or otherwise treated as whole-rock samples in the normal way. All clastic sediment samples were ignited in air to oxidize organic matter. Sample digestion was carried out by conventional techniques using Teflon dissolution vessels. Sm and Nd were separated using a combination of cation-exchange and reverse-phase chromatography as described elsewhere (A. S. Cohen, R.K.O'N. and W. L. Griffin, manuscript in preparation) and mass

spectrometric techniques of isotope analysis followed those described previously[13,53]. The t_{CR} values in Tables 1 and 2 have been calculated only for those samples with $^{147}Sm/^{144}Nd \leq 0.14$.

Results

Clastic sediments. Sm–Nd isotope results for 10 samples of fine-grained clastic sediment collected from greenstone belt associations are presented in Fig. 1 and Table 1. The small range of Sm/Nd ratios ($0.101 < ^{147}Sm/^{144}Nd < 0.125$) is comparable with reported ranges for other Archaean (Table 2) and post-Archaean fine-grained clastic sediments and the particulate loads of modern rivers[11]. Taken together, these results do not show any significant changes in the Sm/Nd ratio of sediments from the Archaean through to the present day, and do not provide evidence for overall changes to more or less acid compositions. However, note that metasediments with $^{147}Sm/^{144}Nd > 0.2$ have been reported from both the Isua and the Malene supracrustal belts of south-west Greenland[54], a ratio that is substantially higher than the more normal values reported by Hamilton *et al.*[13].

The ~3,450-Myr-old Swaziland Supergroup shales have crustal residence ages of 3,500–3,600 Myr for those samples with

143Nd/^{144}Nd ratios are normalized to $^{146}Nd/^{144}Nd = 0.7219$.

* t_{CR} model ages calculated assuming mantle evolution of Nd from $\varepsilon^{4,560\ Myr}_{Nd} = 0$ to $\varepsilon^{0}_{Nd} = +10$. Thus:

$$t_{CR} = \frac{1}{\lambda} \ln\left(1 + \frac{0.513151 - {}^{143}Nd/^{144}Nd}{0.2136 - {}^{147}Sm/^{144}Nd}\right)$$

t_{CR} was calculated only for samples with $^{147}Sm/^{144}Nd < 0.14$, for which samples there is a sufficiently large Sm/Nd fractionation relative to depleted-mantle values for the model age to be reliable, assuming a closed-system evolution. ND, not done.

† ε^t_{Nd} is $10^4 \times$the deviation of $^{143}Nd/^{144}Nd$ measured in a sample from the calculated $^{143}Nd/^{144}Nd$ ratio in a CHUR at time t. ε^t_{Nd} values are calculated for the estimated stratigraphic ages of the samples. Analytical errors result in typical uncertainties in ε^t_{Nd} of $< \pm 0.6$. The effect of uncertainty in stratigraphic age on ε^t_{Nd} is illustrated graphically in Fig. 2.

$^{147}Sm/^{144}Nd$ ratios <0.14 (Tables 1, 2). Samples SL9 and SL583 yield t_{CR} ages and ε^t_{Nd} values (Table 1) inconsistent with the results obtained for the other shales: it may be significant both that the $^{147}Sm/^{144}Nd$ ratio found for SL9 is unusually high (0.177) and that SL583 differs from all other samples in containing >50% Fe_2O_3. The two phyllites from the Pongola Supergroup have $^{147}Sm/^{144}Nd$ ratios typical of fine-grained clastics and t_{CR} values of 2,900 and 3,100 Myr, respectively. For both supergroups, t_{CR} is indistinguishable from the estimated depositional age. Such results indicate that the precursors of the Swaziland and Pongola Supergroup sediments, as for most of the Archaean fine-grained clastic sediments so far analysed (refs 10, 13, 16 and Cambridge unpublished data), had an unresolvable pre-depositional crustal residence and have been derived from essentially contemporary additions to the continental crust presumably associated with the formation of the greenstone belts. However, the normal $^{147}Sm/^{144}Nd$ ratio for these sediments indicates that if volcanic additions were a major source, then they must have possessed low Sm/Nd ratios similar to calc-alkaline volcanics. One of the three metasediments from the ~2,700-Myr-old Yellowknife Supergroup yields a rather higher t_{CR} age of 3,200 Myr. Although penecontemporaneous volcanics in this greenstone belt may have been major contributors to the sediments, there seems to be a requirement for a contribution from a ≥3,000-Myr-old source. Whole-rock Rb–Sr ages of 3,100 Myr, and detrital zircons with ages ≤3,500 Myr, have been reported from the Slave craton[55–58], and sialic material identified petrologically in the Supergroup sediments[27] may be derived from this older basement.

Banded iron formation. Sm–Nd isotope results for 25 samples of BIF are presented in Table 1. These samples include normal powdered whole rocks and, to assess the effects of metamorphism and/or variable provenance of Nd, small samples (≤1 g) cut from individual bands. The $^{147}Sm/^{144}Nd$ ratios of the BIF reported here are more variable than those of fine-grained clastic sediments. It is well established that fine-grained clastic sediments of all ages exhibit a restricted range of Sm/Nd with $0.09 < {}^{147}Sm/^{144}Nd < 0.16$ (mean = 0.115)[10–16,25,54,59,60], which contrasts with the larger range for BIF reported in Table 1, where $0.08 < {}^{147}Sm/^{144}Nd < 0.23$. These results confirm the study of rare-earth elements in BIF made by Fryer[61], which yielded a range $0.09 < {}^{147}Sm/^{144}Nd < 0.19$. t_{CR} values for BIF have only been calculated for whole-rock samples with $^{147}Sm/^{144}Nd <$ 0.14, that is, Sm/Nd ratios considerably lower than model mantle values. The concentration of Nd in BIF is usually <6 p.p.m. (Table 1; ref. 61), but reaches 35 p.p.m. for one of the Lake Superior samples.

In general, the effects of metamorphism on the Sm–Nd isotope systematics of fine-grained clastic sediments are minimal, which renders information concerning their provenance readily accessible. However, the response of the Sm–Nd system in BIF to metamorphism has not been investigated previously, and, if significant, would limit severely the provenance information which can be elicited. The Isua BIF provides an ideal opportunity to assess this possibility because the Isua region was subjected to high-grade metamorphism in the upper amphibolite facies ~3,700-Myr ago, and was further metamorphosed at ~2,500 and 1,600 Myr[36,37].

Specimen 242573 (Table 1) consists of alternating 1–10-mm bands of magnetite or quartz, from which six samples were taken: two are bulk Si-rich and Fe-rich powders respectively, and four are individual adjacent fragments removed from two separate bands. The results obtained (Table 1) are inconsistent with evolution of ^{143}Nd in a reservoir with an initially uniform $^{143}Nd/^{144}Nd$ ratio that became a closed system 3,700 Myr ago. $^{147}Sm/^{144}Nd$ and $^{143}Nd/^{144}Nd$ are correlated positively and indicate mobility of Sm and Nd since 3,700 Myr ago, most probably related to the young metamorphic events identified previously in the Isua area. The perturbation of the Sm–Nd system more than 1,000 Myr after the deposition of the Isua BIF means that the computed initial $^{143}Nd/^{144}Nd$ ratios (expressed as ε^t_{Nd} values; see Table 1 legend) are not valid estimates for these samples at time t, and suggests that in general ε^t_{Nd} values calculated from larger whole-rock BIF samples may be more reliable.

Two whole-rock samples from the ~3,450-Myr-old Fig

The original grain size of the metamorphosed samples is generally unknown
* Model ages calculated as for Table 1.

Table 3 Summary geology of sampled banded iron formations

Deposit	Age (Myr)	Mass (kg)*	Thickness (m)	Area (km^2)	Notes	Refs
Isua	3,750	2×10^{12} (ore only)	200 (ore only)	—	Metamorphosed—amphibolite grade. Original size unknown, may be thickened tectonically	31, 35, 38–40
Fig Tree	3,350–3,540	10^{12}	Generally 6–40, <300	—	Low-grade metamorphism. Many small lenses in clastic sedimentary succession	21, 48, 51
Hamersley	2,300–2,500	10^{17}	<350	100,000	~Unmetamorphosed, T_{max} ~270–310 °C. Five major bands, total 1,000 m thick	45, 47
Lake Superior	2,100–1,850	10^{16}	<240	220,000	Metamorphosed chlorite to sillimanite grades at ~1,860 Myr	41–43
Urucum	~600	10^{15}	>300	>1,000	Unmetamorphosed. Contains lenses of manganese oxides, glaciogenic clastics	52

* Mass data from ref. 2.

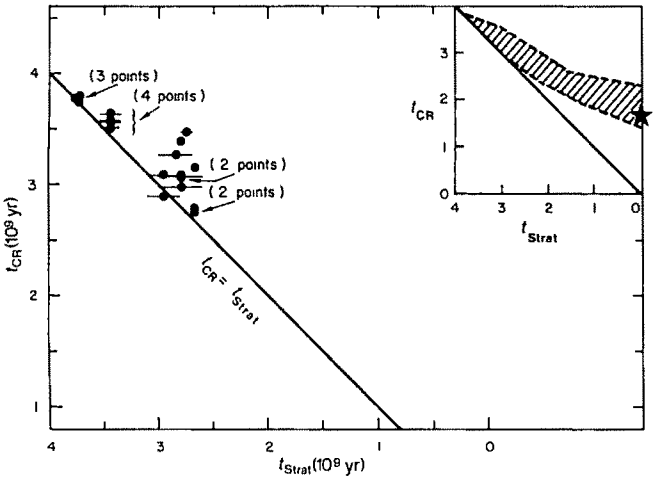

Fig. 1 Comparison of estimated stratigraphic ages (t_{Strat}) and crustal residence ages (t_{CR}) calculated from Sm–Nd isotope analyses (Tables 1, 2). Main graph, Archaean fine-grained clastic sediments. Pre-4,000-Myr contributions to these Archaean sediments cannot be discerned. Most crustal residence ages are ≤200 Myr greater than stratigraphic ages. Inset diagram shows that this relationship does not extend into the Phanerozoic; asterisk represents the mean value for fluvial fine-grained present-day clastic sediments (ref 11); shaded region, world-wide fine-grained clastics.

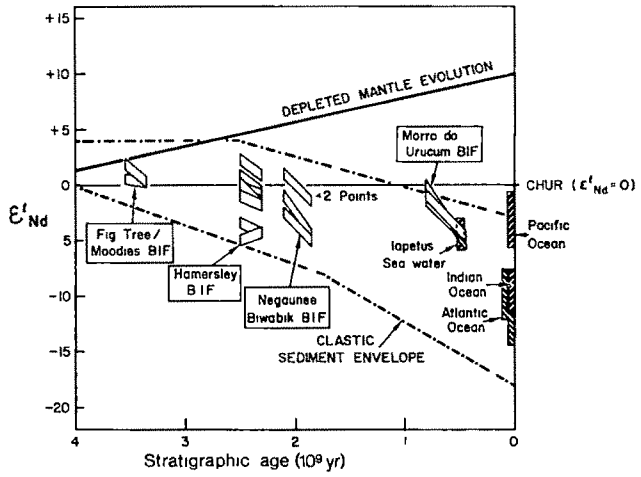

Fig. 2 Banded iron formations. ε^t_{Nd} values for samples of BIF, sea water and ferromanganese deposits from modern oceans and metalliferous sediments deposited in Iapetus. ε^t_{Nd} values are 10^4 times the deviation of initial $^{143}Nd/^{144}Nd$ ratios in a sample from those in a CHUR at time t. Note that all samples have ε^t_{Nd} in the range of coeval clastic sediments. The estimated ε^t_{Nd} of the depleted mantle excludes a dominant mantle supply of Nd into the majority of BIFs. Isua BIF samples and sample SL28B omitted (see text).

Tree/Moodies Groups BIF, which have been metamorphosed to no more than greenschist facies, yield $+0.3<\varepsilon^t_{Nd}<+1.1$ (Table 1), although a small fragment from an individual magnetite band yields a very different ε^t_{Nd} value of -8 and again suggests small-scale mobility of rare-earth elements. Six single fragments and two whole rocks from the virtually unmetamorphosed Hamersley Basin BIF yield a range of values with $-4.7<\varepsilon^t_{Nd}<+1.6$. The four whole-rock samples from the Animikie Basin BIF yield a similar range of ε^t_{Nd} values ($-3.5<\varepsilon^t_{Nd}<0$), and crustal residence ages between 2,500 and 2,700 Myr. The Morro do Urucum BIF is little metamorphosed and yields $-2.9<\varepsilon^t_{Nd}<-2.4$. The calculated ranges in ε^t_{Nd} values for a single BIF are comparable with those in sea water from a present-day ocean basin (Fig. 2), and may reflect real variations in Nd isotope composition in the water masses concerned, or the effects of post-depositional mobilization of Sm–Nd. Although the effects of metamorphic redistribution are severe on the scale of the centimetre banding in the high-grade Isua BIF, they are much less so in the lower-grade BIF. Estimates of the ε^t_{Nd} values for the water masses from which Hamersley, Animikie and Urucum BIF were deposited are based consequently on the results from whole-rock samples, but it must be conceded that the small differences between samples could reflect either initial heterogeneities in the water masses and/or post-depositional redistribution of Sm and Nd.

Chemical and clastic sediments

Note that of 18 fine-grained Archaean clastic sediments with $^{147}Sm/^{144}Nd<0.14$ for which reliable crustal residence ages can be calculated, 13 possess t_{CR} and estimated stratigraphic (t_{Strat}) ages that agree within ~200 Myr (Fig. 1). Notwithstanding the uncertainty in the correct choice of depleted-mantle models used to calculate the t_{CR} values, this observation supports the notion that the Archaean sediment source was dominated by juvenile material that had not resided as part of the continental crust for more than ~200 Myr before its erosion and deposition. No major input of relatively old crust into clastic sediments can be observed until <3,000 Myr ago. Note also that if significant quantities of substantially older crust (that is, >4,000 Myr) existed, then it had either failed to survive by 3,800–3,500 Myr ago, or else sampling to date has not included clastic sediments derived from this material, and they remain undiscovered. The latter explanation would leave open the possibility that such an ancient source supplied materials to the oceans and might occur in chemical sediments.

The $^{143}Nd/^{144}Nd$ ratios measured for modern seawater and pelagic sediments are similar to the global characteristics of the particulate load of the world's major rivers and atmospheric dusts[11,17–20]. Significant shifts to more positive ε^0_{Nd} values in Pacific sea water and ferromanganese deposits may result from a juvenile Nd component with $\varepsilon^0_{Nd}\approx 10$, such as might be supplied from the oceanic ridges or the relatively youthful continental margins around the Pacific (Fig. 2). Chemical precipitates forming in present-day oceans as manganese nodules or Fe-rich sediments associated with spreading-ridge axes[17] have acquired Nd isotope compositions in the ranges exhibited by the water bodies in which they have formed. It is a reasonable expectation, therefore, that the Precambrian iron formations will have similarly sequestered Nd from the water bodies in which they formed. Hooker *et al.*[53] have previously derived estimates for the Nd isotope composition of Iapetus sea water from ~490-Myr-old metalliferous sediments in the Southern Uplands of Scotland. Even though rare-earth mobility may have accompanied burial and diagenesis, it is possible to reconstruct the ε^t_{Nd} of the water bodies concerned from Sm–Nd analyses of BIF, as long as rare-earth immobility has prevailed on the scale of sampling from close to the time of sedimentation. It has been demonstrated above, particularly in the case of Isua, that such immobility cannot be presupposed for BIF. However, less metamorphosed BIF and/or larger scales of sampling have yielded results from which details of the provenance of their rare-earth elements can be deduced.

The principal question is whether some special source of Nd, and therefore possibly of Fe, must be invoked to explain the observations on BIF, or whether average crustal sources such as supplied the clastic sedimentary mass during most of crustal history have prevailed. This situation can be assessed using those measurements on BIF thought to yield reliable estimates of ε^t_{Nd}, by comparing them with similar observations for the clastic sedimentary mass and for modern and Iapetus ocean water (Fig. 2).

We find that ε^t_{Nd} values for the Fig Tree BIF are comparable with those of the contemporary clastic sediments from the Swazi-

land Supergroup, and close to both the chondritic uniform reservoir (CHUR) model or a depleted-mantle model at that time. Thus, the water body from which the Fig Tree BIF was precipitated seems to have received its Nd from a juvenile source whose average previous crustal residence time had not exceeded ~200 Myr. The early Proterozoic BIFs from Lake Superior and Hamersley have variable, mostly negative ε^t_{Nd} values, indistinguishable in this respect from their contemporary fine-grained clastic sediments. Similarly, the Morro do Urucum BIF has ε^t_{Nd} and t_{CR} estimates similar to those for coeval clastic sediments but which display a bias towards slightly more juvenile Nd, as does modern Pacific sea water. In all the post-Archaean BIFs, the Nd could have been derived from an analogue of modern sea water, dominated by Nd typical of that of the average exposed continental crust (as recorded by fine-grained clastic sediments) but also containing a relatively juvenile component. In no case does Proterozoic BIF show evidence for a dominantly juvenile mantle source for its Nd, so that a special source involving unusual amounts of volcanic Nd input seems to be excluded. A direct mantle source of Nd for Archaean BIF cannot be excluded, however, because of the similarity of Nd in the crustal and mantle reservoirs at that time. There is also no evidence for the derivation of a major component of BIF Nd from pre-3,500 Myr continental sources. If relatively ancient continental crust (>4,000-Myr-old) existed at times of BIF deposition, then not only is its contribution to the clastic sedimentary mass unresolvable, but any contribution it made to major water bodies was masked by inputs from more juvenile crustal sources.

The results of this investigation directly address the source of Nd in BIF and demonstrate the importance of continental sources of Nd in the oceans during the Proterozoic as well as at the present day, but leave open to conjecture the source of Fe. The Fe/Nd ratio of the continental crust and typical clastic sediments is $\sim 1.5 \times 10^3$ and in the range 10^3–10^4 for river waters, compared with 10^5 for typical Hamersley BIF containing 35% Fe and 3 p.p.m. Nd. Both Fe and Nd in Precambrian BIF could have been supplied from continental sources if estuaries offered less impediment to iron transfer from rivers to the open ocean than they do today[62–66]. Although the alternative possibility, a submarine hydrothermal source of Fe in BIF (but not for Nd) is appealing[6], it is difficult to evaluate. The Fe/Nd ratio of present-day submarine hydrothermal vent waters is poorly known but apparently high (10^5–10^6)[67–69], and this was probably always the case. Therefore, if the Fe in BIF was derived from such a source, its Nd budget would probably have been dominated by continental Nd in the surrounding sea water, consistent with observations on Nd in modern metalliferous sediments and hydrogenous deposits[7]. In the absence of a more effective tracer for hydrothermally derived iron, it is necessary to consider iron mass-balance. The submarine hydrothermal supply of Fe to the present oceans is estimated to be $\leq 10^{10}$ kg yr^{-1} (ref. 70), yet it is claimed that the Hamersely BIF alone required $\geq 10^{10}$ kg yr^{-1} (ref. 5). On the present limited evidence, a major component of Fe derived from the continents may be required to satisfy the iron mass-balance, unless the hydrothermal Fe input was overwhelmingly greater than the present one.

Conclusions

First, Archaean clastic sediments sampled so far were derived from precursors with short previous histories of crustal residence, generally no more than ~200 Myr. Second, Nd in oxide-facies BIF was derived from source material indistinguishable from that supplying the clastic sedimentary mass. A marine source with a Nd budget similar to that of modern oceans is possible for all BIFs, and a dominantly mantle source is excluded for the post-Archaean varieties. The possibility that Fe may also have been derived largely from continental weathering is not excluded. Third, the input of significant amounts of pre-4,000-Myr clastic material into post-3,800-Myr sediments is excluded by the present data. If continental crust existed in significant quantities before 4,000 Myr, then its erosion products were not incorporated into the surviving Archaean sediments and its signature occurs in neither banded iron formations nor, presumably, the water masses from which they were precipitated. Finally, the similarity throughout Earth history of Nd in coeval fine-grained clastic sediments and BIF, and hence between coeval clastic sediments and ocean water, implies that Archaean clastic sediments may be representative of contemporary crust exposed to erosion as are present-day river sediments.

We thank J. Hoefs for samples from Morro do Urucum and J. Veizer and S. L. Goldstein for useful suggestions. This research was supported by NERC and the Royal Society. Department of Earth Sciences Contribution No. 545.

Transmission and expression of a specific pair of rearranged immunoglobulin μ and κ genes in a transgenic mouse line

Sandro Rusconi*‡ & Georges Köhler†‡

* Institut fur Molekularbiologie II der Universität Zürich, Hönggerberg, CH-8093, Zürich, Switzerland
† Basel Institute for Immunology, Grenzacherstrasse 487, CH-4005 Basel, Switzerland

Two genes that code for a hapten-specific immunoglobulin M (IgM) have been introduced into the mouse germ line. The transgenic antibody represents 10-50% of the serum IgM and is expressed on the membrane of B cells. B-cell hybridoma lines show that a negative feedback inhibition of μ and κ transgenic products on the immunoglobulin heavy-chain rearrangement is possible.

EXPRESSION of immunoglobulin genes depends on an accurate rearrangement of DNA to bring several gene segments (for example, variable (V_H), diversity (D_H) and joining (J_H) for the heavy chain and V_L and J_L for the light chain) into juxtaposition[1-3]. When a complete functional reading unit is achieved in one chromosome, no further rearrangements of the second chromosome occur[4], a phenomenon termed allelic exclusion. The mechanism responsible for this peculiarity of the immunoglobulin system is poorly understood. To alter the normal rearrangement process, we introduced rearranged μ and κ genes into the germ line of Swiss albino mice. Germline transmission and tissue-specific expression occur in several genes, including immunoglobulin heavy- and light-chain genes[5-11]. Here we show transmission and expression of genes encoding a complete antigen-specific antibody molecule.

Transgenic line derivation

The plasmid, microinjected as circular DNA, contains three genes (Fig. 1*a*); rearranged μ and κ genes encoding an IgM molecule with anti-trinitrophenyl (TNP) specificity (Sp6 in ref. 12) and a bacterial gene for neomycin resistance, the latter under control of the simian virus (SV)40 promoter/enhancer. In gene transfer of B-cell myeloma lines, all the genes of this plasmid are functional[13].

DNA isolated from the tails of 5 surviving mice obtained from 13 implanted embryos was hybridized to plasmid pBR322 DNA; in one case (209/F_0, Fig. 1*b*) we obtained weak but significant hybridization. Mating the 209/F_0 male to a random-bred female yielded 10 offspring mice; the DNA from one of them (F_{1a}) hybridizes ~10-fold more strongly with pBR. Now we have obtained 40 offspring of the 209/F_0 founder, of which three carry the gene. We conclude that 209/F_0 has chimaeric spermatogonia. Male and female offspring of the F_{1a} male show ~50% segregation (a total of $31^+/54$ in matings with random-bred Swiss Albino ICR/Z, BALB/c and A/J females), as is expected if the plasmid DNA is integrated in one autosomal chromosome.

The presence of pR-HL_{TNP} sequences was checked in a Southern blot analysis where F_0, F_{1a} and F_2 tail DNA was cut with *Bgl*II and *Pst*I restriction enzymes and probed with an α_1-globin-containing plasmid. Small 2.5- and 3.5-kilobase (kb) *Pst*I fragments and a large 11-kb *Bgl*II fragment were revealed, as predicted from the behaviour of the pR-HL_{TNP} plasmid (Fig. 1*c*, bands marked T). By comparing the intensity of the 'T' bands with endogenous α-globin bands (Fig. 1*c*), we estimate that there are about one and four copies of pR-HL_{TNP} per diploid genome in 209/F_0 and F_{1a} (or F_2), respectively. This can be explained by assuming that in F_{1a} (or F_2) every tail cell carries ~4 copies of pR-HL_{TNP} (a number confirmed in B hybridomas), but in 209/F_0, an average of one cell in four has the same copy number. An analysis of B-cell hybridomas obtained from 209/F_0 lymph node cells also reveals a mosaic distribution of the transfected gene—only 2 out of 19 hybrids analysed expressed Sp6-like IgM.

Specific IgM

Serum immunoglobulin determinations in transgenic and control mice are summarized in Table 1. All transgenic mice have an elevated anti-TNP/sheep erythrocyte (SRBC) agglutination titre correlating with an elevated expression of an IgM-associated idiotypic determinant characteristic of Sp6 IgM. There are also small but significant amounts of Sp6 IgM in the F_0 serum. Quantitative radioimmunoassays, using monoclonal anti-μ for coating and radiolabelled monoclonal anti-μ or anti-idiotypic antibodies to reveal total and idiotypically positive (Id^+) IgM, showed between 140 and 420 μg Id^+-IgM and 380-1,200 μg total IgM in F_2 and M_2 (mating 2) transgenic adult sera. That is, there is a 1,000-4,000-fold increase of Id^+-IgM and a 2-5-fold increase of total IgM in transgenic F_2 or M_2 mice over their normal litter mates. The relatively small increase of total IgM may be insignificant or may be unrelated to the transfection, as similar increases do not occur in the sera of transgenic animals resulting from matings of F_{1a} with BALB/c− and A/J females. We found similar levels of protein A binding, κ-light-chain-bearing immunoglobulins (mostly IgG) and λ-light-chain levels in transgenic and control mice (Table 1). Therefore, the introduced IgM does not interfere dramatically with the normal levels of the intrinsic immunoglobulin classes.

To elucidate further the cells responsible for the high Id^+-IgM concentrations in the serum, we measured immunofluorescence of spleen cells (control values of pR-HL_{TNP}-negative litter mates in parentheses). Approximately 42% (41%) of the cells were stained with an anti-μ reagent and ~27% (3%) and 22% (2%) were double stained with TNP-bovine serum albumin and anti-idiotype, respectively. This shows that spleen B cells express membrane-bound Id^+-IgM. To confirm this expression, we

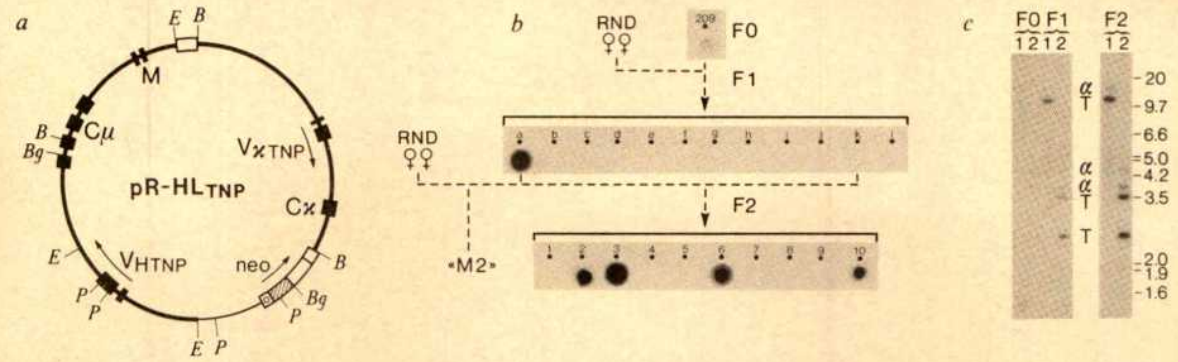

Fig. 1 Transformation of mice with pR-HL$_{TNP}$ DNA. *a*, Schematic representation of the 30-kb DNA used for microinjection, bearing both the functionally rearranged κ light-chain (V_{TNP} and $C_κ$) and heavy-chain (V_{TNP} and $C_μ$) genes, the combined products of which give rise to an antibody specific for the hapten TNP (see refs 12, 13). Thick line, mouse genomic DNA; thick bars, exons; open bars and hatched bars, SV40 and neomycin resistance sequences from the vector pSV2-neo[26]; thin line, plasmid DNA. Restriction sites: E, *Eco*RI; B, *Bam*HI; only the *Bgl*II (Bg) and *Pst*I (P) sites indispensable for the interpretation of the Southern blot presented in *c* are shown. *b*, The pR-HL$_{TNP}$ transgenic mouse line analysed by dot-blot hybridization. Thirteen fertilized eggs that survived pronuclear microinjection of 20–100 molecules of pR-HL$_{TNP}$ were implanted in the oviduct of a recipient female (see ref. 27). From the five offspring, one contained pBR-hybridizing sequences. The F_1 progeny was generated by mating mouse 209 with a random-bred female. The F_2 progeny resulted from *inter se* cross of mouse F_{1a} and the negative female F_{1k}. Repeated crosses of F_{1a} with other females of the same or different strains lead to the 'M_2' (mating 2) generation (to date, 54 individuals) which was screened either by dot or Southern blot hybridization or serum analysis (see Table 1). Conditions for dot-blot: 2 μg DNA from the tail tip[28] was spotted on nitrocellulose filters (loading buffer, 0.5 M NaOH, 1.5 M NaCl (Schleicher & Schuell); 0.45 μm; manipulations essentially as in ref. 29). ^{32}P-nick translated pBR327 (6×10^8 d.p.m. μg^{-1}) was used to probe for the presence of exogenous plasmid sequences in the genomic DNA. *c*, Determination of relative copy number and structural organization of the exogenous pR-HL$_{TNP}$ DNA in the transgenic line 209. The DNA was analysed by Southern blots (details in ref. 28). Each lane contains 1 μg of restricted genomic DNA (1, *Bgl*II; 2, *Pst*I). The hybridization probe was a pBR recombinant clone containing 2.7-kb mouse $α_1$-globin DNA[30] labelled with ^{32}P-CTP. Bands resulting from hybridization with the pBR moiety of pRHL$_{TNP}$ are indicated with T; α indicates the fragments which contain α-globin gene sequences and which serve as an internal control (see text).

made B-cell hybridomas, using as fusion partner the Sp2/0-Ag14 line[14].

B-cell hybridomas

Lipopolysaccharide (LPS)-stimulated lymph node cells of the F_{1a} mouse yields 32 of 72 wells with B-cell hybridoma growth, 30 of which contain anti-TNP-specific Id$^+$-IgM in the supernatant. Supernatants of radiolabelled cultures of independent recloned hybridoma lines were analysed by SDS and isoelectric focusing (IEF) polyacrylamide gel electrophoresis (PAGE) under reducing conditions (Fig. 2; Table 2). Only those hybrids originating from F_{1a} lymph node cells and listed in Table 2 will be discussed here in detail.

For 5 of the 11 F_{1a} hybrids analysed (for example, C5-20-21 and C5-20-22; Fig. 2) a doublet of light-chain-like bands, the weaker of which co-migrated with the Sp6 light chain, was seen after SDS–PAGE. The other six lines (for example E5-28-48 in Fig. 2) show only one strong band at the Sp6 light-chain position. To demonstrate that low concentrations of κ6 are co-expressed with newly rearranged light chains, IEF–PAGE was used. Although κ6 is not seen easily (Fig. 2), it is visible in the original autoradiogram and all lines express it in addition to a cell-line-specific light chain (Fig. 2, arrows). Light chains are easily identified in IEF–PAGE under reducing conditions as isolated bands (heavy chains always run as a series of closely spaced bands). A series of at least three bands characteristic of the Sp6 μ-heavy chain is expressed at varying intensity by all hybrids analysed except H5-35. In addition, in some hybrids, a new set of bands is seen (Fig. 2), which suggests that there is co-expression of μ-heavy chains. This co-expression was confirmed by the subclone C5-20-16, which has lost the pR-HL$_{TNP}$ DNA (not shown) together with the κ6 light chain and idiotype expression, but which synthesizes an IgM with a 20-fold lower TNP/SRBC agglutination titre (Fig. 2; Table 2). Surprisingly, the IEF-bands co-migrating with Sp6 μ-chain are preserved in this line.

Sp6-encoded RNA

To confirm the expression of Sp6 μ- and κ-chains, we performed Northern blot analysis of cytoplasmic hybridoma and Sp6 RNA using $V_μ6$ and $V_κ6$ DNA probes (Fig. 3, Table 2). All lines express the expected 2,4- and 1,2-kb RNA when probed with $V_μ6$ and $V_κ6$, respectively. To quantify the fraction of μ and κ RNA associated with $V_μ6$ and $V_κ6$ variable regions, we performed RNA dot-blot experiments. RNA was blotted on nitrocellulose filters at different concentrations and equivalent samples were hybridized to radiolabelled probes specific for the four elements $V_μ6$, μ constant region ($C_μ$), $V_κ6$ and $C_κ$. The radioactive signals were evaluated quantitatively by scintillation counting of the corresponding excised filter portions (Fig. 3). In all four hybridomas, the intensity of the $V_κ6$ signal is about one-quarter of that of Sp6, whereas the $C_κ$ signal is 1.4–4.6 times stronger than that of Sp6. Thus there is a 6–20-fold excess of $C_κ$ over $V_κ6$ in the four hybridomas analysed. We conclude

Table 1 Immunoglobulin levels of transgenic mice

Serum	TNP/SRBC agglutination titre	Idiotype (μg ml^{-1})	IgM (μg ml^{-1})	Protein A binding (mg ml^{-1})	λ ratio Id$^+$/Id$^-$
F_0	30	0.2	150	2.7	ND

Radioimmunoassays were performed by incubating serially diluted sera into antibody-coated 96-well polyvinyl plates. To measure idiotypic and IgM titres, plates were coated with a monoclonal anti-mouse μ antibody (C2-23; ref. 23), bound material was revealed with a ^{125}I-labelled anti-idiotypic monoclonal antibody (20-5; obtained from P.A. Cazenave) or a second, anti-mouse μ antibody (M41; ref. 23). Absolute amounts were obtained by comparison with purified Sp6 IgM. To measure protein A binding material, plates were coated with protein A and bound material was revealed with an anti-mouse κ monoclonal antibody (187.1; ref. 24). Reference material came from C57BL/6 serum purified on a protein A column. Relative amounts of λ-chains in sera of transgenic against normal mice were measured by coating the plates with an anti-mouse λ antibody (L22.14.4; ref. 25) and revealing bound material with the same ^{125}I-labelled antibody. Agglutination titres on TNP-coupled SRBC (TNP/SRBC) were enhanced with C2-23 antibody. ND, not done.

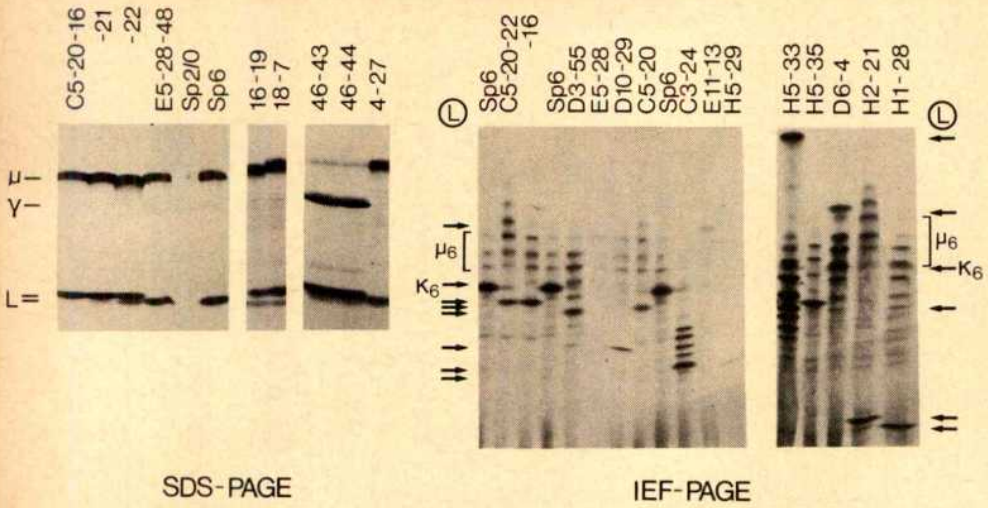

Fig. 2 Separation of reduced immunoglobulin chains. ^{14}C-labelled culture supernatants were obtained and analysed by SDS and IEF-PAGE as described previously[12]. Arrows indicate the positions of endogenously rearranged light chains (IEF-PAGE). Supernatants of lines 16-19, 18-7, 46-43, 44 and 4-27 come from a different fusion and are included to demonstrate co-expression of μ6- and γ-chains (46-43, 44) and of λ1- and κ6-chains (18-7). Antibodies from these lines are TNP- and idiotype-positive.

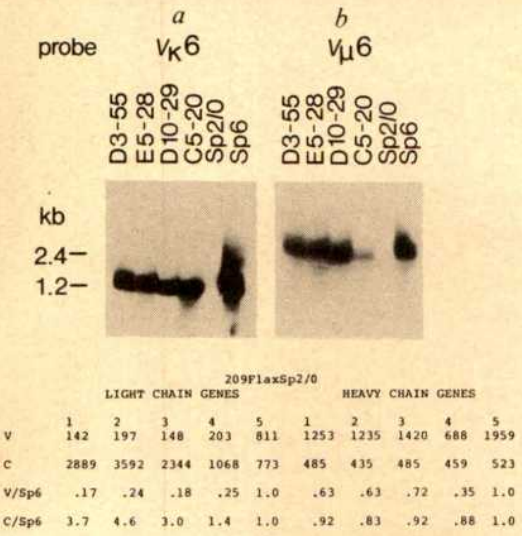
that, at least in the four hybridomas analysed, the Sp6-derived light chain is expressed at about one-tenth of the level of the second (endogenous) κ light chain. A similar analysis of V_μ6-carrying μ RNA reveals that in C5-20, ~40%, and in the other hybrids, ~75% of μ RNA might be derived from Sp6.

Heavy-chain locus rearrangements

In 7 out of 11 hybrids, there is no evidence for co-expression of a μ-chain derived from Sp6 with an endogenously derived μ-chain (Table 2). To exclude chromosome loss and to test for rearrangements in the J_H region, we hybridized the *Pvu*II- and *Xba*I-restricted DNA from all clones with a purified J_H3/J_H4 (*Bam*HI/*Eco*RI) probe (Fig. 4*a*; Table 2), with DNA from the Sp2/0 fusion partner and BALB/c liver as controls.

The Sp2/0 band is present in the DNA of all cloned hybridomas except D10-29 and H5-33. The hybridomas share the following properties: they show one strong and two weaker pR-HL_{TNP}-derived bands (dots, Fig. 4*a*); they have lost the germline J_H band of 4.8 kb (*Pvu*II) and 3.7 kb (*Xba*I) but have replaced it with one or two weaker bands of varying size. We conclude that all hybrids have retained both the chromosome carrying the pR-HL_{TNP} DNA and also either one or both chromosomes encoding the heavy-chain genes (Table 2).



DNA of the hybrid cells, cut with *Pvu*II and *Xba*I restriction enzymes, were also hybridized to two different 5′ *D*-segment probes (Fig. 4*b*; Table 2). If a heavy-chain gene is rearranged to become a complete *V–D–J* unit, the intervening DNA containing the *D* segment is deleted and can no longer be detected with 5′ *D* probes[4]. The DNA of the Sp6 line has two rearranged J_H loci[15], both of which are of the *V–D–J* type, as no band is hybridized with the *D* probes (Fig. 4*b*). The Sp2/0-fusion parent has one rearranged J_H locus in the *D–J* configuration, as most of the germline *D* bands are revealed.

The same rearranged band which has been revealed with the *J3/J4* probe at ~17 kb (*Pvu*II) is seen also with the *D* probe in H10, D3-55 and E5-28. Furthermore, as seen in the DNA cut with *Pvu*II, both *J3/J4*-containing bands of E5-28 (22 and 17 kb) and D10-29 (11 and 6.5 kb) hybridize with the *D* probe. In the E5-28 line, the 22-kb DNA (*Pvu*II) that contains *J3/J4* is not seen easily when hybridized to the *D* probe, it is better visualized in the 3.8 kb band appearing after *Xba*I digestion (the 17-kb *Pvu*II band is hidden by other bands in this digest). Thus, in the E5-28 and D10-29 lines, rearrangements have stopped at both heavy-chain loci at the *D–J* stage, and no endogenous μ-chain could be made. In Table 2 the number of *J* and *D* rearrangements are given for all hybrids analysed.

Table 2 Summary of the characterization of 209/F_{1a} B-cell hybridomas

TNP/SRBC agglutination, IgM and idiotype (Id^+) titres were measured on supernatants of the indicated lines as described for Table 1. For IEF, + indicates a band or a series of bands co-migrating with κ6 or μ6 in the presence of an endogenously rearranged second light (L) chain; SDS pattern, presence of material running at the positions of the μ and κ is indicated; κ6 indicates the presence of a second light-chain band co-migrating with the Sp6 κ-chain. Possible phenotypes are written for proteins as μ6 and κ6 representing Sp6-like IgM, μ and κ representing additional endogenous chains. Among the rearrangements at the J_H locus, *V–D–J*$^-$ indicates a putatively inactive rearrangement. In H2-21, co-expression of two heavy chains is implied by the Id^+/TNP^- phenotype and the IEF pattern, but we were unable to reveal a second J_H-containing DNA band using seven restriction enzymes. In E11-13, using seven restriction enzymes, a J_H-containing DNA band co-migrating with the germ line J_H band was found. ND, not done. * Additional bands present.

Fig. 3 Northern blots on RNA from B-cell hybridomas. Total cytoplasmic RNA (30 μg) was separated on agarose gels as described previously[31]. The filters were probed with ^{32}P-labelled pBR322 plasmid DNA ($2–8 \times 10^8$ c.p.m. μg^{-1}) containing the entire $V_\mu6$ (*a*) or $V_\kappa6$ (*b*) region. Purified fragments containing $V_\kappa6$, C_κ and $V_\mu6$ coding sequences and pABμ-1 containing C_μ (ref. 32) were used to derive the quantitative estimates listed below. Numbers 1–5 correspond to lines D3-55, E5-28, D10-29, C5-20 and Sp6, respectively.

Table 2 also shows the deduced organization of their heavy-chain loci, as well as the putative expression of endogenous heavy and light chains. A V-D-J^--rearrangement is defective for μ protein production. This is shown in D3 by the failure of μ-chain production in its subclone (which had lost the pR-HL_{TNP} DNA) (Table 2). The V-D-J^--alleles of C5-20 and C3-24 were assumed to be defective, as no evidence of a third μ-chain was found by IEF-PAGE.

Discussion

Our analysis shows that not only μ (11) and κ (9) genes separately but also both together can be introduced into the mouse germ line and expressed in an orderly fashion in B cells (IgM membrane deposition, secreted pentameric and functional IgM in serum). A third gene, *neo*, encoding neomycin resistance and under SV40 promoter/enhancer control, does not protect hybrid cells from the toxicity of the neomycin analogue G418, nor do we find *neo*-specific cytoplasmic RNA of the correct size (data not shown). It remains to be seen whether this gene is still intact in transgenic mice.

In normal mice, a cell never expresses more than one heavy-chain product or more than one light-chain product[4,16]. This allelic exclusion is thought to be necessary for effective clonal selection. Expression of the Sp6 light chain in the B hybridomas was at about one-tenth the level of the co-expressed light chain, and no inhibition of intrinsic light-chain rearrangement was observed. This may be possible because an excess of transgenic μ-chain mRNA and protein occurs in the same cell, thus mimicking the situation in normal B-cell development, where μ appear first[17].

Ritchie *et al.*[18] found that light-chain rearrangement is inhibited when both endogenous μ and the transgenic light chain are synthesized in quantities comparable with those in hybridomas derived from normal mice. Our results, on the other hand, indicate that μ-light-chain molecules in low concentrations with an excess of free heavy chains do not have a measurable effect on the process of light-chain gene rearrangement. Thus, the existence of μ light-chain molecules *per se* is not important in the regulation of the V_L-J_L joining mechanism. It does not contradict models in which the amount of light chain is essential in inhibiting rearrangement[19].

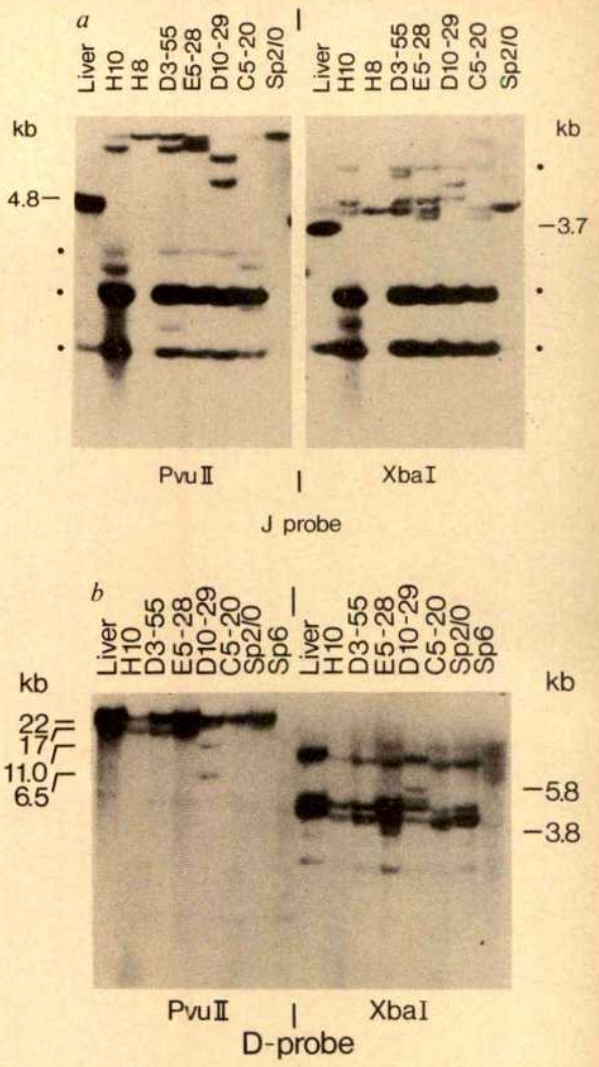

Fig. 4 Joining configuration at the J_H-locus analysed by Southern blotting. *a*, *J* probe; *b*, *D* probe. DNA (15 μg) from the indicated B-cell hybridomas was separated on 1% agarose gels and blotted onto nitrocellulose filters, which were then hybridized to nick-translated, purified DNA probes. The *Bam*HI/*Eco*RI fragment containing the J_H3/J_H4 segment was purified from a pBR322 plasmid containing all four mouse J_H segments (gift of M. Steinmetz). The J_H probe was labelled to 5×10^8 c.p.m. μg^{-1} and was used in the blot shown in *a*. The *Pst*I/*Pst*I fragment containing the 5′ *D*Sp2 segment was purified from the plasmid p4-7-5 (ref. 4; gift of M. Reth). The 5′ *D*Sp2 probe was labelled to 6×10^6 c.p.m. μg^{-1} and was used in the blot in *b*. Cutting the DNA of H10, D3-55 and E5-28 with both *Pvu*II or *Xba*I restriction enzymes reveals a common band hybridizing to the J_H probe, also visualized using the 5′ *D*Sp2 probe (*Pvu*II, 17 kb). This band is hidden in the series of bands seen between 3.8 and 5.8 kb after *Xba*I digestion. The 3.8-kb band of E5-28 DNA (*Xba*I) therefore reflects the DNA coming from the 22-kb (*Pvu*II) band, which is difficult to reproduce in the photograph. All DNA samples were also tested with DFl-16, representative of a second D′-family[4] (data not shown).

Table 3 Comparison of the rearrangement of J_H alleles of various sources

	V-D-J^+	V-D-J^-	D-J (%)	Germ line	Total
Hybrids (this paper)	3	3	12(63)	1	19
Abelson* fetal liver	1	7	18(69)	0	26
Abelson* bone marrow	9	15	7(23)	0	31
Myeloma* silent allele	—	20	12(38)	0	32

* From ref. 4.

At the heavy-chain locus, co-expression of μ-chains occurs in the C5-20 line; the variant C5-20-16, which has lost pR-HL_{TNP}, still synthesizes μ-chain (Fig. 2). Co-expression is also probable in lines H5-33, C3-24 and the γ-chain-expressing lines 46-43 and 44 (Fig. 2, Table 2). The amounts of μ6 produced are low in at least three of the four lines (H5-33, C3-24 and 46-44; Fig. 2). The amounts of μ6 produced by C5-20 could, however, be approximately equivalent to the amount of the endogenously produced μ-chain). In the λ-expressing 18-7 line, μ6 and endogenous μ are made in about equal amounts (data not shown). Nevertheless, of 11 hybrids analysed in detail, 8 express μ6 alone, and as 5 of these retain both heavy-chain loci, chromosome loss in the hybridoma could not account for loss of endogenous μ-chain production (Table 2). By isolation of Sp6/IgM-negative variants of the D3 and E11 lines we have confirmed that there is no endogenous μ production (Table 2).

One of the 19 heavy-chain loci analysed here is arrested in the germline configuration (E11-13), 12 remain in the immature *D-J* configuration and 6 complete the entire *V-D-J* coding unit, even though only 3 of them actually produce μ-chains.

Compared with Abelson murine leukaemia virus-transformed bone marrow or myeloma B-cell lines, the transgenic mouse has a high frequency of cells in the immature joining configuration (Table 3). There are two possible explanations: first, B cells that express Sp6 IgM early in their development might be stimulated by LPS and thereby hybridize earlier than normal B cells. On fusion, the rearrangement machinery is inactivated so that their DNA is frozen in the immature configuration. If, however, light-chain follows heavy-chain gene rearrangement[20-22], this possibility seems unlikely, as all hybrids express an endogenous light chain. Second, early expression of Sp6 IgM might slow down directly the process of J_H rearrangement. As most lines have made the D-J_H rearrangement, this step must be less vulnerable to inhibition, either because D to J joining precedes competence of a B cell for μ expression or because immunoglobulin chains do not greatly affect this step.

Our results agree with models postulating negative feedback control mechanisms of μ-chain on the process of J_H rearrangement[4]. They do not support a mechanism in which allelic exclusion at the heavy-chain locus is explained by elimination of B cells having two μ-producing rearrangements[19].

We thank Carla Jacot-Guillarmod and Beatrice Dolder for technical assistance, Luciana Forni for the immunofluorescence analysis and C. Steinberg for critically reading the manuscript. The Basel Institute for Immunology is supported by F. Hoffmann-La Roche & Co. Ltd.

Gravitational radiation from a solid-crust neutron star

M. Ali Alpar & David Pines

Department of Physics, University of Illinois at Urbana-Champaign, 1110 W. Green Street, Urbana, Illinois 61801, USA

The measured period derivative[1-3] for the millisecond pulsar PSR1937+21[4] is $\dot{P} \simeq 1.05 \times 10^{-19}$, whereas the present upper limit[5] for PSR1953+29[6] is $\dot{P} < 4.2 \times 10^{-17}$. For electromagnetic braking, the combination of rapid rotation with such small period derivatives requires a small ($\sim 10^8$ G) magnetic field. A natural association between rapid rotation and small magnetic field is provided by accretion spin-up scenarios[7-9]. Here we address the analogous problem for gravitational radiation. Balancing gravitational radiation power against the rate of rotational energy loss, we find that if the effective triaxiality $\varepsilon_{\rm eff}$ exceeds $\varepsilon_{\rm max} \sim 10^{-9}$, gravitational radiation alone would spin a millisecond pulsar down at a faster rate than the observed $\dot{P}$. We show that $\varepsilon_{\rm eff} \ll \varepsilon_{\rm max}$, so that gravitational radiation is not likely to play a major role in the evolution of millisecond pulsars even in the absence of damping. Damping times for precession of the solid crust are estimated to be $< 2 \times 10^3$ yr.

The energy loss rate due to gravitational radiation is

$$I\Omega\dot{\Omega} = \frac{32}{5}\frac{G}{c^5} I^2 \varepsilon_{\rm eff}^2 \Omega^6 \qquad (1)$$

where I is the moment of inertia, Ω the angular velocity and $\varepsilon_{\rm eff}$ the effective triaxiality. With P and $\dot{P}$ values similar to those for PSR1937+21,

$$\varepsilon_{\rm max} = 1.9 \times 10^{-9} \left(\frac{\dot{P}_{-19}}{I_{45}}\right)^{1/2} P(\rm ms)^{3/2} \qquad (2)$$

which seems to impose a constraint on millisecond pulsars as their rotational oblateness, $\varepsilon_\Omega \equiv I\Omega^2/4A$, is $\sim 10^7$ times larger (see Table 1).

The moment of inertia tensor of a neutron star with a solid crust is

$$\bar{I} = I_0 \left[\left(1 - \frac{\varepsilon_\Omega}{2} - \frac{b\varepsilon_0}{2}\right)\bar{e} + \frac{3}{2}\varepsilon_\Omega \hat{n}_\Omega \hat{n}_\Omega + \frac{3}{2} b\varepsilon_0 \hat{n}_0 \hat{n}_0 \right] \qquad (3)$$

where I_0 is the moment of inertia in the spherical case (no rotation), ε_Ω the 'rotational oblateness', ε_0 the 'reference oblateness' of the solid crust, b is a coefficient describing its rigidity, $\hat{n}_0$ and $\hat{n}_\Omega$ are unit vectors along the reference axis and the instantaneous angular velocity vector $\vec{\Omega}$, and $\bar{e}$ is the unit tensor[10]. Note that the triaxiality of $\bar{I}$ stems from b, the rigidity of the solid. The corresponding fluid star ($b = 0$) would have

an axially symmetric equilibrium shape. (Wagoner[11] finds that non-axially symmetric perturbations of a fluid neutron star can grow only at angular velocities 1.5–2 times faster than that of PSR1937+21. Friedman[12] finds that non-axial perturbations are stable at $P \simeq 1.5$ ms for some equations of state; this result, however, rests on the assumption that the viscosity is that appropriate for a temperature $T \sim 10^9$ K that is far too high for the quite-old millisecond pulsars. We thus conclude that the underlying fluid equilibrium shape is axially symmetric.)

The $\hat{n}_\Omega \hat{n}_\Omega$ term in $\vec{I}$ acts like the unit tensor $\vec{e}$ on the $\vec{\Omega}$ vector. The kinetic energy, T, then has the same form as that of a symmetric top with symmetry axis $\hat{n}_0$

$$T = \frac{1}{2} I_0 \left[(1 + \varepsilon_\Omega + b\varepsilon_0)\Omega_3^2 + \left(1 + \varepsilon_\Omega - \frac{b\varepsilon_0}{2}\right)\Omega_1^2 + \left(1 + \varepsilon_\Omega - \frac{b\varepsilon_0}{2}\right)\Omega_2^2 \right] \quad (4)$$

where Ω_3 is the component of $\vec{\Omega}$ along $\hat{n}_0$. Then $\hat{n}_0$, $\vec{\Omega}$ and the angular momentum $\vec{L}$ all lie in a plane, which precesses about the fixed $\vec{L}$ axis, with a precession frequency in the non-rotating frame given by[13]

$$\Omega_{pr} = \frac{L}{I_1} = \frac{L}{I_0}\left(1 - \varepsilon_\Omega + \frac{b\varepsilon_0}{2}\right) \simeq \Omega\left(1 + \frac{3b\varepsilon_0}{2}\cos^2\theta_0\right) \quad (5)$$

where θ_0 is the angle between $\vec{\Omega}$ and $\hat{n}_0$. We have a triaxial body, which acts dynamically like a symmetric top because the rotationally induced contribution to the non-sphericity of $\vec{I}$ has $\vec{\Omega}$ itself as a symmetry axis. To diagonalize $\vec{I}$, a rotation in the $(\vec{L},\vec{\Omega})$ plane is required. As the two independent vectors $\hat{n}_0$ and $\hat{n}_\Omega$ lie in this plane, so do two principal axes, $\hat{n}_1$ and $\hat{m}_1$. The $(\vec{L},\vec{\Omega})$ plane is a symmetry plane of the triaxial neutron star, which therefore precesses about $\vec{L}$ at the frequency Ω_{pr}, so that this is also the observed pulsar frequency for a pulsar beam fixed in the body frame.

The gravitational radiation power in a frequency ω is[14]

$$P(\omega) = \frac{2G\omega^6}{5c^5}\{D_{ij}^*(\omega)D_{ij}(\omega) - \tfrac{1}{3}|D_{ii}(\omega)|^2\} \quad (6)$$

where

$$D_{ij}(t) = \sum_{\omega>0} \exp(-i\omega t)D_{ij}(\omega) + \text{complex conjugate} \quad (7)$$

is the moment

$$D_{ij}(t) = M(t)_{ia}M(t)_{jb}\int d^3x' x'_a x'_b \rho(x') = M(t)_{ia}M(t)_{jb}\left(\frac{\text{tr}\, I}{2}\delta_{ab} - I_{ab}\right) \quad (8)$$

Here $\rho(x')$ is the mass density, $\vec{x}'$ is the position vector in the body frame defined by the principal axes and $M(t)$ is the instantaneous transformation matrix from the body frame $\hat{m}_1(t)$, $\hat{n}_1(t)$, $\hat{m}_1(t)\times\hat{n}_1(t)$ to a fixed frame, whose $\hat{x}_3$ axis we choose to be parallel to $\vec{L}$ (see Fig. 1). Gravitational radiation comes out in the frequencies Ω_{pr} and $2\Omega_{pr}$. Diagonalizing $\vec{I}$ to find $\hat{m}_1(t)$, $\hat{n}_1(t)$, $\hat{m}_1(t)\times\hat{n}_1(t)$ and thus the matrix $M(t)$, equations (3)–(8) yield the output power, to lowest order in $b\varepsilon_0$ and $b\varepsilon_0/\varepsilon_\Omega$

$$P(2\Omega_{pr}) \simeq \frac{72}{5}\frac{GI_0^5}{c^5}\Omega_{pr}^6 b^2\varepsilon_0^2 \sin^4\theta_0 \quad (9)$$

$$P(\Omega_{pr}) \simeq \frac{9}{10}\frac{GI_0^2}{c^5}\Omega_{pr}^6(1-\tfrac{3}{2}\varepsilon_\Omega)^2 b^2\varepsilon_0^2\cos^2\theta_0\sin^2\theta_0 \quad (10)$$

Comparing with equation (1)

$$\varepsilon_{eff}^2 = (\tfrac{3}{2}b\varepsilon_0\sin^2\theta_0)^2 + (\tfrac{3}{8}b\varepsilon_0(1-\tfrac{3}{2}\varepsilon_\Omega)\cos\theta_0\sin\theta_0)^2 \quad (11)$$

These are essentially the well-known results for a precessing axially symmetric body[15]. The rotational oblateness $\varepsilon_\Omega \hat{n}_\Omega \hat{n}_\Omega$ contributes to higher order corrections.

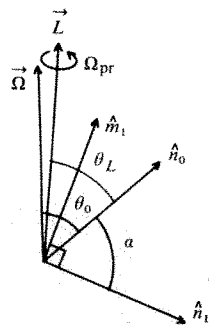

Fig. 1 The reference plane containing $\vec{L}$, $\vec{\Omega}$, $\hat{n}_0$ and the principal axes $\hat{m}_1$ and $\hat{n}_1$ of the triaxial solid-crust neutron star. This plane precesses at the rate Ω_{pr} around the angular momentum axis $\vec{L}$. We have $\theta_L = \theta_0(1 - O(b\varepsilon_0))$ and $\alpha = \pi/2 - \theta_0(1 - O(b\varepsilon_0/\varepsilon_\Omega))$.

We now consider the values of b, ε_0 and θ_0 for a millisecond pulsar that has been spun up by accretion and has been spinning down as a pulsar since the end of the accretion phase[7].

(1) The rigidity, b. A solid with oblateness, ε, and reference oblateness, ε_0, has an elastic energy $B(\varepsilon - \varepsilon_0)^2$; the oblateness increases the gravitational potential energy by an amount $A\varepsilon^2$ above the gravitational energy of a spherical star of the same mass. The coefficient b in equation (3) is defined by $b \equiv B/(A+B)$ and Pandharipande, Pines and Smith[16] have calculated A and B for a variety of neutron star models. Typical values imply $b \sim 10^{-5}$.

(2) The reference oblateness ε_0. ε_Ω is the equilibrium oblateness of a fluid body rotating at angular velocity Ω, $\varepsilon_\Omega \equiv I_0\Omega^2/4A$. The reference oblateness ε_0 is defined as the oblateness of the star at the time of formation of its solid crust, modified subsequently according to its seismic history, through plastic flow or starquakes[17,18]. If we make the conservative assumption that a neutron star spun up by accretion has, at the time of crust solidification, a period of ~ 1 s, the initial value of the reference oblateness is $\varepsilon_0(0) \simeq I_0\Omega_0^2/4A \sim 10^{-6}$. Neglecting plastic flow associated with the logarithmic creep of dislocations in the crust[18], ε_0 will change only through starquakes, which take place when $|\varepsilon_\Omega - \varepsilon_0| \simeq \theta_m$, where θ_m, the critical strain angle of the solid crust, is $\sim 10^{-4}$–10^{-5} for typical terrestrial metals, whereas for a pure Coulomb lattice, which may be a better approximation to the neutron star crust[19], it is $\sim 10^{-1}$–10^{-2}. We consider various possibilities for the evolution of ε_0: (i) $\theta_m \sim 10^{-4}$. ε_0 follows the accretion spin-up and the subsequent pulsar spin-down by a series of quakes, starting at a time when $\varepsilon_\Omega \sim 10^{-4}$, $\varepsilon_0 \sim 10^{-6}$, to its present value $\varepsilon_0 \simeq \varepsilon_\Omega \simeq 10^{-1}$(PSR1937+21) within $\theta_m \sim 10^{-4}$ of ε_Ω. Even if the reference oblateness, ε_0, were also affected by solidification of accreted material, our above conclusion would not change, as the smallness of the critical angle, θ_m, and the consequent large number of quakes during the $\sim 10^8$-yr accretion era and the subsequent and comparably long pulsar era will bring the final ε_0 close to ε_Ω. (ii) $\theta_m \sim 10^{-1}$. The reference oblateness, ε_0, may keep its initial value of $\sim 10^{-6}$ through the entire spin-up era, without reaching the condition $|\varepsilon_\Omega - \varepsilon_0| \simeq \theta_m$ for quakes. The subsequent decrease of ε_Ω, during spin-down as a pulsar, will decrease the difference $\varepsilon_\Omega - \varepsilon_0$; the present reference oblateness is $\varepsilon_0 \simeq \varepsilon_0(0) \sim 10^{-6}$. For large $\theta_m \sim 10^{-1}$, one may consider the possibility that ε_0 grows by solidification of accreted material in a way that does not follow the evolution of ε_Ω. However, the magnetic field that channels the accreted material plays a negligible part in the equilibrium energy balance, on the star's surface in comparison with rotation; $(B^2/8\pi)(4\pi R^3/3I_0\Omega^2)$ is $\sim 4\times 10^{-6}$, for $B = 10^{12}$ G and $P = 1$s, and $\sim 10^{-19}$, for $B = 10^8$ G and $P = 1.5$ ms. Furthermore, although the total amount of matter accreted is $\sim 0.1 M_\odot$, it is unlikely that this can adhere, in a metastable way, to the magnetic-field-accretion geometry and solidify to change ε_0 on timescales as long as the accretion time of $\sim 10^8$ yr; the temperature of the accreted matter is in the X-ray range through this era, so

Table 1 Values of $\varepsilon_{\rm eff}$ and ε_Ω for the millisecond and binary pulsars

Pulsar	1937+21	1953+29	1913+16	0820+02	0655+64	'Ordinary'
P(ms)	1.6	6.1	59	865	196	200
$\dot{P}(10^{-19}\,{\rm s\,s^{-1}})$	1.05*	7.8†	86	10^3	<10‡	10^5
$\varepsilon_{\rm eff}(I_{45}^{-1/2})$	3.8×10^{-9}	8×10^{-8}	8×10^{-6}	1.5×10^{-3}	$<1.6\times10^{-5}$	1.7×10^{-3}
$\varepsilon_\Omega(I_{45}/A_{53})$§	4.1×10^{-2}	2.7×10^{-3}	2.8×10^{-5}	1.3×10^{-7}	2.5×10^{-6}	2.5×10^{-6}

The last column lists $\varepsilon_{\rm eff}$ and ε_Ω for P and $\dot{P}$ values typical of an ordinary pulsar.
* Ref. 3.
† Scaling as $P^{4/3}$ from the observed value for PSR1937+21. The present observational upper limit is $\dot{P}<4.2\times10^{-17}$.
‡ Present upper limit (A. G. Lyne, personal communication).
§ A is the coefficient in the additional gravitational potential energy, $A\varepsilon^2$, of the star due to an oblateness ε with typical values $\sim10^{53}$ erg (ref. 16).

diffusion and plastic flow timescales are likely to be much shorter than 10^8 yr.

(3) The angle θ_0 between $\hat{\boldsymbol{n}}_0$ and $\hat{\boldsymbol{n}}_\Omega$. This can also change through quakes. Pines and Shaham[20] have shown that the critical value of θ_0 for such a 'θ-quake' is reached when $3\varepsilon_\Omega\varepsilon_0\theta_0^2\simeq\theta_{\rm m}^2$. The different possibilities are: (i) for $\theta_{\rm m}\sim10^{-4}$ and $\varepsilon_0\simeq\varepsilon_\Omega\sim10^{-1}$, the critical value of θ_0 is $\sim10^{-3}$. Thus, a crust with a small critical angle cannot sustain any misalignment between $\hat{\boldsymbol{n}}_0$ and $\hat{\boldsymbol{n}}_\Omega$ greater than $\sim10^{-3}$ rad. $\theta_0\simeq0$ at initial solidification and cannot exceed $\sim10^{-3}$ through the star's history. (ii) For $\theta_{\rm m}\sim10^{-1}$, $\varepsilon_\Omega\simeq10^{-1}$ and $\varepsilon_0\simeq10^{-6}$, no bound is imposed on θ_0. Starting at $\theta_0\simeq0$ at solidification, θ_0 could in principle grow arbitrarily, without inducing a 'θ-quake' in such a strong crust; but one needs an evolutionary reason for a secular increase of θ_0 and the only candidate, solidification of accreted material persisting through the 10^8-yr accretion phase, is ruled out by the considerations given above in connection with the related question of the evolution of ε_0 for a $\theta_{\rm m}\sim0.1$ crust.

(4) The effect of pinned superfluidity. The presence of a pinned superfluid will not alter the situation. Shaham[21] has investigated the effect of the pinned superfluid on the rotational dynamics of a neutron star. Pinning leads to an angular momentum $\vec{L}_{\rm f}$ that is constant in the rotating frame of the star. Shaham shows that the precession frequency in the rotating frame is of the order of $L_{\rm f}/I_0$. We find

$$\frac{L_{\rm f}}{I_0}\simeq\frac{I_{\rm p}}{I_0}(\Omega+\omega_{\rm cr})\simeq\frac{I_{\rm p}}{I_0}\Omega\simeq10^{-2}\Omega \qquad (12)$$

where $I_{\rm p}\simeq10^{-2}I_0$ is the moment of inertia of the pinned superfluid and $\omega_{\rm cr}\leqslant1$ rad s^{-1} is a critical frequency for unpinning[22,23]. The corresponding frequency in the non-rotating frame is given by

$$\Omega_{\rm pr}=\Omega\left(1+{\rm O}\left(\frac{L_{\rm f}}{I_0\Omega}\right)+\frac{3}{2}b\varepsilon_0\cos^2\theta_0\right)=\Omega(1+{\rm O}(10^{-2}))\simeq\Omega \qquad (13)$$

For the values of $L_{\rm f}$ given by neutron star pinning parameters, the gravitational radiation emitted by the neutron star deviates little from that in the absence of pinning. As $\Omega_{\rm s}$, the rotation rate of the pinned superfluid, exceeds Ω by at most the critical frequency, $\omega_{\rm cr}$, that is, $|\vec{\Omega}_{\rm s}-\vec{\Omega}|<\omega_{\rm cr}\leqslant1$ rad s^{-1}, the angle ϕ between $\vec{L}_{\rm f}$ and $\vec{\Omega}$ will be small, that is, $\phi<\omega_{\rm cr}/\Omega\sim10^{-3}$. The angle $\theta_0-\theta_L$ between $\vec{\Omega}$ and $\vec{L}$ is also small. Using $\vec{L}=\vec{I}\cdot\vec{\Omega}+\vec{L}_{\rm f}$ we find $\theta_0-\theta_L\simeq(I_{\rm p}/I_0)\phi<(I_{\rm p}/I_0)(\omega_{\rm cr}/\Omega)\sim10^{-5}$. The deviations of $\vec{\Omega}$ and $\vec{L}_{\rm f}$ from the direction of $\vec{L}$ are very limited. A comparison with our calculation for gravitational radiation in the absence of pinning shows that the only effect on $M(t)$ is to replace $O(b\varepsilon_0)$ expressions for the angle $(\theta_L-\theta_0)$ with another negligible quantity, as $\theta_L-\theta_0$ is now $(I_{\rm p}/I_0)(\omega_{\rm cr}/\Omega)\sim10^{-5}$. The lowest-order results for the gravitational radiation output are not affected, nor are our evaluations of the effective triaxiality under different assumptions for the strength of the crust solid.

(5) The expected value of $\varepsilon_{\rm eff}$. We thus conclude that the effective triaxiality, $\varepsilon_{\rm eff}$, in equation (11) is: (i) $\varepsilon_{\rm eff}\simeq\frac{3}{8}b\varepsilon_0\theta_0\simeq\frac{3}{8}\times10^{-5}\times10^{-1}\times10^{-3}\simeq4\times10^{-10}$, if $\theta_{\rm m}\sim10^{-4}$; (ii) $\varepsilon_{\rm eff}\simeq b\varepsilon_0\simeq10^{-5}\times10^{-6}\simeq10^{-11}$, if $\theta_{\rm m}\sim10^{-1}$.

(6) Intrinsic triaxiality. Intrinsic triaxiality of the solid reference figure adds a term $\eta(\hat{\boldsymbol{l}}_0\hat{\boldsymbol{l}}_0-\hat{\boldsymbol{m}}_0\hat{\boldsymbol{m}}_0)$ to $\vec{\boldsymbol{I}}$ in equation (3), where η is the 'reference triaxiality', and $\hat{\boldsymbol{l}}_0$, $\hat{\boldsymbol{m}}_0$, $\hat{\boldsymbol{n}}_0$ form an orthogonal frame. It follows that $\varepsilon_{\rm eff}$ acquires a term of the order of $b\eta$, and that $\eta\leqslant\theta_{\rm m}$. Thus, $b\eta\leqslant10^{-5}\times10^{-4}\simeq10^{-9}$, if $\theta_{\rm m}\sim10^{-4}$. In the 'no quake' case, $\theta_{\rm m}\sim10^{-1}$, η retains its initial value, $\eta=\eta(0)\leqslant\varepsilon_0(0)\sim10^{-6}$, and one finds $b\eta\leqslant10^{-5}\times10^{-6}\simeq10^{-11}$, if $\theta_{\rm m}\sim10^{-1}$. Both limits are less than the observational limit $\varepsilon_{\rm max}$.

In conclusion, our results in parts (5) and (6) above show that gravitational radiation poses no problem for the observed $\dot{P}$ values of millisecond pulsars. A consideration of damping of the solid crust's precession through its coupling to the superfluid neutron star core strengthens this conclusion. The damping time $\tau_{\rm W}$ is[24,25]

$$\tau_{\rm W}\simeq\frac{\Omega}{\Omega'_{\rm pr}}\tau\simeq(\tfrac{1}{2}b\varepsilon_0)^{-1}\tau \qquad (14)$$

where $\Omega'_{\rm pr}$ is the precession frequency in the body frame and τ is the crust-core coupling time. A recent investigation[26] of the interaction of quantized vortices in the core neutron superfluid with electrons and protons yields a coupling time $\tau_{\rm v}\simeq20P({\rm s})$. The dynamical coupling time τ for the neutron superfluid is then $\tau({\rm s})\equiv\tau_{\rm v}/x\simeq400P({\rm s})$, where x, the ratio of the number of protons to that of neutrons, is typically $\sim5\%$. From equation (14) and the above value of τ, we obtain a damping time $\tau_{\rm W}({\rm yr})\leqslant1{,}300$ yr for PSR1937+21, using $b\varepsilon_0\sim10^{-11}$, whereas with pinning, $\Omega/\Omega'_{\rm pr}\sim100$ and $\tau_{\rm w}\simeq1$ min.

We thank Fred Lamb and Naoki Iwamoto for bringing this problem to our attention, Mal Ruderman and Jacob Shaham for useful discussions and Jim Applegate and Roger Blandford for pointing out an error in our initial calculations. This research was supported by research grants NSF PHY80-25605 and NASA NSG-7653.

Hubble's constant and exploding carbon–oxygen white dwarf models for Type I supernovae

W. David Arnett*, David Branch† & J. Craig Wheeler‡

* Enrico Fermi Institute, University of Chicago, Chicago, Illinois 60637, USA

‡ Department of Astronomy, University of Texas, Austin, Texas 78712, USA

The immediate progenitor of a Type I supernova (SN I) is thought to be a mass-accreting carbon–oxygen (C–O) white dwarf in a binary system. When the mass of the white dwarf approaches the Chandrasekhar mass (1.4 $M_\odot$) the C–O nuclear fuel ignites, part of the star is incinerated to radioactive ^{56}Ni, and the thermonuclear energy completely disrupts the star. The optical luminosity results from the trapping and thermalization of the γ rays and positrons emitted by the decay of ^{56}Ni through ^{56}Co to stable ^{56}Fe. The amount of ^{56}Ni synthesized, M_{Ni}, and the corresponding peak luminosity, L_{max}, can be used with the observed Hubble diagram for SN I to determine the value of Hubble's constant, H_0. We argue here that if this model is correct, M_{Ni} is in the range 0.4–1.4 $M_\odot$, the best estimate being 0.6 $M_\odot$, and that H_0 is in the range 39–73 km s^{-1} Mpc^{-1} with a best estimate of 59 km s^{-1} Mpc^{-1}. This line of reasoning does not require knowledge of the temperature of the supernova and, therefore, is not subject to the uncertainties associated with attempts to determine supernova luminosities and distances by the Baade method[1]. It relies on the physical correctness of the model, which is subject to independent tests.

For SN I, analytical solutions[2] for the light curves predict that at the time of maximum bolometric luminosity, L_{max} is equal to the instantaneous decay luminosity of the ^{56}Ni and ^{56}Co independent of the opacity and the precise form of the deposition function. Numerical calculations confirm the insensitivity of the peak bolometric luminosity to opacity[3] and show that the radiated power is equal to the rate of radioactive deposition at bolometric maximum to within 15%. The time between explosion and maximum luminosity in the B-band is observed to be 15 ± 2 days (ref. 4), which implies that maximum bolometric luminosity occurs at 17 ± 2 days (ref. 3). It follows that $L_{max} = 2.2 \pm 0.2 \times 10^{43}\ M_{Ni}$ erg s^{-1} $M_\odot^{-1}$. This is a significant simplification; at times away from maximum luminosity, the luminosity is affected by the opacity of the matter and hence its composition, thus introducing additional uncertainty.

For an exploding white dwarf, a rigorous and extreme upper limit on M_{Ni} is 1.4 $M_\odot$. Optical spectroscopy of extragalactic SN I[5] and X-ray spectroscopy of remnants of SN I in our Galaxy (C. Sarazin, personal communication) show that the ejected matter contains synthesized elements such as silicon and sulphur, and unburned carbon (presupposing the model) and oxygen in addition to iron-peak elements so the entire 1.4 $M_\odot$ cannot be ^{56}Ni.

A lower limit on M_{Ni} follows from the observed kinetic energy and velocities. To an excellent approximation the kinetic energy of ejected matter is the difference between the thermonuclear energy released and the net binding energy of the white dwarf. Nuclear conversion of C–O to ^{56}Ni produces 1.4×10^{51} erg $M_\odot^{-1}$. Detailed hydrodynamic calculations[6,7] for exploding white dwarfs show, however, that less than half of the material actually becomes ^{56}Ni. Some of the energy release is associated with the production of other elements. Calculations, which treat the nonradial flow in a crude way but the nucleosynthesis in detail[8,9], give a similar result; 3.1×10^{51} erg of nuclear energy is released per solar mass of synthesized ^{56}Ni. The net binding energy is 0.5×10^{51} erg, so $E_\kappa 2/10^{51} = 3.1\ M_{Ni} - 0.5$. Note that E_κ depends strongly on M_{Ni} for $M_{Ni} < 0.4\ M_\odot$, and goes to zero as M_{Ni} approaches 0.16 $M_\odot$. Numerical simulations[3] have shown that at least 0.4 $M_\odot$ of ^{56}Ni (corresponding to 0.74×10^{51} ergs of nuclear energy) must be synthesized to account for velocities at the photosphere, inferred from optical spectroscopy[5], of 10,000–12,000 km s^{-1} during the first few weeks after maximum light. We regard $M_{Ni} > 0.4\ M_\odot$ as a conservative lower limit because, in the context of the model, it imples that, although another $\approx 0.4\ M_\odot$ is burned to other species, 0.6 $M_\odot$ of C–O is not burned at all. Smaller amounts of C–O in the ejecta are indicated by both the optical[5] and X-ray spectroscopy (C. Sarazin, personal communication). Taking all available evidence, we consider the best current estimate for the nickel produced to be $M_{Ni} = 0.6\ M_\odot$ (1.86×10^{51} ergs of nuclear energy). Thus, our best estimate of L_{max} is 1.3×10^{43} erg s^{-1}, with limits of 3.05×10^{43} (1.4 $M_\odot$ Ni) and 0.87×10^{43} erg s^{-1} (0.4 $M_\odot$ Ni).

The transformation from bolometric luminosity L_{max} to absolute blue magnitude M_B, required for comparison with observed SN I, is straightforward[3,10]. At the time of maximum luminosity, the observed flux distribution for $\lambda > 0.4\ \mu$m resembles that of a 20,000 K blackbody, while only a small fraction of the flux is emitted at $\lambda < 0.4\ \mu$m (ref. 5). When the model luminosity is distributed in this way, we find $M_B = 19.23 - 2.5 \log L_{max}/10^{43}$. Note that the colour temperature enters only as a convenient parameter for distributing the model luminosity over wavelength, and that the relation between L_{max} and M_B depends only weakly on its value. An understanding of the atmospheric processes which determine the flux distribution is not required for our present purpose. We simply use the observed distribution. The best estimate of M_B is -19.5, with limits of -20.4 and -19.1.

The predicted values of M_B are related to H_0 through the observed dependence of the apparent magnitudes of SN I on the redshifts of their parent galaxies. To bypass the issues of interstellar extinction in the parent galaxies and departures from ideal Hubble flow in the local Virgo supercluster we restrict our attention to SN I in elliptical and lenticular galaxies having recession velocities >3,000 km s^{-1}. There are six such SN I (including three in the Coma cluster) having well-determined apparent magnitudes at peak. After allowing for interstellar extinction in our Galaxy[11], using $M_B = M_{pg} + 0.3$ (ref. 12) when necessary, and allowing for a difference of 0.1 magnitude between the apparent blue magnitude at 15 (optical peak) and 17 days (bolometric peak) after the explosion we find $M_B = -18.4 \pm 0.2 + 5 \log(H_0/100)$, in good agreement with calibrations done previously[12,13]. The predicted values of M_B then correspond to a best estimate of $H_0 = 59$ km s^{-1} Mpc^{-1}, a rigorous lower limit of 39 km s^{-1} Mpc, and a conservative upper limit of 73 km s^{-} Mpc^{-1}. The uncertainties in the time of bolometric maximum and in the absolute magnitude calibration give an r.m.s. uncertainty for each of these values of $\leq 10\%$. This is small compared with the uncertainty associated with the ejected nickel mass.

The arguments expressed above can be summarized in the relationship $H_0 = 46 \pm 4\ M_{Ni}^{-1/2}$ km s^{-1} Mpc^{-1}. We have argued that values of H_0 in excess of about 73 km s^{-1} Mpc^{-1} would require $M_{Ni} < 0.4\ M_\odot$, and that the corresponding kinetic energy and velocities would be too small. A high value of H_0 could be reconciled with exploding white dwarfs as SN I if only a portion of the matter is ejected, with the remainder forming a neutron star. Kinetic energy and nickel mass would become uncoupled because some kinetic energy would come from the binding energy of the neutron star. Studies of galactic remnants of SN I indicate, however, that there is no evidence that neutron stars are left behind[14,15].

The discussion above has rested on the tacit assumption that all SN I have identical properties. Observationally, this is a tenable proposition, except for a few supernovae (SN 1885a, 1954a, 1962l, 1964l, 1980i, 1983n) which have shown definite spectroscopic and/or photometric peculiarities, and theoretically it is attractive because the ignition of carbon necessarily occurs near the Chandrasekhar mass. There is some evidence, however, for a correlation between peak absolute magnitude and the rate of decline of the initial post-peak light curve[16–18].

If the peak luminosities of normal SN I do cover a finite range, the values of H_0 quoted here are likely to be too high, because, owing to observational selection effects, the SN I beyond the local supercluster will tend to be more luminous than the much nearer SN I, such as 1972e in NGC5253 and 1981b in NGC4536, whose characteristics are used to estimate the nickel mass.

These results are entirely independent of methods for determining distance to Type II supernovae, which involve an understanding of the atmosphere and spectral line-forming regions. In addition, although model dependent, this method is independent of the traditional 'distance ladder' approach.

Hydrated interplanetary dust particle linked with carbonaceous chondrites?

Kazushige Tomeoka & Peter R. Buseck

Departments of Geology and Chemistry, Arizona State University, Tempe, Arizona 85287, USA

Recent mineralogical and geochemical studies of interplanetary dust particles (IDPs) provide convincing evidence that they contain materials that formed in the early solar nebula. Some chondritic IDPs contain hydrated phases and may be related to CI and CM carbonaceous chondrites. However, detailed mineralogical data of the hydrated IDPs are extremely limited. We report here the results of transmission electron microscope (TEM) observations of a hydrated IDP containing Fe-, Mg-rich smectite or mica as a major phase. The sheet silicate appears to have formed by alteration of anhydrous silicates. Fassaite, a Ca, Al clinopyroxene, also occurs in this particle, and one of the crystals exhibits solar-flare tracks, clearly indicating that it is extraterrestrial. Fassaite is a major constituent of the Ca-, Al-rich refractory inclusions (CAIs) found in the carbonaceous chondrites. Its presence in this particle, therefore, suggests that there may be a link between hydrated IDPs and carbonaceous chondrites in the early history of the Solar System.

The hydrated particle studied here, 'Skywalker' (NASA no. r21-M3-5A), was collected from the upper stratosphere by NASA U-2 aircraft. Sandford *et al.*[1] showed that its infrared spectrum contains absorption bands at ~3,400 cm^{-1} and ~1,600 cm^{-1}, which they attributed to the presence of water. A large deuterium enrichment, measured with the ion probe[2], provides strong evidence that Skywalker contains a unique isotope record, and this was probably established in or before the early Solar System[3]. Thus, Skywalker is of great interest, particularly regarding its relations to the carbonaceous chondrites.

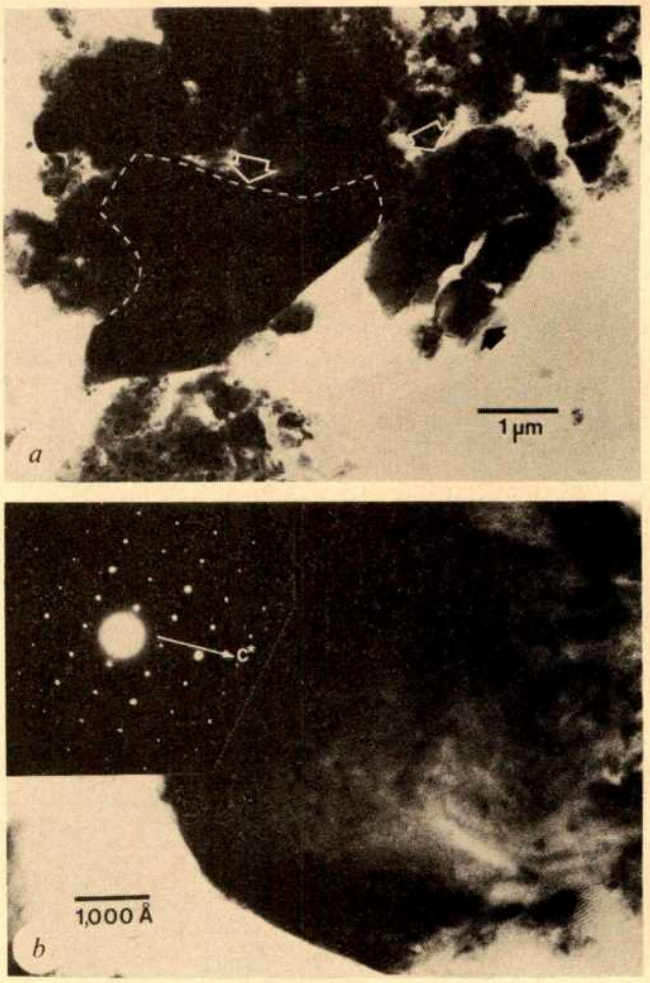

Fig. 1 *a*, Fassaite grains (indicated by arrows) in one of the Skywalker aggregates; surrounding them are clusters of the smectite/mica and pyrrhotite grains. The clustered grains on the right are apparently broken fragments of a single grain, ~2.5 μm in diameter. The grain on the left is the largest single crystal found in Skywalker. *b*, Magnified image of the fassaite grain indicated by a small arrow in *a*, showing solar-flare tracks. The SAED pattern in the inset, obtained from the same grain, corresponds to [101] of clinopyroxene.

TEM imaging and chemical analysis by energy-dispersive X-ray spectroscopy (EDS) have been used to study the microstructures and compositions of the constituent minerals of Skywalker. Structural identifications were made by selected-area electron diffraction (SAED), convergent-beam electron diffraction and high-resolution imaging. The analyses of individual grains were performed using a finely focused beam (~800 Å in diameter). Quantitative data were derived for silicate minerals using thin-film X-ray microanalysis[4]. Details of the experimental procedure and reference standards for the quantitative analyses are given elsewhere[5].

A portion of Skywalker was placed on a carbon film, then mounted on a TEM grid. The sample on the grid consists of six aggregates, ranging from 4 to 7 μm in size, and numerous finer grains. EDS spectra, obtained using a broad beam, show that the particle falls into the chondritic subset of Brownlee[6]. Based on its infrared spectrum, Sandford *et al.*[1] placed Skywalker in the small group of hydrated IDPs.

The pyroxene occurs as a cluster of five grains that range up to 4.5 μm in diameter; four are apparently broken fragments of a single crystal (Fig. 1). Their SAED patterns correspond to clinopyroxene. The grains contain major amounts of Mg, Al

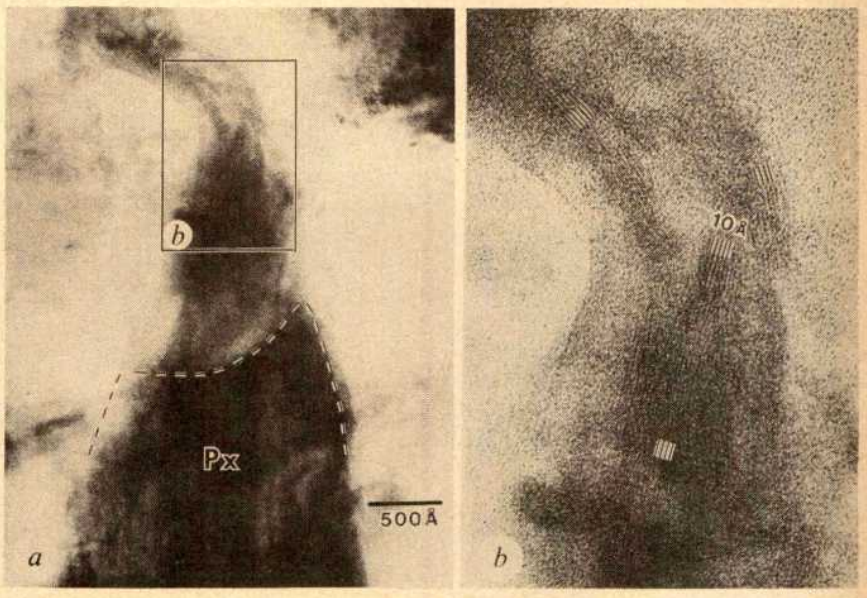

Fig. 2 *a*, A low-magnification TEM image of an enstatite grain. Above the dashed line is the phyllosilicate. *b*, A high-resolution TEM image of the phyllosilicate from the boxed area in *a*, displaying the curved fringes with ~10-Å spacing.

and Ca and minor amounts of Ti, Cr and Fe (Table 1). Using the ratios given in Table 1, the proposed chemical formula is $[Ca_{0.7}Mg_{0.8}Al_{0.4}](Si_{1.8}Al_{0.2})O_6$, which is consistent with its designation as fassaite[7].

Fassaite occurs in both terrestrial and meteoritic samples. It is of special interest in meteorites because it is a major constituent of the primitive and refractory CAIs that are prominent in the CV carbonaceous chondrites[8,9] and that also occur in the CM[10,11] and ordinary chondrites[12,13]. Fassaite in CAIs shows a wide range of Al content (9–22 wt% Al_2O_3) and Ti content (2–18 wt% TiO_2), but it is commonly enriched in both these elements and depleted in Fe relative to fassaite in terrestrial samples[8,9]. The fassaite in Skywalker is aluminous, low in Ti and Fe (Table 1). The high Al and low Fe contents distinguish Skywalker fassaite from terrestrial fassaite[7]. Furthermore, the limited compositional similarity between the fassaite in the IDP and the carbonaceous chondrites raises at least the possibility that there is a genetic relationship between the two occurrences.

Fossil nuclear tracks occur in one of the fassaite grains (Fig. 1*b*). Such tracks in IDPs were first described from olivines and pyroxenes in ordinary chondritic IDPs by Bradley *et al.*[14]. The tracks probably resulted from IDP exposure to solar cosmic rays before capture by the Earth[15]. Laboratory experiments show that nuclear tracks in silicates can be annealed by pulse (2 s) heating to 600 °C (ref. 15). Thus, the tracks provide evidence both that fassaite in Skywalker is extraterrestrial and that it has not been severely heated since track implantation, even during atmospheric entry.

† Na, K and Mn are excluded.

Both Skywalker and Low-Ca[5], which is the only other hydrated IDP that has been studied by TEM, contain a mineral that has a distinctly layered appearance in TEM images. It contains Si, Fe, Mg, Al and has an interlayer spacing of 10–12 Å; average cation/silicon ratios for the mineral in Skywalker are 0.30 (Mg/Si), 0.28 (Fe/Si) and 0.08 (Al/Si), and for the mineral in Low-Ca they are 0.49 (Mg/Si), 0.26 (Fe/Si) and 0.09 (Al/Si). Based on these criteria, plus the infrared evidence for hydrated phases, we[5] have identified it in Low-Ca as an Fe-, Mg-rich smectite or mica, which we hereafter call smectite/mica. The same identification also holds for Skywalker.

Skywalker also contains small amounts of an Fe-rich phyllosilicate; average cation/silicon ratios are 0.21 (Mg/Si), 0.79 (Fe/Si) and 0.09 (Al/Si). Both smectite/mica and Fe-rich phyllosilicate occur as aggregates of poorly crystalline, fine fibres similar to those illustrated in ref. 5. As in Low-Ca, smectite/mica occurs in close association with Fe–Ni sulphides, mostly rounded grains (~1,000 Å) of nickeliferous pyrrhotite, whereas the Fe-rich phyllosilicate is rarely associated with sulphides. The Fe-rich phyllosilicate exhibits weak powder electron-diffraction lines at ~4.6, ~2.6 and ~1.5 Å. Its poor crystallinity hindered further structural characterization. Smectite/mica in Skywalker is commonly more Fe-rich and Mg-poor and shows a wider variation in these elements than that in Low-Ca. This variation probably results from partial mixing with the Fe-rich phyllosilicate.

Platelets of enstatite pyroxene and forsterite olivine, containing up to a few atomic per cent of Fe and ranging in diameter from 0.1 to 3 μm, are common in Skywalker, in marked contrast to Low-Ca, where olivine is rare and no pyroxene was found[5]. Olivine platelets commonly display strong strain-field contrast and complex patterns of Moiré fringes. Pyroxene platelets typically show a disordered stacking of clino- and ortho-enstatite[16,17] (Fig. 3). Similar platelets of olivine and pyroxene are also common in anhydrous IDPs[18,19]. Bradley *et al.*[19] suggested that such pyroxene platelets are probably primary vapour-phase condensates that could have formed in the primitive solar nebula.

Figure 2 shows a grain consisting of Mg–Fe pyroxene at one end and phyllosilicate at the other. The high-resolution TEM image (Fig. 2*b*) displays curved fringes characteristic of phyllosilicate and having a spacing of ~10 Å. EDS analysis indicates

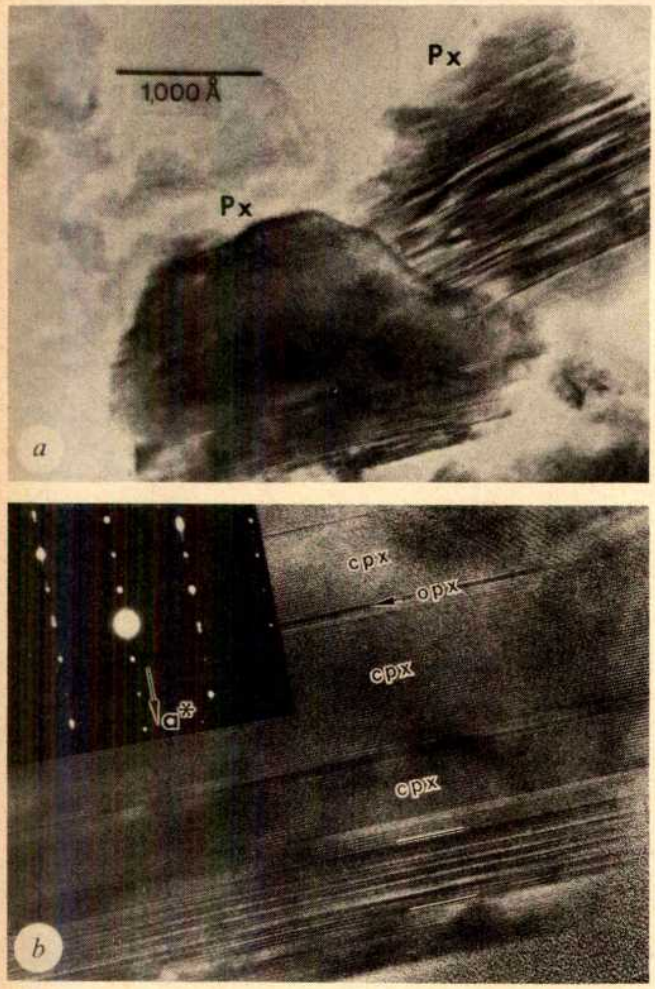

Fig. 3 *a*, Enstatite platelets. *b*, A high-resolution TEM image of part of the pyroxene grain at the borrom of *a* and its SAED pattern (inset). The image shows regions of clinopyroxene (cpx), orthopyroxene (opx) and stacking disorder of cpx and opx (between lines); cpx and opx have fringe spacings of 9 and 18 Å. Streaking of reflections along a* in the diffraction pattern results from stacking disorder of cpx and opx.

that the phyllosilicate is much richer in Fe than the pyroxene; Al was not detected from either the pyroxene or the phyllosilicate. Although the actual boundary between the two minerals is poorly defined, the external edge is clearly continuous around both minerals, and the pyroxene and the phyllosilicate are certainly parts of the same grain. Many small grains of smectite/mica also occur along the edges of other pyroxene crystals. By analogy with images obtained of terrestrial[20,21], meteoritic[22] and synthetic samples[23], we believe that the phyllosilicate was produced by alteration of the pyroxene. It is, therefore, reasonable to assume the past occurrence of aqueous alteration in the history of this IDP, although it is not possible to say whether liquid or vapour was responsible for the alteration.

An unidentified mineral containing major Fe, Mg and minor Ca, Mn and Si is widespread and is commonly associated with smectite/mica; it occurs in rounded grains, 500 Å to 1 μm in diameter. A similar phase was also found in Low-Ca[5], but it has not been reported from either other IDPs or meteorites and so may be unique to the hydrated IDPs.

Fassaite has not been reported previously from IDPs; its discovery provides important information regarding the origin of the hydrated IDPs. The bulk compositions of the chondritic IDPs as well as their isotope compositions and mineralogy suggest a strong similarity between IDPs and carbonaceous chondrites. If fassaite in Skywalker formed by processes related to the formation of CAIs, then its presence provides evidence suggesting that the hydrated IDPs contain primitive materials that formed in the early solar nebula. The hydrated IDPs, like carbonaceous chondrites, presumably have not experienced extensive high-temperature metamorphism since their accretion.

Although there are definite mineralogical similarities between hydrated IDPs and carbonaceous chondrites, our TEM studies also reveal important differences. The phyllosilicates in the CI and CM meteorites are mostly serpentine- or septechlorite-type minerals[24–29] rather than the Fe- and Mg-rich smectite or mica in both Low-Ca and Skywalker. The phyllosilicates in the carbonaceous chondrites are commonly much better crystallized than those in the IDPs. Low-Ca and Skywalker are thus probably not broken fragments of carbonaceous chondrites, and they may well have originated from distinct sources.

Petrographical studies[26–30] suggest that the CI and CM phyllosilicates were produced largely by aqueous alteration of olivines and pyroxenes. The present study provides evidence suggesting that the IDP phyllosilicates were also formed by alteration of Fe-Mg pyroxene. The differences in phyllosilicate mineralogy may then reflect the distinct environments in which the alteration occurred. If the alteration occurred within the parent bodies—and this is only an assumption at present—the contrast in mineralogy may reflect differences between comets and asteroids, the presumptive parent bodies of IDPs and carbonaceous chondrites[31,32].

The hydrated and non-hydrated IDPs have similar bulk compositions and isotope characteristics but different mineralogies. A question arises as to whether the distinct mineralogies reflect different environments. During or after accretion from the solar nebula, the IDPs may have experienced distinct physicochemical conditions or different degrees of thermal metamorphism. To resolve this question, additional mineralogical and isotope data are required as well as a better understanding of the range of types of chondritic IDPs. Work is in progress towards achieving these goals.

We thank Dr R. M. Walker and his co-workers at Washington University for providing the Skywalker IDP and for helpful discussions. We also thank Drs D. E. Brownlee, R. Christoffersen and L. Grossman for useful discussions and Dr K. Keil for a helpful review. Electron microscopy was performed at the electron microscope facility in the Center for Solid State Science at Arizona State University. This work was supported by NASA grant NAG 9-59.

Magnetic reversals and mass extinctions

David M. Raup

Department of the Geophysical Sciences, University of Chicago, Chicago, Illinois 60637, USA

Previous analyses of the time distribution of reversals of the Earth's magnetic field have yielded mixed results. Some authors have claimed significant periodicities of order 10^7 yr[1,2] whereas others have reported failure to reject null hypotheses of random spacing at that scale[3–6]. Because of repeated suggestions that field reversal is linked to biological extinction[7–12], further analysis of the magnetic time series is appropriate. I present here the results of a study of the reversal record of the past 165 Myr. A stationary periodicity of 30 Myr emerges (superimposed on the non-stationarities already established by others[5]), which predicts pulses of increased reversal activity centred at 10, 40, 70, ... Myr BP.

The database is the compilation of magnetic reversals for the late Jurassic to present interval (0–165 Myr BP) by Harland *et al.*[13]. These data, constituting the magnetostratigraphical timescale for the best-known part of the reversal record, were culled heavily by Harland *et al.*[13] to eliminate minor excursions and other short-term or local effects and were presented as the time boundaries of 148 magnetic intervals (chrons and subchrons), yielding $148 \times 2 = 296$ reversal events. Figure 1 shows the distribution of these events in geological time, which shows, among other things, the well-known quiet period of the late Cretaceous (83–118 Myr BP), with reversal activity decreasing before and increasing after the quiet period.

In developing the statistical methodology for this analysis, a magnetic reversal is assumed to be an isolated event; thus, it is not important whether the field shifted from normal to reversed or vice versa. The analytical procedure, which follows that of Stothers[14] and Raup and Sepkoski[15], has as a central feature a 'goodness-of-fit' metric applicable to any postulated stationary periodicity. This metric is calculated as follows. For a given trial period (such as 20 Myr), a predicted sequence of events is defined and placed on the timescale in a completely arbitrary phase position (such as −10, 10, 30, 50, ... Myr BP). Then, the fit is assessed as the standard deviation of departures of the observed events from the predicted event closest to each. Thus, in the hypothetical example used here, an event observed at 14 Myr BP would show a departure of +4 Myr from its closest predicted event (10 Myr BP), an observed event at 48 Myr BP would show a departure of −2 (from the 50-Myr BP prediction) and so on. The standard deviation of these departures is a measure-of-fit for a given phase position, which is then shifted by a small increment (to, for example, −9, 11, 31, 51, ... Myr BP) and the standard deviation of departures is recalculated.

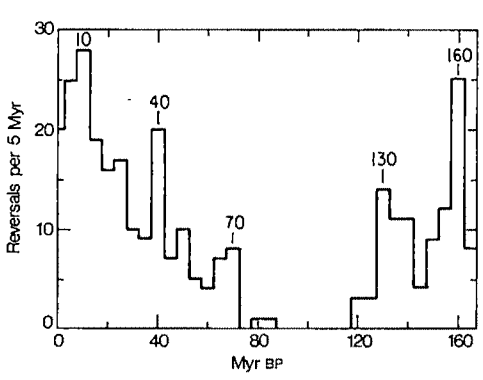

Fig. 1 Frequency of 296 magnetic reversals in 5-Myr intervals (data from ref 13).

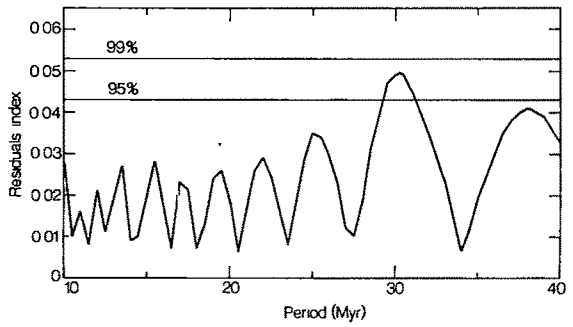

Fig. 2 Spectrum of residuals index ($n = 296$) constructed using the method of Stothers[14] The residuals index is the measure of goodness of fit of the data to a given period.

This process is repeated for a series of phase increments (totaling at least a full period) and the lowest value of the standard deviation is taken as the goodness-of-fit. We thus have estimates of goodness-of-fit and best-fit position for the trial period. The method is particularly appropriate for time series exhibiting missing or missed data because waiting times between events are never examined explicitly. Also, the method contains no assumption that the frequency behaviour is sinusoidal, contrary to conventional Fourier techniques.

Stothers[14] showed that the standard deviation can be normalized for period length as follows. Residuals index

$$(P\sqrt{(n^2-1)/12n^2} - \sigma)/P$$

where P is the period length, n is the number of observations and σ is the standard deviation of departures (above). With random data, the residuals index is constant over a range of P (but see below).

Given an observed time series, the residuals index may be calculated for a sequence of P values and a spectrum of goodness of fit produced, which is shown in Fig. 2 for the magnetic reversal time series; periods greater than 40 Myr are not included because the residuals index is unstable above $P = 40$ with this particular time series. There are a number of well-defined peaks, but this is not surprising; indeed, random input of the same general character often gives comparable spectra and so it is important to assess the probability that the spectrum is not just the product of chance. Using a bootstrap technique, the real-time series was randomized by scrambling the intervals between successive magnetic reversals; the first and last reversals were used as fixed endpoints and all intervals in between were rearranged by standard Monte Carlo techniques. Each randomized version of the data thus retained most of the fabric of the true series, but the placement of reversals was changed; each had a quiet period

Table 1 Goodness-of-fit and phase for magnetic reversal data

Period (Myr)	Goodness-of-fit: % of simulations with poorer fit than the real data			Phase in best-fit position, age of cycle no. 1			
	0–165	0–83	118–165	(Myr BP)	0–165	0–83	118–165
22	83.6	43.2	96.8		4 49	4 59	4.07

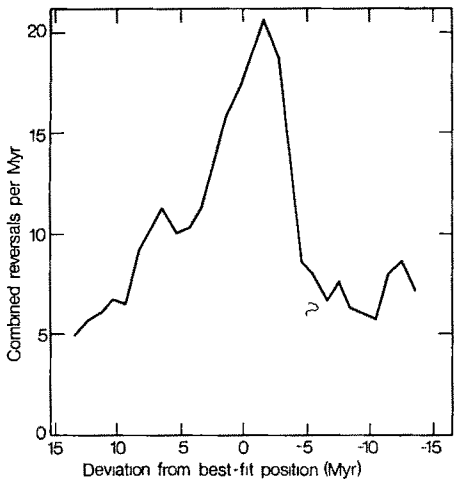

Fig. 3 Composite cycle of magnetic reversal activity plotted as a 3-point moving average. With a 30-Myr period in best-fit position (zero on the horizontal axis), the data from all cycles have been superimposed ($n = 296$).

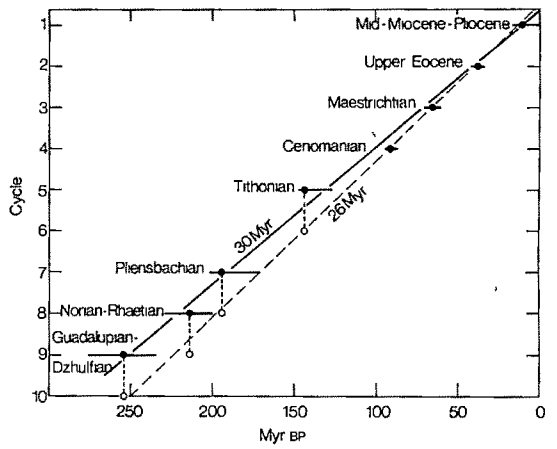

Fig. 4 The distribution by age and cycle number of the eight significant biological extinctions of the last 250 Myr (solid dots). Error bars indicate the maximum possible age spread, including that implied by the several available geological timescales[25]. The solid diagonal corresponds to a 30-Myr period in the best fit position indicated by the magnetic reversal data. If the 26-Myr period is used, the oldest four extinctions must be advanced one cycle each (open circles) and the fit is improved substantially (dashed diagonal).

of the same length, but its position was unpredictable. A spectrum, such as that in Fig. 2, was calculated for each of 200 simulations and the point of highest residuals index for each simulation was recorded. The results are summarized by the two horizontal lines in Fig. 2; 95 and 99%, respectively, of the simulated spectra were contained totally below the designated lines.

The peak corresponding to a period of 30 Myr stands out and is clearly above the 95% line, from which it can be concluded that it is unlikely that the peak is an accident or artefact of the method (Fig. 2). The null hypothesis in this case comes from the above randomization scheme. It is non-Poisson in that the distribution of intervals (waiting times) between events is maintained; only their order has been randomized. Tests with two alternative null hypotheses will be discussed below.

With the 30-Myr peak in Fig. 2 as a starting point, a more detailed investigation of periods in that region was undertaken. For each 1-Myr interval from 22 to 33 Myr, the fit of the real data (measured by the standard deviation of departures) was compared with that of 1,000 simulations of the type used earlier. The results are shown in columns 2 and 5 of Table 1. In column 2, goodness-of-fit is expressed as the percentage of simulations showing a poorer fit (higher standard deviation); the period at 30 Myr is the highest with 99.4%. Column 5 gives the best-fit position expressed as the geological age (in Myr BP) of the most recent pulse of reversal activity and this position for the 30-Myr period is 10.04 Myr BP.

To check these results, the analysis was repeated with non-overlapping segments of the time series, using the Cretaceous quiet period as the demarcation. These results are shown in the remaining columns of Table 1. For the younger segment (0–83 Myr BP), goodness-of-fit values are not as high as for the whole series but the one for 30 Myr is the highest. Also, the best-fit position is identical at 10.04 Myr BP. For the older segment (118–165 Myr BP) all periods show excellent fit, making it difficult to distinguish between them. This is not unreasonable because this segment is only 45 Myr long and contains only two of the events predicted by the complete time series. Note, however, that the best-fit position for the 30-Myr period estimated from this short segment is 10.05 Myr BP, essentially identical to the other estimates for this period. Thus, the analyses of segments can be regarded as confirming a 30-Myr period with a best-fit phase position of 10 Myr BP.

I conclude that the reversal time series probably shows a stationary periodicity predicting elevated reversal activity at 30-Myr intervals beginning at 10 Myr BP. Extrapolating from this conclusion, Fig. 1 shows that the record is dominated by the Cretaceous quiet period with reversal activity increasing in both directions. The 30-Myr periodicity is superimposed on this broader first-order change and can be seen as localized peaks at 10, 40, 70, 130 and 160 Myr BP; the predicted peak at 100 Myr BP is missing because of overall reduction in reversal activity (the quiet period).

I emphasize that a statistical confidence level cannot be assigned to the 30-Myr periodicity. Although the data clearly favour this periodicity over the null hypothesis of random ordering of the same data, an unknown number of stationary and non-stationary models might give as good or a better fit. The 30-Myr stationary model is, nevertheless, the simplest alternative to the random model and seems to be well supported by the data.

Confidence in the 30-Myr periodicity depends on the null hypothesis against which it is tested; it was therefore tested against two other hypotheses. The first is a simple Poisson model where randomization was achieved by 'dropping' 296 points on a 0–165-Myr timescale using uniformly distributed random numbers; the result was identical, within sampling error, to that reported in Table 1. The second variant reproduced the non-stationarities reported by McFadden and Merrill[5]. Once again randomization was achieved by a Poisson method, but in this case the linear decrease in reversal activity before the Cretaceous quiet period and the linear increase after that were used to bias the selection of simulated events. The probabilities used were drawn from linear fits to the actual data following the interpretation of McFadden and Merrill[5]. The result, identical to that reported in Table 1 (99.4% of simulations showing a poorer fit than the real data), confirms further the conclusion that the observed periodicity is superimposed on the larger-scale changes in reversal frequency.

Figure 3 shows the frequency distribution of reversal events in a single composite 30-Myr period. The relatively smooth and symmetrical distribution supports the hypothesis of a 30-Myr period with a best-fit position centred at 10, 40, 70, ... Myr BP. If other periods or phase positions are used to construct the composite, the distribution breaks down.

These results are in good agreement with other analyses[1,2]. Using Walsh spectrum analysis applied to a much longer series of magnetic reversal data, Negi and Tiwari[1] recognized several periodicities and claimed statistical significance for those at 32 and 285 Myr. Mazaud *et al.*[2], working with the reversal data younger than the Cretaceous quiet period, found a 15-Myr periodicity, which is precisely in phase with the 30-Myr period reported here. Their strongest peaks occurred at 10 and 40 Myr BP and it is not clear (nor especially important) whether the 30-Myr period is a harmonic of the 15-Myr period or vice versa.

What is the relevance of these results to biological extinction? This question involves possible relationships between extinction, comet or asteroid impact and magnetic reversal as well as possible periodicities in all three. The link between extinction and magnetic reversal is supported by some studies[7-12] but challenged by others[16-17]; that between extinction and impact is more nearly established because of the iridium and/or other evidence for impact at four separate extinction times—late Eocene[18-19], terminal Cretaceous[20-21], terminal Permian[22] and late Devonian[23]. Further, the suggestion that extinctions and impact events are both periodic and in phase[12,24-26] strengthens the case for causal linkage. A proposed link between large-body impact and magnetic reversal is more tenuous, but is supported by some evidence, specifically the temporal coincidence of magnetic reversals with three of the four well-dated tectite-strewn fields[27]. It is thus not impossible that at least some reversals are caused by comet or asteroid impact and it is in this context that the relationship between periodic intensification of reversal activity and periodic extinction becomes important.

For the most recent several cycles, the fit between extinctions and reversal intensity is reasonable in view of the extinctions at 11.3, 38 and 65 Myr BP[25] and the magnetic reversal peaks at 10, 40 and 70 Myr BP. But because the most probable periodicity for extinctions is 26 Myr[15,25], the two systems move out of phase going backwards in time. This is illustrated in Fig. 4, which shows an attempt to fit the 30-Myr periodicity to the eight significant extinctions of the past 250 Myr and shows also the 26-Myr fit to the same extinction points. Except for the first three events, the discrepancy between the two periods is clearly non-trivial.

The discrepancy can mean either there are independent periodicities operating with no causal connection or that the statistical uncertainty of the analyses is large enough to accommodate a single period somewhere in the 26–30-Myr range. The situation is complicated further by the fact that Rampino and Stothers[12] re-analysed the extinction data and found a best-fit period of 30 ± 1 Myr, with phase position at 10 ± 7-Myr BP. They used a regression method that assumes that all cycles are present in the data, although they noted that removing this restriction restores the 26-Myr period of Raup and Sepkoski[15,25].

The discrepancies in analytical results mean that no unequivocal conclusion can be drawn; however, there is a possibility that biological extinction, magnetic reversal and large-body impact are linked.

I thank M. R. Rampino, J. J. Sepkoski Jr, S. Stigler and R. B. Stothers for discussions and also G. E. Boyajian for literature search and for help with the analysis of the magnetic data. The work was supported by NASA grant NAG 2-237.

Lead isotope differences between whole-rock and phenocrysts in recent lavas from southern Italy

M. Cortini* & P. W. C. van Calsteren†

* Istituto di Geologia & Geofisica, University of Naples, 80138 Naples, Italy
† Department of Earth Sciences, Open University, Milton Keynes MK7 6AA, UK

In southern Italy, there are several active volcanoes which occur in diverse geotectonic settings. Isotope determinations on coexisting minerals and whole-rocks from zero-age lavas from Vesuvius, Etna and Stromboli reveal an isotope equilibrium for Sr isotopes[1] but not for Th (ref. 2). Analyses for Pb in the same samples also reveal differences in isotope composition, and in all cases the phenocrysts are less radiogenic than the whole-rocks. We argue here that the Pb and Th isotope composition of the magmas changed during and after fractional crystallization, possibly by crustal assimilation or by addition of mantle-derived fluids and that whole-rock Pb isotope data are not representative of the magma sources.

Stromboli forms part of the Aeolian island arc, probably along a destructive margin between the European and African plates. It is characterized by virtually uninterrupted eruption of leucite tephrites and basaltic andesites belonging to the high-K-calc-alkaline series. Model calculations based on trace elements indicate an origin by partial melting of a parent material inhomogenously enriched by a Th/light rare-earth element/P-rich metasomatic fluid, probably derived from the subducting plate[3].

Etna is a large alkali basalt volcano, with minor early tholeiitic lavas, producing mainly hawaiites and mugearites. Its geochemistry is largely consistent with its within-plate setting but a minor modification of its source by subduction-derived phases is likely[3].

Vesuvius is best known for its explosive-effusive eruptions of high-K trachytes and leucite tephrites; they probably derive from a comparatively recently enriched mantle source, by analogy with nearby Roccamonfina[4]. Fractional crystallization and cumulus formation took place in various magma chambers at different levels in the crust; the incorporation of limestone fragments, high in the crust, had little effect on the volcanic rocks.

Table 1 shows the results of our analyses of the Pb isotope composition of whole-rock and mineral separates of lavas and ejected cumulates of well-studied samples. Separated minerals are either phenocrysts, considered to have crystallized from the coexisting magma, or biotite separated from nodules which have been interpreted as cumulates[5].

Pb was separated using a 0.1-ml AG 1×8 ion-exchange column, eluted with 1M HBr and stripped with 2 ml H_2O. Pb was loaded on a Re filament with phosphoric acid and silica gel. Isotope ratios were measured using our software on a VG54E mass spectrometer. The NBS 981 standard was run in the same conditions and from the collated results a bias factor of 1.00047 AMU^{-1} was calculated. Measured results were corrected using this factor to minimize the effects of instrumental mass fractionation. The total procedure blank is <2 ng; sample weights were adjusted to contain an estimated 1 μg Pb.

Our data for the Vesuvius 1944 lava are in agreement with Vollmer and Hawkesworth[6], while those from the Etna lavas compare well with the data of Carter and Civetta[7]. Reproducibility may be estimated from the two duplicate whole-rock analyses.

There are no significant differences in Sr isotope ratios (Table 1) between phenocrysts and their whole-rocks, indicating that phenocrysts are indeed co-magmatic. Differences in Sr isotopes between Vesuvius samples from different magma batches can be explained by mixing two endmembers with very similar major-element, but different isotope, compositions[1].

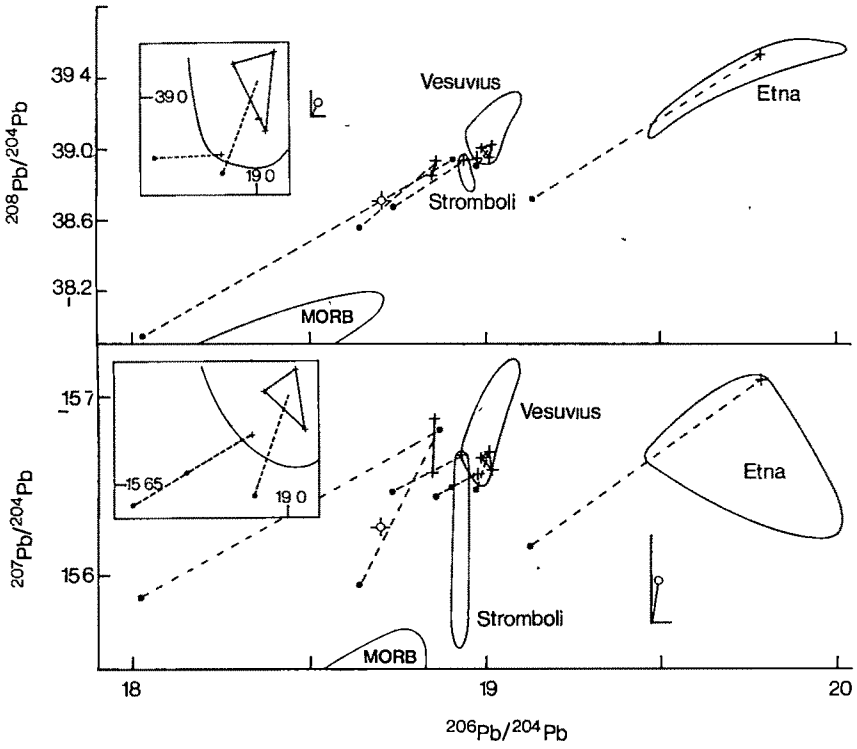

Fig. 1 Pb isotope diagram. Solid lines connect whole-rock duplicates; dashed lines tie whole-rock and mineral. Inset, Vesuvius lava data on a larger scale. ⊹, Average modern Pb[16]. ⌊, The error on replicate analyses of NBS 981 and the applied correction. Top of MORB field from ref. 17.

Pb isotope compositions are plotted in Fig. 1 together with fields constructed using the present data and some from other workers[6-9]. All phenocryst and cumulate nodule data plot away from the whole-rock fields towards less radiogenic compositions. The largest displacement of plagioclase with respect to the whole-rock from which it was separated is from Etna, and is well outside the experimental error. Deviations for the Stromboli and Vesuvius–Castello di Cisterna pairs are smaller but still significant. Data for the Vesuvius 1944 lava are strictly within error, but display a similar relation.

In the case of the cumulate nodules, there are also large differences between biotite and whole-rock analyses. These data suggest that the Pb isotope composition of the respective magmas changed during and after fractional crystallization, although the Sr isotope composition was not affected. (For Sr, a difference in isotope composition caused by mass-dependent fractionation would be eliminated by the standard correction procedure as its effect is indistinguishable from the instrumental fractionation.) Mass-dependent Pb isotope fractionation effects will be parallel to the NBS 981 correction vector. Clearly, none of the mineral, whole-rock tie-lines are parallel to this vector and the most probable explanation is mixing of two components with different Pb isotope composition. The actual nature of the components is difficult to assess but it can be inferred that the magma source had Pb isotope ratios even less radiogenic than indicated by the phenocrysts or cumulate minerals but probably still more radiogenic than mid-ocean ridge basalts (MORB). Slopes of tie-lines on Fig. 1 between minerals and whole-rocks are ~0.12, suggesting an age of ~2,000 Myr for the radiogenic component. Our data do not indicate whether the mixing process involved bulk assimilation, exchange of Pb through interaction with fluids or addition of Pb by metasomatic fluids in the mantle. However, for Vesuvius, fractional crystallization has probably taken place in the mantle at pressures greater than the stability limit of

plagioclase[5]. Thus, a mantle component is probably involved. Furthermore the $^{230}Th/^{232}Th$ activity ratios[2,10,11] summarized in Table 1 also show differences in isotope composition between whole-rock and minerals in most cases. Capaldi *et al.*[2] have argued that these differences do not have any significance for the age but indicate open system behaviour, and they propose contamination of the magmas with mantle fluids. This must have been a recent event because the high decay rate of the ^{238}U daughter products[12] involved will establish a new equilibrium in 0.2 Myr.

The observed differences in mineral/whole-rock Pb isotopes also imply that whole-rock data alone are not representative of the magma sources, at least in the cases of Vesuvius, Stromboli and Etna. The observed variations suggest that the magma sources are less radiogenic than the whole-rock and probably even the mineral data.

We thank Nick Rogers and Chris Hawkesworth, for useful comments, John Taylor for drawing the diagram and Carol Whale for typing the manuscript. Work at the Open University by M.C. was funded by a NATO fellowship grant.

Andean-trending mobile belts in the Brazilian Shield

M. Litherland, B. A. Klinck, E. A. O'Connor & P. E. J. Pitfield

British Geological Survey, Keyworth, Nottingham NG12 5GG, UK

Much of the Phanerozoic Andean mountain chain is floored by Precambrian basement[1–3], in places as old as 2,000 Myr[4,5], but relations between these rocks and those of the Brazilian Shield have long been obscure, mainly because of the intervening Cenozoic sedimentary cover. We describe here recent work over the Bolivian sector of the Brazilian Shield (Fig. 1) which shows a pattern of Proterozoic mobile belts approximately parallel with the Andean chain to the west. When the trends of these Bolivian belts are projected towards the Andes under the Cenozoic cover, their ages broadly accord with those of the Andean basement. Our interpretation is that the two domains are linked in the form of a chain of five Andean-trending mobile belts with a combined width of ~1,000 km, becoming progressively younger to the west with ages ranging from 1,300 Myr to the present.

An Anglo-Bolivian mineral exploration project has completed recently the reconnaissance mapping of the Bolivian Precambrian shield (refs 6–8). The outcrop pattern is determined largely by the San Ignacio Orogeny[7], a medium- to high-grade tectono-metamorphic event, which established a complex of granulites, gneisses and metasedimentary schist belts as well as extensive syn- to post-tectonic granites dated by Rb/Sr at 1,350–1,300 Myr BP (ref. 6 and M.L. *et al.*, in preparation) (Fig. 2). The protolithic rocks of the granulites are considered to be a thick sedimentary sequence and a calc-alkaline plutonic suite, which Rb/Sr studies[6] indicate to be at least 2,000 Myr old, the age of the Trans-Amazonian Orogeny[9]. The semipelitic gneisses, in part higher-grade equivalents of the schist belt, are composed of a metamorphosed sequence of pelites and psammites, with minor volcanics, mafic igneous sills, ironstones and graphitic and calcareous sediments[7]. Palaeocurrent directions preserved in low-grade belts indicate a northerly provenance, from the direction of the present Amazonic Craton[6] (Fig. 3). The schist belt sequence is thought to belong to a San Ignacio Cycle of deposition following the Trans-Amazonian Orogeny[6].

The trend of the San Ignacio Belt is defined by the upright third phase of folding (Fig. 3), which was accompanied by penetrative deformation and the generation of the syntectonic granites[6]. This event folded the granulite-gneiss-schist metamorphic sequence established during the earlier sub-horizontal tectonic phase of the Orogeny[6].

It is now proposed that the limit of the San Ignacio Orogeny in Brazil is the Ciriquiqui arc of mafic/ultramafic intrusives[10] (Fig. 3) which follows the San Ignacio trend. North-east of this line there are relatively undeformed supracrustal sequences, the Beneficiente Group and the Roosevelt Volcanic Formation (Fig. 2), dated at 1,600 Myr BP[10], which rest unconformably on older Xingu Complex basement. These supracrustal units belong[11] to a 1,700–1,400-Myr BP phase of faulting, volcanism, plutonism and sedimentation. They are cut by the anorogenic 1,300-Myr BP Providencia Granites[10] (Fig. 2), accompanied by a widespread K/Ar resetting of older dates, the Madeira event[11], a cratonic reactivation which we relate to the effects of the adjacent San Ignacio Orogeny. Other Brazilian geologists[12,13] classify these same 1,700–1,400-Myr BP rocks as part of the Rio Negro-Juruena Belt, interpreted[14] as a magmatic arc accreted to an older Amazonic nucleus to the north-east.

When the San Ignacio Belt is projected along its west north-west to north-west course under the Cenozoic cover (Fig. 4), it can be linked to similar gneisses and granulites found as massifs in the Columbian Andes which give Rb/Sr and U/Pb dates of 1,300–1,200 Myr BP[15]. Rocks of the Brazilian Shield to the east of this area have undergone the Parguazan reworking of

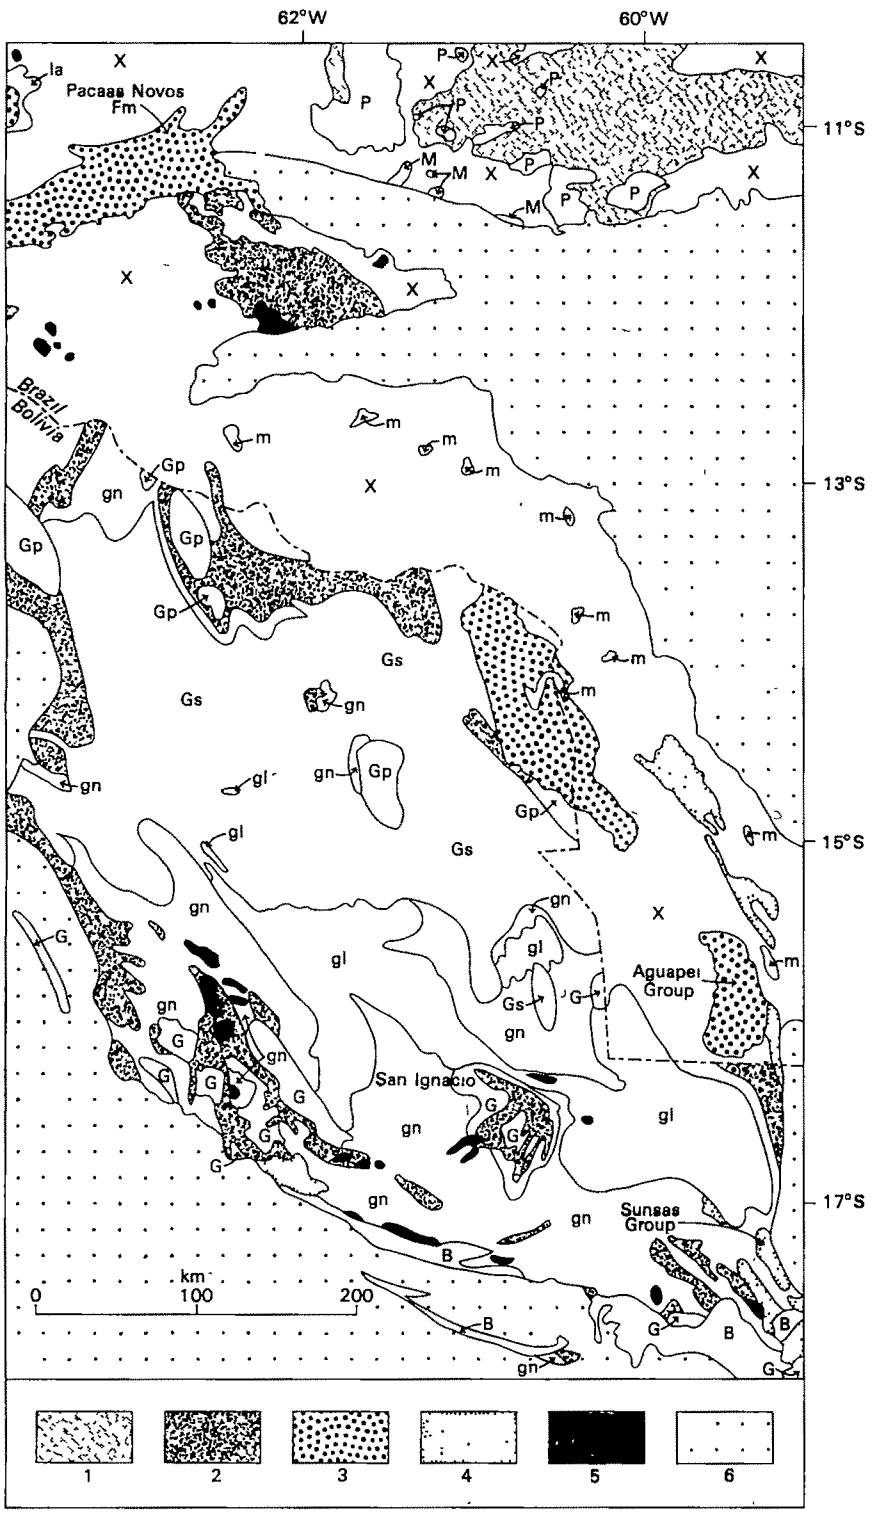

Fig. 2 Precambrian geology of eastern Bolivia[6,8] and adjacent Brazil[26]; tectonic contacts and Mesozoic igneous units omitted. The protolithic rocks of the following are all ≥1,400 Myr BP: gl ≡ granulites; gn ≡ gneisses; X ≡ Xingu Cx; (1) platform Beneficiente Group and Roosevelt Volcanic Formation; (2) San Ignacio schist belts. Of ~1,300 Myr BP: M ≡ mafic/ultramafic intrusives; P ≡ anorogenic Providencia Granites; G ≡ orogenic granites (Gs, syntectonic; Gp, post-tectonic). Of 1,300–1,000 Myr BP: (3) platform Sunsas Group; (4) mobilized Sunsas Group; la ≡ basalt lavas. Of ~1,000 Myr BP: m ≡ mafic/ultramafic intrusives; (5) Rondonia/Sunsas granites. B ≡ Brasiliano Cycle sediments (~600 Myr BP); (6) Phanerozoic cover.

1,500 Myr BP[16] and also exhibit the ~1,300-Myr BP K/Ar resetting known locally as the Nickerie event[15].

Traced southwards through the Bolivian shield area the fold trends of the San Ignacio Belt swing from east south-east through south-east to south (Fig. 3). This is a primary swing and unrelated to secondary deformation of San Ignacio Orogeny age[6]; it can even be identified across the later Sunsas shear zones[7] (Fig. 3). Further south, the San Ignacio Belt is projected west of the 1,700-Myr BP Rio Apa Complex[17] (Fig. 4), but its continuation through Paraguay is conjectural.

The 1,300-Myr BP San Ignacio Orogeny was followed by a period of clastic dominantly-shallow-water deposition, forming the Sunsas and Vibosi Groups in Bolivia[6,7] and their Brazilian correlatives, the Aguapei Group and Pacaas Novos Formation[10], which are locally intercalated with basaltic lavas (Fig. 2). Thicknesses are in the range of 800–5,000 m and there is always a marked basal unconformity. Palaeocurrent directions indicate a northerly source and there are similarities in volcaniclastic suites with those of the older San Ignacio schist belt psammites. Outcrops of this regional unit occur as prominent ridges, representing metamorphosed synformal infolds, or as mesas of flat-lying relatively-undisturbed strata. These can be used as lithostratigraphical indicators in elucidating the tectono-metamorphic history of the Sunsas Orogeny, dated by Rb/Sr and K/Ar at 1,000 Myr BP[6]. Two mobile belts can be recognized separated by a cratonic zone of undisturbed basement capped by Sunsas Group mesas (Figs 2 and 3). The west north-west trending Sunsas Belt is bounded and segmented by curvilinear

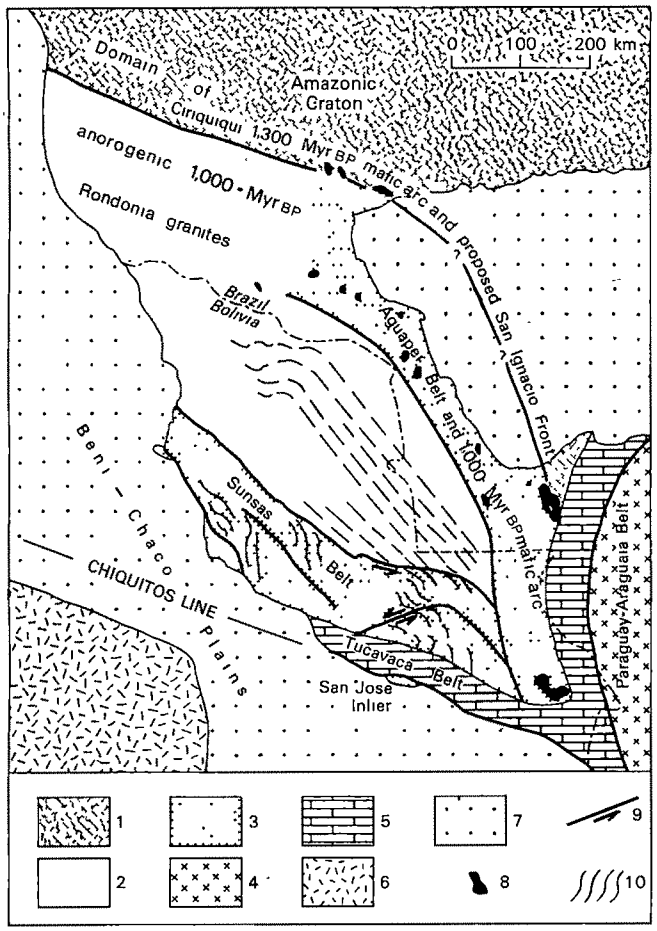

Fig. 3 Geotectonic elements of eastern Bolivia and environs. Fig. 4 Present interpretation of main South American geotectonic units; dashed lines indicate projection below South American Platform cover[11]. (1) Cratonic nucleii (≥1,400 Myr BP); (2) San Ignacio Mobile Belt (1,300 Myr BP); (3) Sunsas and Aguapei Mobile Belts (1,000 Myr BP); (4) Brasiliano Mobile Belts (600–500 Myr BP); (5) Eastern Cordillera (Palaeozoic); (6) Western Cordillera (Mesozoic–Cenozoic); (7) 1,000-Myr BP shear zone. I, S and B refer respectively to San Ignacio, Sunsas and Brasiliano orogenic ages of sub-Andean basement rocks. Partially reworked tracts of older rocks within Brasiliano belt terrain[11] are omitted.

sinistral shear zones which enclose sectors marked by coeval upright folds, metamorphism to garnet-grade and a penetrative deformation which cuts earlier recumbent 'thin-skin' folds in the Sunsas Group. Syn- and post-tectonic granites were developed accompanied by tin- and tantalum-bearing pegmatites[7,8]. The Aguapei Belt (Fig. 3), in contrast, is a domain of faulting, folding and mafic-ultramafic intrusives. It seems to deflect the Sunsas shears in a dextral sense (Fig. 3) and follow the trend of the older San Ignacio Belt.

Tracing the Aguapei Belt to the north-west, the folding dies out and the mafic/ultramafic intrusives give way to the domain of the 1,000-Myr BP anorogenic Rondonia granites[18] (Fig. 3). When the Sunsas Belt is projected west north-west to the Andes (Fig. 4), however, it lines up with probable 1,000-Myr BP basement rocks in Ecuador[3]. Sunsas Orogeny-age rocks also floor sectors of the Andes in Bolivia[19] and Peru[1] and may represent older nuclei of an extensive Sunsas Belt within the proposed Brasiliano Belt (Fig. 4).

The Upper Proterozoic–Eocambrian Brasiliano (Pan-African) Cycle of the eastern Bolivian shield is restricted to the western fringe of the eugeosynclinal Paraguay–Araguaia Belt[11] and the west north-west-trending Tucavaca Belt of miogeosynclinal rocks[7] (Fig. 3), bordered to the south by a tectonic front giving reset K/Ar dates of 520 Myr BP[6] in the San José inlier (Fig. 3). The Brasiliano sequences extend under the Phanerozoic cover further south to link up[20] with the Andean-trending 600–500-Myr BP Brasiliano belt recognized in the Sierra Pampeanas of Argentina[21] and other sectors of the sub-Andean basement[1,3] (Fig. 4). The Tucavaca front was reactivated during the Phanerozoic as the Chiquitos Line[22] (Fig. 3) controlling the distribution of Palaeozoic, Cretaceous and Cenozoic sedimentary basins[6].

The Phanerozoic Andean chain can be divided into the Palaeozoic fold belt of the Eastern Cordillera and the Mesozoic–Cenozoic belt of Andean orogeny of the Western Cordillera[1–3]. Figures 3 and 4 illustrate the parallelism of the Bolivian San Ignacio and Aguapei Belts with the Arica 'elbow': the major swing from north to west north-west in the trends of both the eastern and western Cordilleras parallel to the continental margin. There is also a parallelism between the west north-west-trending segment of the elbow and the Sunsas and Tucavaca Belts. The projected continuation of the belts away from the Bolivian outcrop (Fig. 4) accords broadly with the known Precambrian ages of the Andean basement. Thus, an enlarged Andean chain, ~1,000 km wide, can be proposed, consisting of five mobile belts which become progressively younger to the west towards the present continental margin. There is the possibility of an even older sixth belt within the Amazonic Craton (Fig. 4), in the form of the Parguazan reworking of 1,500 Myr BP[16] representing the north-west sector of the Rio Negro–Juruena Belt[13]. Whether such apparent continental growth layers relate to accretion of new crust or reworking of old must depend on the status of the 2,000-Myr BP Arequipa Massif[4] (Fig. 4). Palaeomagnetic studies[5] suggest it is not an allochthonous post-Jurassic microplate but an integral part of the American plate, continuous beneath the Andes with the Brazilian Shield and possibly extending further west before the onset of Mesozoic closure/subduction[1]. If its position with respect to the Amazonic Craton has not changed since 2,000 Myr BP, then all five belts are probably ensialic, with continental margin subduction beginning in the Phanerozoic. However, if the Massif arrived after that time, then the San Ignacio Belt could have developed along a pre-Pacific oceanic suture. In either case, it appears that the trend of the

1,300-Myr BP San Ignacio Belt has controlled those of subsequent orogenies as well as the present shape of the continental margin, suggesting a longstanding tectonic regime established within the continent and perhaps related to the formation of the Pacific Ocean.

The identification of Proterozoic elements in an enlarged Andean chain would augment, at least locally, the number of peripheral mobile belts which young towards the southern continental margin of Gondwanaland[23], with implications regarding the mechanisms of formation, such as accretion or reworking[24], of the Brasiliano (Pan-African) belts Traced to North America, the 1,300-Myr BP San Ignacio Belt may deviate from the circum-Pacific chain to link up[15] with the Grenville Belt of the North Atlantic chain[25].

The field work in eastern Bolivia was carried out with colleagues at the British Geological Survey (BGS) and counterparts at GEOBOL under a technical cooperation agreement funded by the Overseas Development Administration, Foreign and Commonwealth Office. D. P. F. Darbyshire (BGS) was responsible for the age determination programme. This letter is published with the permission of the Directors of BGS and the Servicio Geologico de Bolivia (GEOBOL), La Paz. We thank Dr E. J. Cobbing, Professor U. G. Cordani and Dr B. G. N. Page for helpful criticism.

Oceanic solitons, nutrient pulses and phytoplankton growth

P. M. Holligan*, R. D. Pingree† & G. T. Mardell†

* Marine Biological Association of the United Kingdom, Citadel Hill, Plymouth PL1 2PB, UK
† Institute of Oceanographic Sciences, Brook Road, Wormley, Godalming, Surrey GU8 5UB, UK

Phytoplankton growth in the sea is influenced by internal wave activity both through vertical displacements of the pycnocline, which cause fluctuations in the light environment for photosynthesis, particularly in the subsurface chlorophyll maximum[1,2], and through mixing processes associated with energy dissipation[3]. In shallow continental-shelf waters, mixing by internal waves can lead to pulses of nutrients in the nutrient-depleted surface layers[4]. In the deep oceans, increased nutrient fluxes resulting from internal wave mixing have also been postulated to explain anomalously high primary production values[5], but this phenomenon has not been observed directly. Here we present the first evidence from a deep (4,000 m) oceanic environment for nutrient mixing by large soliton-like internal waves[6-9], generated more than a day before at the shelf edge. The observations were made in the Bay of Biscay (Fig. 1*a*), where the level of nitrate is considered to be a major factor regulating the standing stock and productivity of phytoplankton in surface water during the summer months[10,11], as in other areas of the eastern North Atlantic Ocean[12].

Earlier studies along the edge of the north-west European shelf showed that internal waves are generated in discrete groups or packets close to the 200-m contour and propagate on-shelf with on-shelf tidal streaming[13]. These are best developed at spring tides[14]. Synthetic Aperture Radar (SAR) images from the Seasat satellite indicate that internal waves also travel outwards from the shelf-break into the deeper waters of the Bay of Biscay[13]. Our investigations during large spring tides at the end of August 1984, confirmed the existence of these oceanic solitons, which were detected acoustically (Fig. 1*b*) as they propagated normally and away from (~210°) the shelf edge. Each packet of two to six large waves (followed by a train of smaller waves) was formed on a single tidal excursion. The peak-to-trough amplitude of these larger waves was 50–80 m, with a wavelength of 1–1.5 km and a phase speed of ~1.1 m s^{-1}. With calm winds (< 5 m s^{-1}), similar characteristics were found at distances of up to 240 km from the shelf-break, corresponding to a travel time of more than two days Throughout this time, the solitons could be seen visually and by radar as parallel bands of rough and smooth water of up to 10 km in length with associated lines of floating debris and scum. Records from a towed, undulating CTD-fluorometer system[15,16] also show the presence of large internal waves (Fig. 1*c*, *d*). Within the limits of spatial resolution set by the sampling strategy, the variations in the depth of the subsurface chlorophyll maximum[17] were consistent with the temperature (density) structure. These variations produce large fluctuations in ambient light conditions for the plant cells; for example, given a typical value for the extinction coefficient, k, of 0.08 m^{-1}, the light intensity at the level of the chlorophyll maximum in Fig. 1*d* is estimated to range from ~6.0 to 0.03% of surface values.

Although the echo traces showed no overturning[18] on a vertical scale of the internal wave amplitude, expendable bathythermograph (XBT) temperature profiles through individual waves exhibited occasional temperature inversions (Fig. 2) These temperature profiles are representative of the density profiles, as changes in salinity with respect to depth were both small (~0.05‰ from the surface down to 200 m) and destabilizing. The inversions cannot be interpreted in terms of interleaving between adjacent water masses, as horizontal salinity gradients above and below the pycnocline were also very weak (< 0.01‰ over 10 km). The most probable explanation, therefore, is active vertical mixing, at low Richardson Number conditions, due to the passage of the internal wave[19]. Areas of surface roughness, ~5 m across, in smooth water near the internal wave crests (Fig 3) indicated small-scale turbulent events within the surface mixed layer. Local increases in surface nutrients (NO_3, NO_2, Si; Fig. 4*a*) were also detected as the wave packet passed the ship, similar to nutrient patches observed on the shelf in 1983 (P.M.H., R.D.P. and G.T.M., unpublished data), in association with a large amplitude internal wave packet propagating on the continental shelf[14]. The smoothing effects in the nutrient sampling system are such that the spatial extent of the nutrient patch (Fig. 4*a*) is unresolved and, as far as the instrumentation is concerned, is equivalent to a point source. The ephemeral nature of nutrient changes associated with internal waves was also a feature of measurements from the Southern Californian Bight[4].

All crossings of the shelf break between 20 August and the period of strongest tides on 29–30 August had shown characteristic surface cooling and enhanced chlorophyll fluorescence[17] but

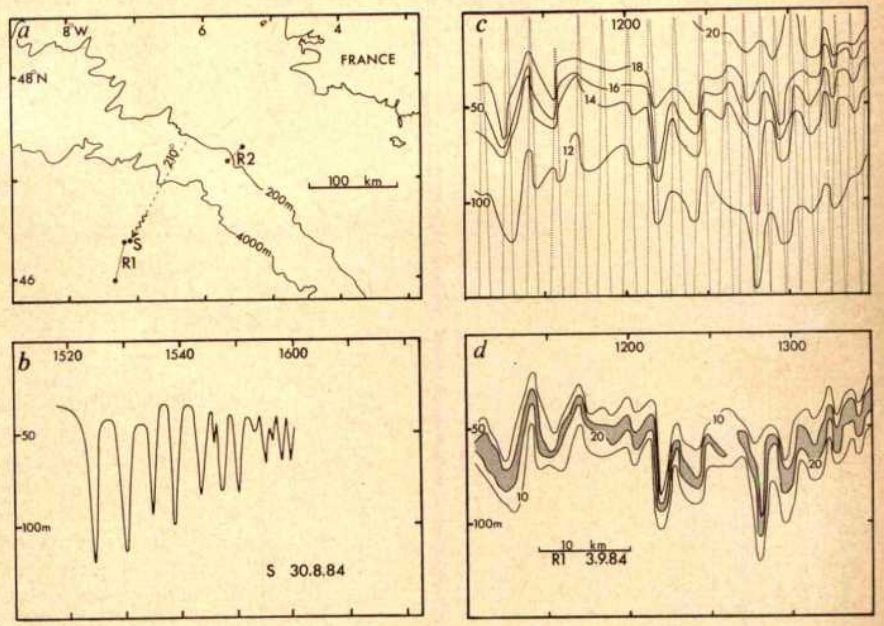

Fig. 1 *a*, Bathymetric map of the northern Bay of Biscay. The wavy arrow indicates the direction of soliton propagation and points to the location (S) of the observations shown in Figs 1*b*, 2, 3 and 4*a*. R1 and R2 are the ship's tracks for the hydrographic records illustrated respectively in Figs 1*c*,*d* and 4*b*. *b*, Depth of the scattering layer (corresponding approximately to the 14 °C isotherm) against time (GMT) at a position ~140 km from the shelf-break (see *a*) as the RRS *Frederick Russell* steamed 020 °T at 5 knots on 30 August 1984. The internal waves are propagating from right to left (in the figure) in a direction 210° as determined from the ship's radar. A XBT section and temperature profiles through the leading wave of the soliton packet are shown in Fig. 2. A surface nutrient pulse was observed at 15:38 GMT (Fig. 4*a*). Water depth is 4,600 m. *c*,*d*, Undulator records for 11:00–13:30 GMT 3 September 1984, showing the distributions of temperature (°C) and chlorophyll fluorescence (arbitrary units) against depth (m). The fluorescence contours correspond to chlorophyll-*a* concentrations of about 0.4 and 0.8 mg m^{-3}. The dotted lines in *c* indicate the path of the towed undulator system.

uniformly low (<0.2-μM) surface nitrate values. On 1–2 September, however, nitrate concentrations up to 1.5 μM were found at a location close to the 200-m contour (Fig. 4*b*), with values >1 μM over a distance of ~7 km normal to the shelf edge corresponding to a band of cold water. Throughout this period winds were weak (<5 m s^{-1}) and variable in direction, indicating that the increase in surface nutrients close to the shelf-break resulted from the cumulative and continuous effects of strong tidal streams and internal wave activity rather than from wind-induced upwelling[20].

During the summer months, the coupled effects of tides and wind promote vertical mixing within the relatively shallow (<200-m) water column on the continental shelf. By contrast, in the deep water environment of the Bay of Biscay, bottom mixing by tides is irrelevant and the effect of wind-mixing above a relatively deep pycnocline (~50 m, Fig. 1*c*) is much reduced so that vertical nutrient fluxes across the seasonal pycnocline are relatively weak[10]. Furthermore, the subsurface chlorophyll maximum acts as a sink for nutrients mixed upwards from below the pycnocline[21]. Under these conditions phytoplankton growth in the surface waters tends to be restricted by the rate of nutrient supply from biological regeneration processes[11,22,23]. The occurrence of the observed density inversions, surface nutrient patches and surface turbulence features in association with solitons indicates that mixing by internal waves is an important physical mechanism for maintaining upward fluxes of nutrients (another mechanism may be mesoscale eddies[24]) as has been suggested[5] for the North Pacific gyre. This is likely to be particularly significant at the level of the subsurface chlorophyll maximum in the pycnocline, where mixing by internal waves will produce more frequent nutrient pulses than are encountered at the sea surface.

Mixing by spring-tide solitons will be repeated at fortnightly intervals throughout the summer and influence phytoplankton

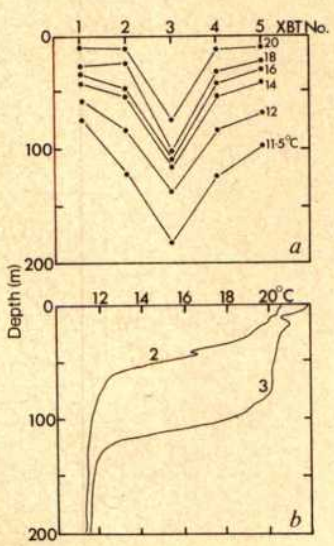

Fig. 2 *a*, Expendable bathythermograph (XBT) section across the first wave in the soliton packet illustrated in Fig. 1*b*. *b*, XBT profiles through the leading wave of the soliton packet showing temperature inversions.

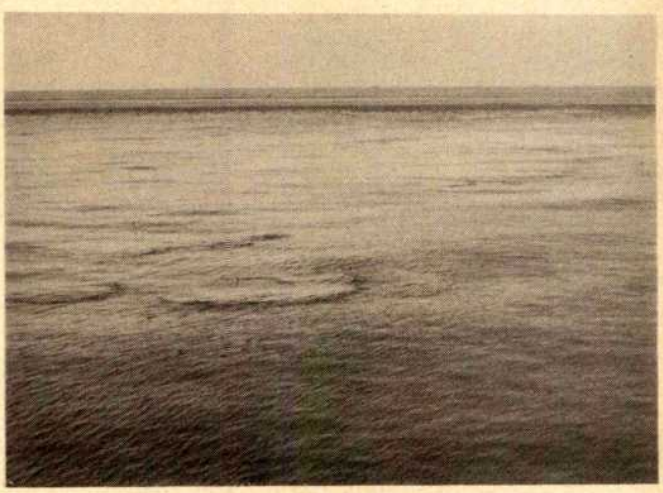

Fig. 3 Sea surface state at position S (Fig. 1*a*) within soliton packet (Fig. 1*b*) at 15:00 GMT, 30 August 1984. Rough water, corresponding to the internal wave troughs, appears as dark bands towards the horizon. Surface layer turbulence is shown as disturbed patches, ~5 m across, in the foreground. Water depth is 4,600 m.

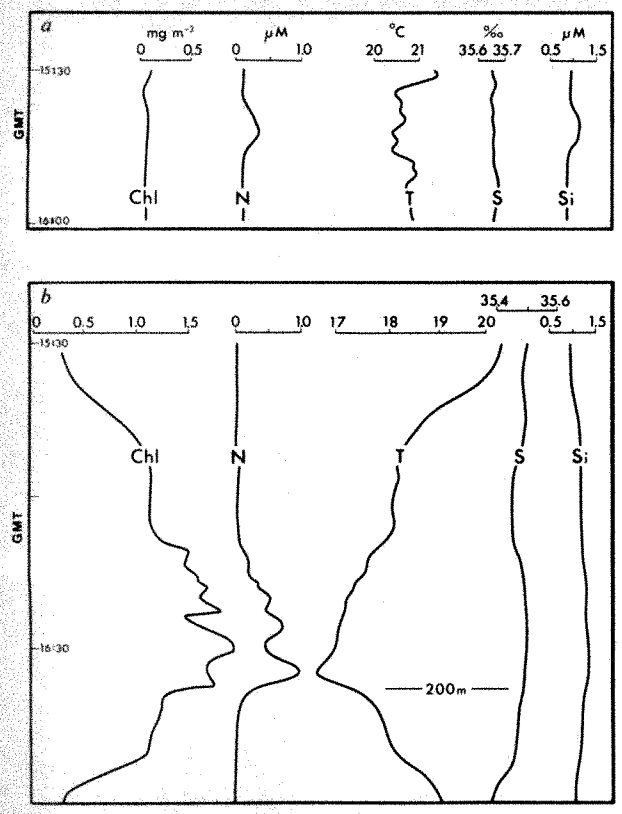

Fig. 4 Continuous surface (3.5-m) records of chlorophyll-*a* (Chl. mg m^{-3}) nitrate (N, μM), temperature (*T*, °C), salinity (*S*, ‰) and silicate (Si, μM) for *a*, position S, 15:30–16:00 GMT, 30 August 1984, and *b*, track R2, 15:30–17:00 GMT, 2 September 1984, crossing the shelf-break at 16:37 GMT. The ship's positions are shown in Fig. 1*a* and in both cases the ship was heading in a southwesterly direction.

growth in the thermocline at great distances from the shelf-break. The horizontal extent of this effect will vary because of interaction with wind mixing and changes in the depth of the thermocline resulting from the generation of near inertial oscillations[25]. At times of stronger winds, it is anticipated that mixing events due to instabilities associated with the passage of internal waves will occur more frequently and the nutrient pulses will then be more concentrated in the slope region.

We thank John Smithers, Bob Longmore and the Research Vessel Services Computing Group for assistance at sea.

Lake acidification in Galloway: a palaeoecological test of competing hypotheses

Richard W. Battarbee*, Roger J. Flower*, Anthony C. Stevenson* & Brian Rippey†

* Palaeoecology Research Unit, Department of Geography, University College London, 26 Bedford Way, London WC1H 0AP, UK
† Limnology Laboratory, The University of Ulster, Traad Point, Magherafelt, Co. Derry BT45 6LR, UK

Possible causes of lake acidification in Britain include acid precipitation, heathland regeneration, afforestation and post-glacial natural acidification (long-term change). In Galloway, south-west Scotland, several lakes with non-afforested catchments have been acidified by approximately 1 *p*H unit since about 1840[1,2], which clearly precludes long-term change and afforestation as causes of the present acidity, but does not discriminate between the possible effects of heathland regeneration and acid precipitation; it *could* be argued that a decline in upland farming in this area led to an increase in acid heathland communities capable of promoting lake acidification during this period of time. Here we use pollen analysis to show that there is no evidence for an increase in *Calluna vulgaris*, the most important heathland species, over the past 200 yr or so, and we substantiate the acid precipitation hypothesis by demonstrating substantial increases of the heavy metals Pb, Cu and Zn in the sediment since about AD 1800.

Surface water acidification has been variously ascribed to the effects of acid precipitation[3], land-use change[4], afforestation[5,6] and long-term change[7], the importance of which can be assessed by palaeoecological techniques. We consider the last two of these processes first.

Long-term acidification is well known, having been recognized in Scandinavia[8–11], Britain[12–15] and North America (ref. 16 and J. Ford, unpublished results). In Britain it has been suggested that this process is the cause of contemporary acidity in upland tarns of the English Lake District and that certain lakes were so acidic by 1800 that no further change can have occurred since then[7]. Although this supposition has not yet been examined in the context of the Lake District, it is clear that the present acidity of lakes with granitic catchments in Galloway cannot be explained in this way; diatom analysis indicates that rapid acidification of these lakes has occurred since about 1840, after long periods of stability[1,2].

Recent afforestation, although responsible for accelerated soil erosion[17] and other undesirable ecological changes, is also of little significance as lakes with non-afforested catchments were

Table 1 Physical and chemical characteristics for Loch Enoch

Altitude (m)	493	
Lake area (ha)	50	
Catchment area (ha)	186	
Catchment: lake area	3.7	
Maximum depth (m)	~36	
Temperature (°C)	7.0 (4.4)	
Conductivity (μS_{18} cm^{-1})	30.0 (8.0)	37*
*p*H (range)	4.4–4.7	4.5*
H^+ (μeq l^{-1})	28.9 (6.8)	28
Na^+ (μeq l^{-1})	58.3 (24.4)	126
K^+ (μeq l^{-1})	6.7 (4.6)	6
Ca^{2+} (μeq l^{-1})	10.5 (3.5)	21
Mg^{2+} (μeq l^{-1})	16.5 (7.2)	37
Al (μeq l^{-1})	10.0 (4.4)	16
Cl^- (μeq l^{-1})	100.9 (18.0)	146
SO_4^{2-} (μeq l^{-1})	44.5 (12.9)	89

Numbers in parentheses indicate standard deviations for the mean values calculated from eight measurements made between November 1981 and November 1982. The catchment area excludes lake area.
* Data in the last column are from ref. 33.

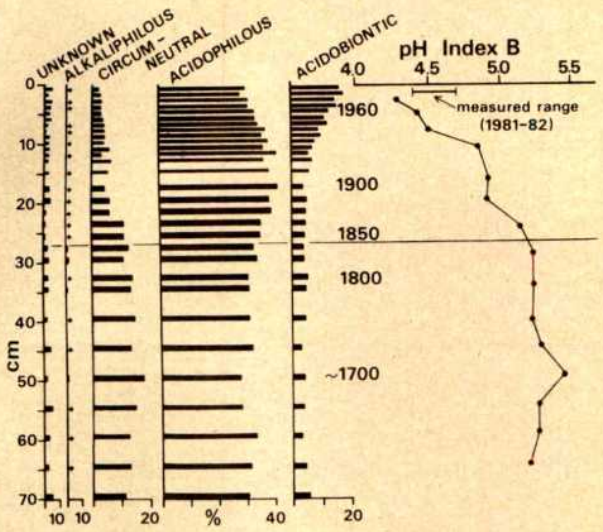

Fig. 1 Summary diatom diagram from Loch Enoch showing changes in the proportions of the various *p*H groups through time. Dominant taxa are as follows: (1) circumneutral, *Anomoeoneis vitrea* (Grun.) Ross; (2) acidophilous, *Eunotia veneris* (Kütz). O. Müll., *E. alpina* (Naeg.) Hust., *Tabellaria flocculosa* (Roth.) Kütz., *Frustulia rhomboides* v. *saxonica* (Rabh.) de Toni; (3) acidobiontic, *T. quadriseptata* Knudson, *T. binalis* (Ehr.) Grun., *Navicula höfleri* Cholnoky. Dates are based on ^{210}Pb measurements[17], and *p*H is reconstructed using index B[11]. Horizontal line signifies point of change.

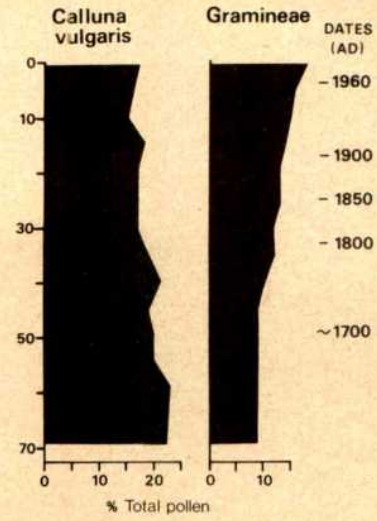

Fig. 2 Proportions of *C. vulgaris* and Gramineae pollen from the Loch Enoch sediment core.

acidified, and those with afforested catchments began to be acidified, in the late nineteenth and early twentieth century, well before the beginning of afforestation[1].

A hypothesis involving change in land use has been proposed to explain recent lake acidification in Norway[4,18]. It maintains that acidity generated by soil processes is substantially greater than that received from atmospheric deposition and that an increase in the formation of acid humus in soils as a result of a decline in upland agriculture is likely to be of more significance than an increase in the acidity of precipitation.

In Galloway it may be expected that a similar decline in grazing would lead to the greater dominance of *C. vulgaris* in particular, and to a regeneration of heathland communities in general[19]. This hypothesis would be rejected if it could be shown that such a land-use change was absent or was inadequate to explain the observed acidification of the lakes concerned, and we would then need to evaluate the acid precipitation hypothesis.

To carry out these tests we have used diatom analysis, pollen analysis and trace metal analysis of a dated lake sediment core from Loch Enoch, a 50-hectare, 36-m deep multi-basin lake situated at an altitude of 493 m on the Merrick in the Rhinns of Kells region of Galloway. The catchment is non-afforested and the vegetation is dominated by *Molinia caerulea* and *C. vulgaris*.

We obtained a sediment core from the centre of the south-east basin of the lake and determined a linear sediment accumulation rate of ~1 mm yr^{-1} using ^{210}Pb analysis[17]. Diatom analysis shows the onset of recent acidification at ~30 cm, dated to about 1840 (Fig. 1). The index B *p*H reconstruction[11] gives a *c.*1840 *p*H of 5.2 and a present *p*H of 4.3, slightly more acidic than the measured range of *p*H values (see Table 1). The strong increase in acidobiontic diatoms registered in the diagram (Fig. 1) include *Tabellaria binalis* (Ehr.) Grun. and *Tabellaria quadriseptata* Knudson, species that typically increase in a similar way at other sites in the region[1,20].

If acidification was caused by a change in land use in the catchment of the lake, in accordance with the above hypothesis, we would expect historical records to show a decline in grazing and consequent regeneration and expansion of heathland on approximately the same timescale. As records of sheep numbers over the past 150 yr are available only for large administrative regions[21], it is more appropriate to test this prediction using pollen analysis of the lake sediment core itself. This has been performed using standard procedures[22] on samples selected at 5-cm intervals from the top of the core. The full pollen diagram shows very little change over the past 200–300 yr, except in the relative proportions of *C. vulgaris* and Gramineae, the taxa of greatest interest (Fig. 2). However, rather than an increase in *C. vulgaris*, as would be expected were the land-use hypothesis valid at these sites, there is a gradual decrease in this species and a reciprocal expansion of Gramineae; similar results have been obtained from the analysis of cores from other lakes in the area both in terms of percentage and flux change (unpublished results). These results are not unexpected as they agree with contemporary observations that all the non-afforested lake catchments in this area are grazed and repeatedly burnt over, a process that in the west of Scotland favours *M. caerulea* and keeps *C. vulgaris* young and palatable for both cattle and sheep[23].

Having rejected three hypotheses for the recent acidification of Loch Enoch, we retain only the acid precipitation hypothesis. This hypothesis would be questionable if we could not show that Loch Enoch and other similar Galloway lakes have received atmospheric pollutants that may be associated with industrial emissions. We therefore analysed the trace metal content of the sediments (Fig. 3).

Total sedimentary Zn, Cu and Pb concentrations were determined by flame atomic absorption after $HF/HNO_3/HClO_4$

Table 2 Background sedimentary concentrations, fluxes and recent fluxes of Zn, Cu and Pb in a sediment core from Loch Enoch

	Zn	Cu	Pb
Background concentration, μg g^{-1}	25.4	6.2	74.6
Standard deviation (less than 32 cm depth, $n = 12$)	7.4	4.6	23.3
Background sedimentary flux, mg m^{-2} yr^{-1} (average value for 32–61 cm)	6.1	1.5	17.8
Recent sedimentary flux, mg m^{-2} yr^{-1} (average value for 0–10 cm)	35.5	8.3	67.0
Anthropogenic sedimentary flux, mg m^{-2} yr^{-1} (recent, background flux)	29.4 (83)	6.8 (82)	49.2 (73)

Calculations were made using trace metal concentrations (Fig. 3) and sediment wet density, dry weight and accumulation rate (ref. 21). Numbers in parentheses indicate % anthropogenic flux of total metal influx.

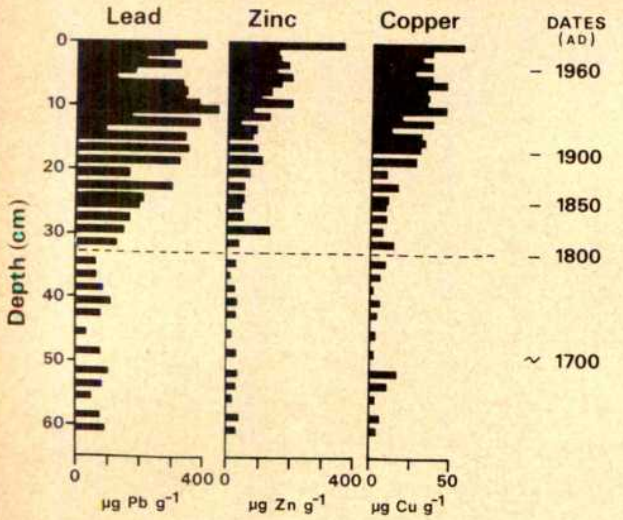

Fig. 3 Concentrations of Pb, Zn and Cu from the Loch Enoch sediment core. Dotted line signifies point of change.

digestion, the precision of the results are, respectively, 4.7, 0.9 and 3.8 μg g^{-1} ($n = 14$). The background concentrations (Table 2) show that there are no geochemical anomalies in the catchment. The slightly lower Cu and Zn and somewhat higher Pb concentrations, compared with the mean for freshwater sediments[24], are a result of the granites in the catchment[25]. The increased concentrations (Fig. 3) and sedimentary fluxes (Table 1) can be accounted for by increased deposition from the atmosphere[26], a situation common in remote and rural lakes[27–29]. It has been shown that atmospheric contamination of lake waters by trace metals is correlated with acidification[30,31], and that contamination of sediments is correlated with sedimentary evidence of acidification[26,27,32]. This latter relationship holds true for Loch Enoch and all these relationships are consistent with expectations derived from the acid precipitation hypothesis.

We cannot prove that an increase in acid deposition was responsible for the acidification of Loch Enoch and similar lakes in Galloway, but we have shown that alternative hypotheses, as presently formulated, are inadequate. Land-use change may play a part in other areas, but at present it is clearly not applicable to the Galloway sites. For this hypothesis to be tested by palaeoecological means, examination of an acidified site in an area of low acid deposition, where heathland regeneration has occurred concurrently, is required.

We thank the Central Electricity Generating Board for funding this work, CERL, Leatherhead, for carrying out chemical analyses of Loch Enoch water samples, Stuart Phethean for help with fieldwork, Kevin Odell for radiometric data, Peter Appleby for ^{210}Pb computations, and Richard Skeffington and Gwyneth Howells for comments on the manuscript.

Sediment and pollen evidence for an early to mid-Holocene humid period in the eastern Sahara

J. C. Ritchie*, C. H. Eyles† & C. V. Haynes‡

* Scarborough Campus and †Department of Geology, University of Toronto, Scarborough, Ontario, Canada M1C 1A4
‡ Departments of Anthropology and Geosciences, University of Arizona, Tucson, Arizona 85721, USA

A major problem in the study of Holocene palaeoenvironments of the arid and wind-deflated Sahara is the low preservation potential of sediments from which a record of past climatic change can be established. Several indirect and imprecisely dated pieces of evidence have suggested humid episodes in the Holocene that may have supported more productive ecosystems and denser human populations than today. Searches for reliable proxy data on past climates, however, have failed to yield satisfactory results. We report here the discovery of buried lake muds in north-west Sudan, in the hyperarid core of the Eastern Sahara, which yield sedimentological and palynological data clearly interpretable as recording an early to mid-Holocene humid episode that supported a relatively-deep stratified lake surrounded by tropical savanna woodland vegetation.

The site lies in the Oyo Depression in NW Sudan at 19°16′N and 26°11′E, 510 ± 20 m above sea level (Fig. 1). The depression is surrounded by bedrock and contains Holocene lacustrine sediments buried by variable depths of dune sand[1]. It lies in the hyperarid core of the Sahara, with an estimated mean annual rainfall of ~5 mm (ref. 2), northerly winds with mean daily average velocity of 2–20 km h^{-1}, daily average relative humidity of 20–60% and estimated evaporation rates of ~5 m yr^{-1} (ref. 3). The area is in the zone of absolute desert vegetation whose southern limit is ~500 km south of the site[4] (Fig. 1). Vegetation is confined to oases, supported by artesian water, and to wadi channels where episodic rainstorms produce transient communities of annuals and herbaceous perennials[4].

Table 1 Radiocarbon dates from the Oyo sediments

Site and depth from surface (cm)	Material analysed	Radiocarbon laboratory number	Age (yr BP)
Hole-6, 170–180	Algal sapropel	SMU-1232	4,920 ± 200
Hole-6, 270–280	Algal sapropel	SMU-1233	5,880 ± 80
Hole-6, 310–320	Algal sapropel	SMU-1231	6,100 ± 80
Hole-6, 460–470	Algal sapropel	SMU-1230	8,490 ± 90
Hole-6, 460–470	Charcoal	AA-253	8,030 ± 280
Auger-1, 460	Charcoal	A-2826	8,900 ± 120
Auger-1, 180	Algal sapropel	A-2820	4,590 ± 140
Well-2, 200	Charcoal	A-2951	8,720 ± 170

The auger-1 site samples were collected from the basin sediments 150 m north-west of the hole-6 pit; the well-2 charcoal sample was recovered from the base of the Zone I sediments exposed in a hand-dug well 260 m west of the hole-6 pit, at a depth of 200 cm from the surface, near the margin of the basin. The analyses were conducted at the Radiocarbon Laboratory of Southern Methodist University, Texas (SMU) and at the Arizona National Science Foundation Regional Facility for Accelerator Mass Spectrometry, Tucson, Arizona (A).

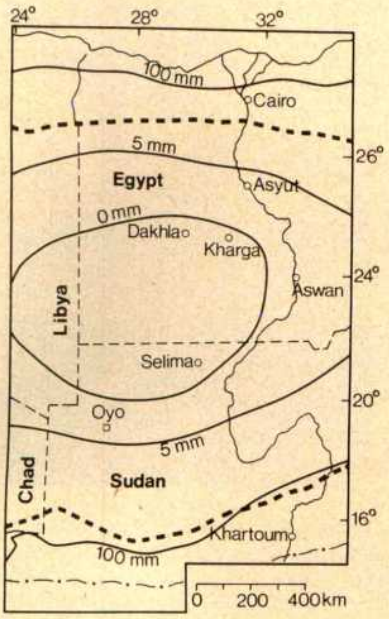

Fig. 1 Map of the Eastern Sahara region showing the location of the Oyo site, the 0, 5 and 100-mm mean annual precipitation limits (after Dubief[2]), the northern and southern limits of absolute desert (- - -) and the northern limit of the savanna (-·-·-·-) (both after White[4]).

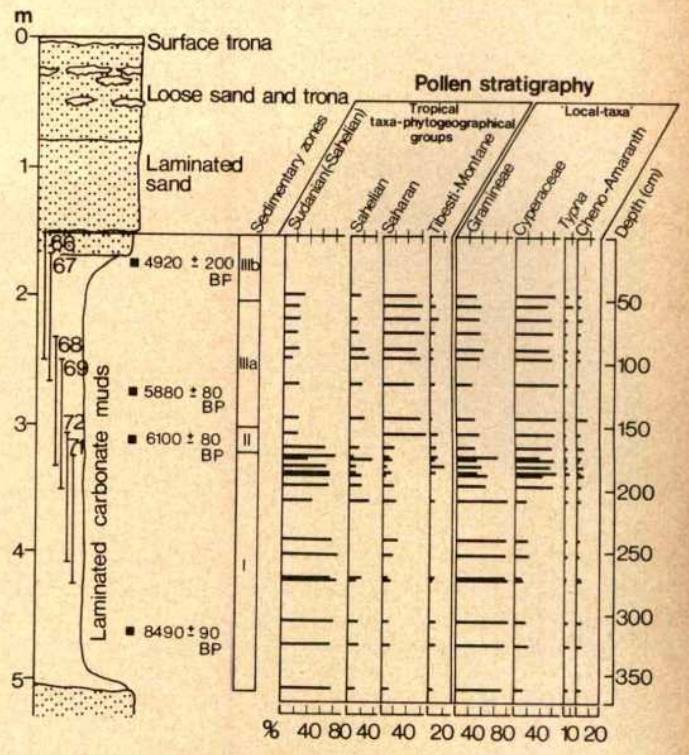

Fig. 2 A summary diagram showing the sediment stratigraphy, positions of the hole-6 1-m tray samples (numbered), positions and values of the radiocarbon age estimates and the pollen stratigraphy of the main groups. The phytogeographical pollen groups are expressed as percentages of the tropical taxa and the sum of the local taxa is the pollen total for the 'local' percentages.

The sample site is in a small basin, ~1.0×0.5 km in size, in a 2-km wide depression open to the south-west and bounded by sandstone escarpments. The sediments were discovered in 1980 and sampled in 1982 and 1983, by hand augering and by digging a 5-m deep pit (hole-6 pit) in the centre of the basin[1]. Undisturbed overlapping 1-m lengths of sediment were recovered from the pit face in aluminium trays each 5 cm in width and depth. The lowest levels were collected by discontinuous bulk sampling because groundwater made tray sampling impossible. Four levels in hole-6 pit and three from nearby auger holes were dated by radiocarbon analysis (Fig. 2, Table 1). The radiocarbon dates of algal sapropel can be considered to be maximum values because of the possibility of error due to older carbonates. The charcoal from the 460–470-cm level in hole-6, dated by the tandem accelerator mass spectrometer (TAMS), indicates a potential discrepancy, but the large standard deviation precludes any firm conclusions about the magnitude of the carbonate error.

Sedimentological analysis suggested that the sequence can be divided into three major zones[5]. Zone I consists predominantly of finely laminated (0.1–1.0-mm) carbonate muds interbedded with sequences of pure white and grey laminae, dark organic bands and bioturbated horizons. The finely laminated muds are composed of green/brown and cream microcrystalline dolomite with trace amounts of clay minerals. Annual deposition of these couplets is suggested by comparing sedimentation rates estimated from ^{14}C dates (Fig. 2; 1 cm every 11–15 yr) with the counted average of 13 couplets cm^{-1}. Units of pure white and grey laminations consist predominantly of calcite with minor amounts of quartz and dolomite and are always associated with dark organic-rich bands composed of algal remains (Fig. 3).

Zone I sediments indicate carbonate deposition in a stratified lake with stagnant bottom waters[6–8]. The predominance of dolomite with an olive-green colour and absence of burrowing organisms through most of this zone suggests reducing conditions, characteristic of arid perennial lakes receiving a restricted seasonal supply of fresh water[8]. The association of white and grey laminations, organic bands and bioturbated horizons (Fig. 3) suggests that episodic increased inflow of calcium-bearing freshwater into the basin and/or temperature fluctuations are responsible for triggering calcite precipitation, algal blooms and weakening of the halocline.

Zone II sediments consist of laminated carbonate muds similar to the green/brown and cream laminations of zone I but with irregularities in thickness, abundant soft sediment deformation structures and evidence of downslope resedimentation and slumping of sediment blocks. Such increased sediment instability may have been caused by lowered lake levels.

Zone III consists of a coarsening upwards sequence of highly deformed muds and sands. The deformed and crudely bedded dolomitic muds of zone IIIa contain significant amounts of windblown sand, which may indicate shallowing of the lake body. Final desiccation is indicated by the crudely bedded and bleached aeolian sands of zone IIIb (Fig. 2).

So far, 55 pollen taxa have been recorded (by J.C.R.) in the sediments, belonging to the following phytogeographical groupings[9–12]: (1) Sudano-Sahelian taxa, found today in the tropical savannas of north-central Sudan and adjacent territories of Africa; (2) Sahelo-Saharan taxa with modern distribution in the thorn scrub and herbaceous desert belt of North Africa; (3) Saharan taxa, today confined to the Sahara and adjacent Arabian deserts. (These tropical taxa ((1)–(3) above) are listed in Table 2.) (4) Tibesti-Montane elements, so designated because the nearest pollen source is the Tibesti Massif, represented here by *Artemisia*, *Ephedra* (two types) and *Erica arborea*; (5) Mediterranean taxa, represented by rare occurrences in a few levels of *Betula*, *Picea*, *Pinus* and *Quercus*; and (6) a group of taxa of uncertain geographical affinity (Gramineae, Cyperaceae, *Typha*, Compositae–Asterae, Compositae–Fenestratae, Chenopodiaceae–Amaranthaceae, Leguminosae and *Myriophyllum*). Many of the tropical taxa are plants with low pollen productivity (for example *Piliostigma*, *Grewia*) and, in addition, several produce large (>60-μm) pollen grains with low dispersal capacity (*Acacia*, *Abutilon*, *Delonix*, *Hibiscus*, *Commicarpus*, *Grewia tenax* and *Pavonia*); thus, although they occur in low concentrations (100–500 grains ml^{-1}), their presence, in a state of excellent preservation, suggests that the source plants were close to, or in, the sedimentary basin.

Table 2 Tropical pollen taxa recovered from the sediments, grouped according to their phytogeographical affinities

Sudanian (-Sahelian)	Sahelian (Sudanian)	Saharan
Acacia cf. *sieberana*	*Abutilon*	*Aerva*
Borreria radiata	*Acacia* cf. *nilotica*	*Cleome*
Boscia	*Acacia* cf. *senegal*	*Maerua*
Cadaba	*Acacia* cf. *seyal*	*Salvadora*
Celtis integrifolia	*Acacia* cf. *raddiana*	*Tamarix*
Chlorophytum	*Atractylis*	
Commicarpus	*Balanites*	
Commiphora	*Blepharis*

Grewia cf. *tenax*	*Capparis*	
Hibiscus (2 taxa)	*Cassia*	
Lannea	*Chroxophora*	
Pavonia	Combretaceae	
Piliostigma cf. *thonningii*	*Corchorus*	
Piliostigma cf. *reticulatum*	*Ottelia*	
Ruellia	*Phyllanthus maderspatensis*	
Zizyphus	*Polygala* cf. *erioptera*	

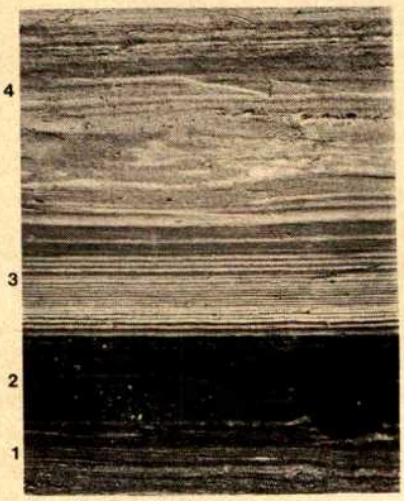

Fig. 3 Segment of Zone I (188–193 cm) sediments, showing: (1) finely laminated green/cream dolomite-rich muds; (2) finely laminated dark organic unit; (3) pure white/grey laminae, thinning upwards; (4) bioturbated laminated muds. Sample hole is 1 cm in diameter.

Gramineae and Cyperaceae, the dominant taxa in all samples, have pollen concentrations between 10,000 and 60,000 grains ml^{-1}, indicating both a regional and local component.

The pollen stratigraphy shows a close correlation with the sediment zones (Fig. 2). The lower levels, 360–170 cm, exhibit a predominance, among the tropical taxa, of Sudano-Sahelian elements of which *Grewia tenax* and *Piliostigma*, both tree taxa characteristic of the modern deciduous savanna zone, are notable. Zones II and III of the sediment column are characterized by an abrupt increase in Sahelian and Saharan elements, typical of modern Sahelian savannas and thorn scrub vegetation. A significant change in the proportions of Gramineae and Cyperaceae occurs at approximately the Zone I/II boundary (Fig. 2). This change is difficult to interpret, but the relative increase in Cyperaceae could have been caused by a lowered lake level producing a larger marginal marshy zone; alternatively, part of the increase may have been the result of an expansion of such important dune taxa as *Cyperus conglomeratus*.

The sediment, pollen and radiocarbon data from this site indicate (1) that between 8,500 and 6,100 yr BP the Oyo depression supported a relatively deep stratified lake with stagnant bottom water and annual inputs of fresh water, surrounded by a continuous deciduous savanna vegetation, similar to that found today ~500 km to the south; (2) that at about 6,000 yr BP a reduction in precipitation and/or an increase in evaporation initiated a shallowing of the lake; and (3) that between 6,000 and 4,500 yr BP the lake became still shallower and the tropical Sudano-Sahelian savannas were replaced by *Acacia*-thorn savanna and scrub-grassland. Finally, at 4,500 yr BP the lake basin dried out and was covered subsequently by aeolian sediments, whereas the vegetation, in the form of desert scrub-grasslands, disappeared from all habitats except at oases and wadis.

The Holocene lake at Oyo was probably groundwater supported, as at Merga Lake, 40 km to the south-east, today[13]. Recent isotope investigations of shallow groundwater in the region support a model of direct recharge[14–16] through the oases depressions, as opposed to subsurface flow over great distances, such as from the Enedi highlands in the case of Oyo.

The palaeoclimates suggested by the above conclusions are: for Zone I, a humid tropical climate with annual monsoonal rainfall of at least 400 mm; for Zones II and III, a progressive increase in aridity with annual precipitation declining from 300 mm at 6,000 yr BP to <100 mm at 4,500 yr BP. These reconstructions corroborate previous conclusions based on evidence from laminated lake sediments[17–20], East Mediterranean sapropels[21], geomorphology and archaeology[22,23] and Nile River flood history[24]. Our results provide the first conclusive demonstration of vegetation and climate change in the early to mid-Holocene of the eastern Sahara. They agree with tentative conclusions of Maley[25–27] for the distant Lake Chad record, with the general Holocene lake level trends for north-east Africa[28,29] and with changes in the position of the African monsoon predicted on the basis of Milankovitch orbital forcing factors[30,31]. Detailed sediment, radiocarbon and pollen analyses of the Oyo deposits will be reported elsewhere.

The fieldwork was supported by funds (to C.V.H.) from the NSF (Grant EAR-8312651), the National Geographical Society and the Smithsonian Institute Foreign Currency Program; C.V.H. thanks Dr Bahay Isawi of the Geological Survey of Egypt for his cooperation, the Department of Geological and Mineral Resources of the Sudan for field support and Donald L. Johnson, John W. Olsen and Ahmed Swedan for help in the field; the TAMS radiocarbon dates are provided by the Arizona-NSF Regional Facility for Accelerator Mass Spectrometry. We thank the Natural Sciences and Engineering Research Council of Canada for a Postgraduate Scholarship (C.H.E.) and an operating grant (A6320) (J.C.R.) and Mme Daneille Duzer and Dr Jean Maley for help with the palynological analyses while J.C.R. was at the Laboratoire de palynologie, CNRS, Montpellier, France (visit arranged by Mme M. Van Campo). We also thank Keith Bennett, Les Cwynar, Nick Eyles and Tim Barrett for helpful comments, and K. A. Hadden for technical assistance.

A terrestrial fauna from the Scottish Lower Carboniferous

S. P. Wood*, A. L. Panchen† & T. R. Smithson†

* 'Mr Wood's Fossils', Unit 8, Abbotsford Rise, Livingston, West Lothian EH54 6QD, UK
† Department of Zoology, The University, Newcastle upon Tyne NE1 7RU, UK

Despite several important discoveries, extending over more than 120 years, our knowledge of early land vertebrates is still sparse. The earliest tetrapod remains are known from the Upper Devonian of East Greenland[1–3] and Australia[4–6], but the tetrapod fossil record does not become plentiful until Coal Measure times, in the Upper Carboniferous, some 50 Myr later. Finds in the Lower Carboniferous are very few indeed. Apart from two localities in West Virginia, USA[7,8], and one in Nova Scotia, Canada[9], all other Lower Carboniferous tetrapod sites are from the Viséan of Fife and the Lothian Region, Scotland[10,11]. We report here the discovery of an assemblage of terrestrial animals from a new Lower Carboniferous locality in the Lothian Region. Specimens were collected from the East Kirkton Limestone in the Brigantian stage of the Scottish Viséan, and include the first articulated amphibian skeleton to be found in the Lower Carboniferous of Europe in the twentieth century. This find is the earliest well-preserved amphibian skeleton ever discovered. The associated fauna is remarkable for the presence of myriapods, scorpions, the earliest known harvestman and several other types of amphibian. The presence of such forms, together with the striking absence of fishes, suggests that the amphibians form an integral part of a terrestrial fauna; terrestrial amphibians are otherwise unknown before the Upper Carboniferous Coal Measures.

The earliest Lower Carboniferous tetrapod sites are in the Oil Shale Group (Fig. 1), and the fauna consists of the aïstopod *Lethiscus*[12], the colosteid temnospondyl *Pholidogaster*[13] and a form of unknown affinities, *Doragnathus*[14]. There is also a series of specimens, including three incomplete skeletons, which are attributable to the Adelogyrinidae[15]. The principal amphibian find reported here is not attributable to any of these taxa. The site from which it comes is a new one in the Lothian Region. The specimen was found in the East Kirkton Limstone in sediments originating from the East Kirkton Quarry, near Bathgate, West Lothian. The limestone is very localized and separated by the Riccarton Hills Lavas from the overlying Hurlet Limestone, which marks the boundary between the Upper Oil Shale Group and the Lower Limestone Group (Fig. 1)[16]. The underlying Bankhead Tuffs separate it from the Raeburn Shell Bed, which in West Lothian probably forms the base of the Brigantian[17].

In striking contrast to other Scottish Mississippian tetrapod localities, there is a complete absence of fish remains at this horizon. The matrix in which the amphibians were found is a peculiar laminated cherty limestone[18], and initial associated discoveries suggest a unique environment of deposition. Most notable among these is what appears to be the earliest known fossil harvestman (Arachnida: Opiliones)[19] (Fig. 2). A number of myriapods and scorpions have also been found. Together with these small arthropods are several incomplete specimens

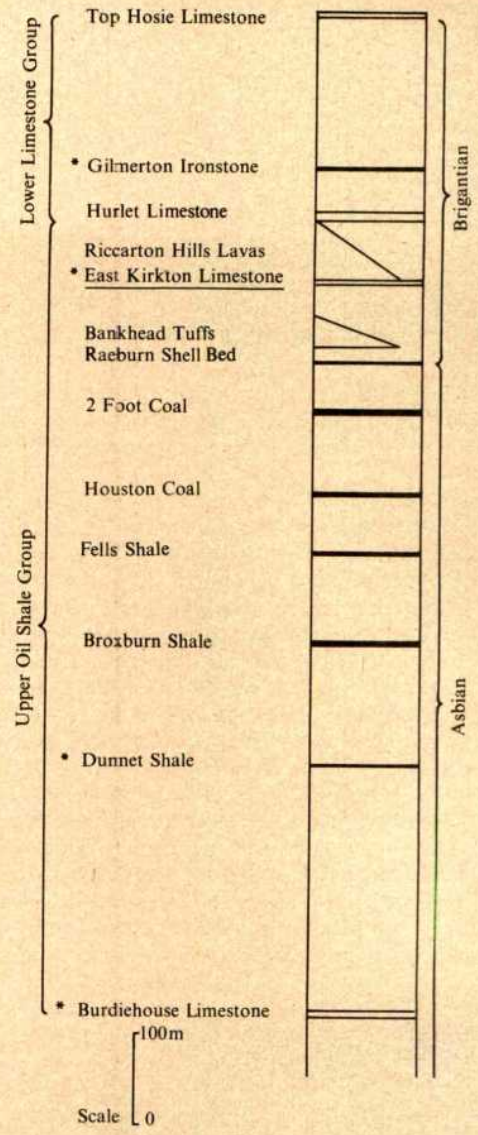

Fig. 1 Generalized section of the Upper Viséan of West Lothian, Scotland (after Geological Survey of Great Britain (Scotland), Sheet 32W). *Amphibian horizons.

Fig. 2 Fossil harvestman (Opiliones) from the East Kirkton Limestone (SPW: G480). Natural size.

of gigantic eurypterids. *Hibbertopterus scouleri* has already been described from the East Kirkton Limestone[20], but the new material cannot be referred to any Scottish Lower Carboniferous species.

The principal find (field no. SPW: 2042 A/B) consists of a tetrapod skeleton of some 40 cm overall length. It is preserved in part and counterpart on two blocks of limestone. The principal block (Fig. 3) shows the skeleton as it was when originally collected. The skull, vertebral column, girdles and limbs are all in natural articulation and the specimen is completed by the tail, which is defined by its investing scales. The specimen is remarkable for the intact preservation of the hands and feet, with ossified carpals and tarsals, and should greatly augment our understanding of the early evolution of the tetrapod limb.

The skull is similar to those of edopoid and dissorophoid temnospondyls from the Upper Carboniferous and Lower Permian[21,22]. The orbits and interpterygoid vacuities are relatively large, the otic notches are distinct and there is no visible trace of a lateral line canal system. However, the sutures between the bones of the skull roof and palate are difficult to trace and a detailed study will be necessary before the relationships of this new species can be established. The vertebrae appear to be of the primitive temnospondyl type, with separate intercentra and pleurocentra surrounding a persistent notochord. The general morphology of the appendicular skeleton is also similar to that of temnospondyls, with a four-digit manus and five-digit pes, but the structure of the carpus and tarsus, as well as the phalangeal formulae of the hands and feet, remain to be determined. Six other specimens from the East Kirkton Limestone are provisionally attributed to this species. They include a skull of similar size to that of the complete skeleton (Fig. 4), a pelvis with paired hind limbs, and two incomplete skeletons.

A second temnospondyl species is represented in the fauna by an incomplete and poorly preserved skeleton. It differs from the complete skeleton illustrated in Fig. 3 in being much shorter-bodied and with limbs of different proportions. Anthracosaur amphibians have also been found. Caudal vertebrae, similar to those of *Proterogyrinus*[23], have been collected, together with two incomplete humeri which resemble closely those of *Eoherpeton*[24].

There is no sign in the complete amphibian skeleton of an aquatic mode of life; lateral-line canals seem to be absent and the skeleton, particularly that of the limbs, is remarkably heavily ossified. This is also true of the other amphibian remains, and, in the light of the associated arthropods, it seems probable that they represent the only known pre-Coal Measure terrestrial vertebrate fauna. Complete preparation and description of this new material is under way, but will take some time. Meanwhile, we anticipate that further exploration of the East Kirkton Limestone will yield more evidence of the early Carboniferous land fauna. It is hoped that this will result in the discovery of the forerunners of the many amphibian groups which appear suddenly in the Upper Carboniferous. We do not exclude the possibility of the discovery of the earliest reptiles.

We thank Drs C. Burton and W. D. I. Rolfe (Glasgow University) for identifying the fossil arthropods and Dr A. R. Milner (Birkbeck College) for valuable criticism of the manuscript.

Multiple innervation of tonic endplates revealed by activity-dependent uptake of fluorescent probes

Jeff W. Lichtman, Robert S. Wilkinson & Mark M. Rich

Department of Physiology and Biophysics, Washington University School of Medicine, 4566 Scott Ave., St Louis, Missouri 63110, USA

During development of the vertebrate nervous system, there is a widespread reduction in the number of axons innervating target cells[1]. This phenomenon, often called synapse elimination, has been particularly well studied at the neuromuscular junction of developing twitch muscle fibres[2,3]: following a period of polyneuronal innervation, axonal branches are retracted, usually leaving each twitch fibre endplate innervated by only one axon. Here we describe a new technique for the study of synapse elimination—activity-mediated uptake of fluorescent probes. These probes selectively and supravitally label all the terminals of individual axons. The technique is used here in adult and embryonic snakes to study the innervation pattern of a thin muscle containing two fibre types: twitch fibres, which are fast-contracting and have propagated action potentials, and tonic fibres, which are slow-contracting and lack action potentials. We find that twitch muscle fibres, as expected, eliminate all polyneuronal innervation during development; in contrast, tonic fibre endplates remain polyneuronally innervated into adulthood. The persistence of multiple innervation at tonic endplates may be related to the lack of action potential activity in tonic muscle fibres.

The labelling technique takes advantage of endocytosis at the synaptic terminals of stimulated axons[4] to accumulate fluorescent molecules at synapses. Our method allows living terminals to be viewed with light microscopy, but, unlike other supravital techniques[5,6], the synapses of different axons in the same preparation can be stained selectively with different-coloured probes.

We have at present three fluorescent probes that are internalized selectively by active nerve terminals; they are sulphonic acid derivatives of fluorescent molecules of low relative molecular mass (rhodamine, fluorescein and 8-hydroxypyrene; see Fig. 1 legend). Each probe emits at a different peak wavelength (red, green and blue, respectively). Brief stimulation (5–10 min) of a muscle nerve in a bath containing one of the probes labels all the terminals of the stimulated motor axons. Sequential stimulation of individual motor axons in the presence of different-coloured probes allows the relationship among terminals of different axons to be visualized.

The innervation of twitch and tonic muscle fibre endplates was examined in the transversus abdominis muscle of the garter snake; this muscle comprises ~200 segmental components, each of which extends from a rib to the ventral midline of the animal[7]. Each segmental component is supplied by a nerve containing 4–5 twitch and 3–4 tonic motor axons. The muscle is only one fibre thick, thus all the nerve–muscle contacts are visible in living preparations. A useful feature of this muscle is that the segmental components form an uninterrupted sheet, so that adjacent segmental nerves occasionally innervate the same band of endplates. By stimulating one segmental nerve in the presence of one fluorescent probe and then stimulating the adjacent nerve in the presence of a different-coloured probe, we could label separately all the terminals of two populations of axons in the same endplate band in either adult or embryonic snakes.

Initially the probes were used to study the pattern of innervation at the border region between adjacent segmental muscles. The results (Fig. 1*a*) showed that twitch fibre endplates innervated by one segmental nerve (red) are interspersed with endplates innervated by the adjacent segmental nerve (green). None of the individual twitch fibre endplates showed a mixture of red and green boutons, which would have indicated innervation by axons from both nerves.

In contrast, tonic muscle fibre endplates in adult snakes showed a very different pattern of labelling: when one of the segmental nerves was stimulated in the presence of the red probe and the adjacent nerve in the presence of the green probe, many of the tonic fibre endplates near the segmental border contained a mixture of both red and green synaptic boutons (Fig. 1*b*). Such 'mixed' endplates were found in each of 15 preparations in which there was a continuous endplate band crossing segmental boundaries. This observation indicates that, in maturity, tonic fibre endplates near the segmental boundaries are frequently innervated by axons from both segments.

To determine whether multiple innervation is typical of tonic fibre endplates throughout the muscle rather than just at the borders, we labelled a single tonic motor unit with the red probe, and all the other motor units within that segment with the blue probe (Fig. 1*c*). In this way we could examine every endplate site contacted by a single tonic motor axon. Each of two tonic units (from two snakes) studied in this way contributed 25–30% of synaptic boutons on the tonic muscle fibres in the muscle (1,477/5,539 and 1,305/4,571), yet each innervated 44% of the total number of tonic fibre endplates (98/223 and 102/234), suggesting that many of the endplates are multiply innervated. In fact, in both motor units, most of the endplates having red boutons, and thus innervated by the separately stimulated motor unit (85% and 54%), were also innervated by other axons as demonstrated by the presence of blue boutons at the same endplate (Fig. 1*c*). In contrast, three experiments in which a twitch motor unit was selectively labelled in the same manner as the tonic units (see above) revealed uniformly single innervation of twitch fibres: none of the twitch fibre endplates having red boutons, and thus within the separately stimulated twitch motor unit, also had blue boutons.

To estimate the number of axons that converge at a tonic fibre endplate, the numbers of red and blue boutons were counted at each tonic endplate site. The fraction of the total number of boutons contributed by the separately stimulated motor unit [red/(red + blue)] indicates the percentage of that endplate supplied by one axon and thus provides an approximation of the number of innervating axons. At multiply innervated endplate sites (those with both red and blue boutons), the identified motor axon formed, on average, less than half of the boutons (46% and 23%), arguing that many tonic fibre endplates are doubly innervated and occasional endplates are innervated by more than two axons.

The anatomical evidence for single innervation of twitch fibres and multiple innervation of tonic fibres was confirmed electrophysiologically. Intracellular recordings at the endplate sites of 50 twitch fibres (paralysed with curare or formamide[8]) always showed a single step in the postsynaptic response to a gradually increasing strength of stimulus to the muscle's nerve; a single step indicates recruitment of only one innervating axon (Fig. 2*a*). Physiological confirmation of multiply innervated tonic fibre endplates is more complicated as each tonic muscle fibre has several endplates[9,10]. Thus, both the presence of multiple steps in the postsynaptic response to gradually increasing nerve stimulation and the risetime of these steps must be considered to obtain unambiguous evidence for multiple inputs at a single endplate site. Intracellular recordings from tonic muscle fibres immediately adjacent to one endplate site (located with Nomarski optics) showed the presence of such multiple innervation (Fig. 2*b–d*). Of 57 tonic endplates studied electrophysiologically, 49% seemed to be singly innervated (see Fig. 2*b*), 44% doubly (see Fig. 2*c*) and 7% triply innervated (Fig. 2*d*), all consistent with the degree of multiple innervation assessed anatomically.

Studies of developing snake muscles suggest that the differing innervation patterns of twitch and tonic fibre endplates arise during development because of more vigorous synapse elimination from twitch than from tonic muscle fibres. The transversus abdominis muscle was dissected from late embryonic snakes (stages 35–36)[11]. The activity-selective fluorescent probes worked well in embryos, although endplates were smaller than

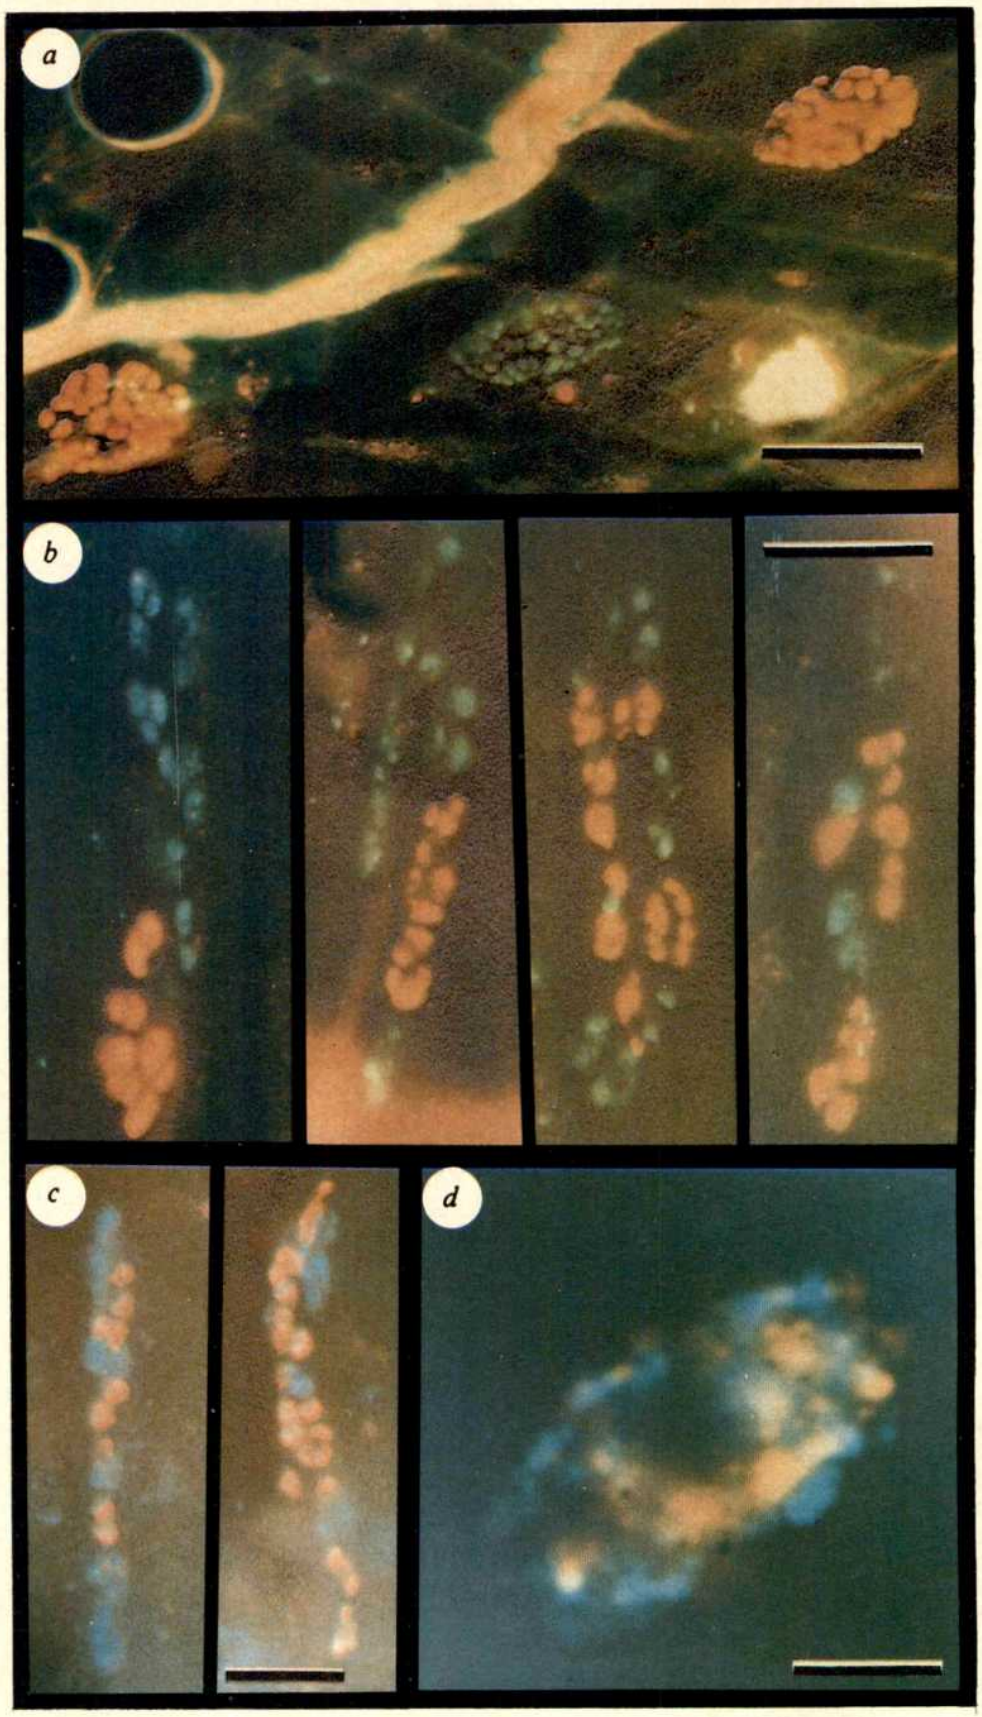

Fig. 1 Photomicrographs of activity-mediated uptake of fluorescent probes by motor axon terminals in the adult and embryonic transversus abdominis muscle of the garter snake *Thamnophis sirtalis*. ***a***, At the segmental boundary, adult twitch muscle fibres innervated by adjacent segmental nerves are interspersed. None of the twitch terminals studied was innervated by both segmental nerves. The figure shows two red-labelled nerve terminals supplied by the more rostral segmental nerve (left); between them is a green terminal from the more caudal segmental nerve (right). The rostral segmental nerve was stimulated for 5 min (75 Hz, 3 s on/2 s off) in a bath containing Ringer's solution and sulphorhodamine 101 (0.1 mg ml^{-1}; Molecular Probes Inc., Junction City, Oregon). The preparation was washed in Ringer's for 30 min, placed in Ringer's containing 0.1 mg ml^{-1} fluorescein 5,6-sulphonic acid (Molecular Probes Inc.), and the adjacent (caudal) nerve stimulated in the same manner. The preparation was washed for 30 min, fixed in 4% paraformaldehyde for 30 min and mounted on a slide in *p*-phenylenediamine phosphate-buffered saline/glycerin solution[23] to prevent fading. Living material may also be used but exciting light levels must be kept low to prevent bleaching and damage. Calibration bar, 35 μm. ***b***, Individual tonic endplates at the border of adjacent segmental muscles are frequently innervated by axons from both segmental nerves. With the same stimulus paradigm as in *a*, most tonic endplates in the border region showed a mixture of green and red boutons. Farther from the segmental border, tonic endplates containing both types of boutons declined, becoming all red in the rostral segment and all green in the caudal segment. Calibration bar, 10 μm. ***c***, The synaptic contribution of one motor axon to multiply innervated tonic endplates. To assess the proportion of synapses contributed by one axon in a multiply innervated endplate, the boutons of all the motor axons were labelled with the blue fluorescent probe 8-hydroxypyrene trisulphonic acid (Eastman Organic Chemicals, Rochester, New York) by stimulating the segmental nerve at supramaximal strength (same procedure as above); boutons of a single tonic motor axon were subsequently filled with the red probe (and, concomitantly, partially depleted of the blue probe) by selectively restimulating it alone in the presence of sulphorhodamine 101. A single tonic motor unit was activated by locating a tonic axon near an endplate (with Nomarski microscopy) and stimulating it with an extracellular electrode. This stimulation technique retrogradely activates the entire motor unit[24]; extracellular recording from the proximal nerve showed a single action potential, thus only one motor axon was active. The figure shows two of the 102 endplates innervated by the stimulated tonic axon (the boutons of the separately stimulated axon are red; the rest are blue). Calibration bar, 10 μm. ***d***, Multiple innervation of a twitch endplate in an embryonic snake muscle. Using the same stimulus procedure as in *a* and *b*, the motor axons from adjacent segments were labelled with the red and blue probes. Although all endplates were smaller than in adults, twitch endplates were still recognizable by virtue of their round shape and larger size than tonic endplates. Unlike adult preparations, embryonic twitch endplates at the segmental border received input from both segments, indicating innervation by more than one axon. Calibration bar, 5 μm. *a–c*, Photomicrograph double exposures using two sets of barrier and excitation filters. *d*, Photograph of a digitally stored video image.

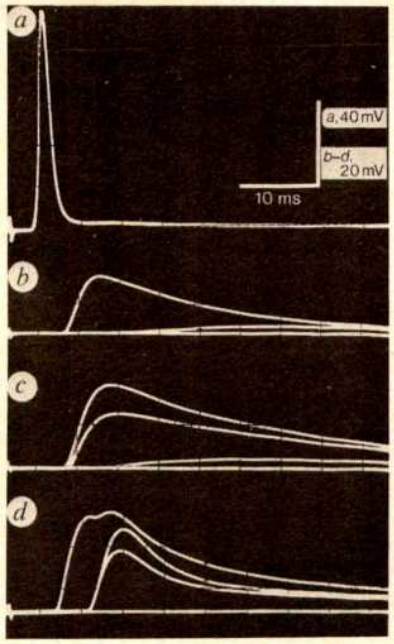

Fig. 2 Intracellular recordings from adult twitch and tonic muscle fibres in the transversus abdominis muscle of garter snakes, treated with formamide to induce muscle paralysis without reducing the amplitude of synaptic potentials[8]. *a*, Twitch fibres were identified by their large endplates. Recordings near the endplate always showed a single, large regenerative response in the postsynaptic potential. The unitary postsynaptic response is evidence of innervation by a single motor axon. Similar results were obtained with curare added to the bath in sufficient concentration to make synaptic potentials subthreshold. *b–d*, In tonic fibres, multiple steps in the postsynaptic response to nerve stimulation were often seen. Each panel is an intracellular record from a different tonic muscle fibre; all recordings were made adjacent to a tonic endplate viewed with Nomarski optics. The neighbouring endplate site was singly innervated in *b*, doubly innervated in *c*, and triply innervated in *d*. We interpret the large-amplitude, fast-rising steps as inputs to the nearby endplate, whereas the smaller and slower rising synaptic potentials are presumably inputs to the adjacent endplate sites (at a distance of ~1 mm). No potentials intermediate in risetime and amplitude to the two classes shown here were seen, suggesting that the source of the slow-rising potentials was an adjacent endplate and that more distant synaptic inputs were below the resolution level of our recordings. None of the tonic fibres showed regenerative membrane responses.

in adults and individual synaptic boutons were more difficult to discern. In contrast to the innervation of adult muscles (Fig. 1*a*), both twitch and tonic muscle fibre endplates at the segmental boundary in embryonic muscles showed innervation from both segmental nerves (Fig. 1*d*). Multiple innervation of twitch fibres was found in each of five embryonic muscles studied. However, by 1 week after birth (10 animals) no evidence of multiple innervation of twitch fibre endplates was found using either the fluorescent probes or intracellular recording. This result indicates that synapse elimination at twitch fibre endplates effectively removes all but one input to these muscle fibres perinatally. Tonic muscle fibre endplates, however, showed evidence of polyneuronal innervation throughout development and into adulthood.

It is uncertain why tonic endplates should retain multiple innervation. One possible explanation is suggested by an observation on doubly innervated[12] neuromuscular junctions of some frog twitch fibres—these multiply innervated sites are unusual because the inputs are weak and, when repetitively stimulated, are often unable to depolarize the muscle fibre sufficiently to generate action potentials[12]. Thus, the persistence of multiple innervation at tonic fibre endplates may be related to the fact that tonic muscle fibres generally lack action potential activity[10] regardless of the amplitude of their synaptic inputs (see Fig. 2). Indeed, several experiments suggest that the activity of postsynaptic cells influences synapse elimination[13–20], perhaps by allowing the postsynaptic cell to reward some inputs trophically at the expense of others[21,22]. The ability to view selectively the terminals of living axons undergoing synaptic rearrangement should provide a direct experimental approach to resolving this problem.

We thank Drs C. Forehand, D. Purves and J. Sanes for critical comments. This work was supported by grants from the NIH and Muscular Dystrophy Association. J.W.L. is a Sloan Fellow.

Activation of protein kinase C potentiates isoprenaline-induced cyclic AMP accumulation in rat pinealocytes

David Sugden, Jiri Vanecek, David C. Klein, Thomas P. Thomas* & Wayne B. Anderson*

Section on Neuroendocrinology, Laboratory of Developmental Neurobiology, National Institute of Child Health and Human Development and * Laboratory of Tumor Immunology and Biology, National Cancer Institute, Bethesda, Maryland 20205, USA

The pineal gland has proven to be an excellent model for the study of adrenergic control systems[1]. Noradrenaline, released from sympathetic nerve terminals in the pineal gland, regulates a large nocturnal increase in melatonin synthesis by stimulating the activity of arylalkylamine *N*-acetyltransferase (NAT, EC 2.3.1.87) 30–70-fold[1,2]. An essential step in both the induction and maintenance of high NAT activity is an increase in intracellular cyclic AMP[3,4]. Noradrenaline acts via β-adrenoceptors to increase pineal cyclic AMP by activating adenylate cyclase[5], and the activation of pineal α_1-adrenoceptors[6] potentiates β-adrenergic stimulation not only of NAT[7,8] but of both cyclic AMP and cyclic GMP[9–11]. Here we describe investigations designed to test whether α_1-adrenergic potentiation of β-adrenergic stimulation of pineal cyclic AMP involves protein kinase C. Our results suggest that kinase activation is involved and the data provide the first demonstration of a synergistic interaction between Ca^{2+}-phospholipid-dependent protein kinase (protein kinase C) and neurotransmitter-dependent stimulation of cyclic AMP.

Pinealocytes were prepared from female Sprague–Dawley rats (5 weeks old, 120 g) by trypsinization[12] and incubated (10^5 cells per 0.5 ml, 37 °C, 95% O_2/5% CO_2) in suspension culture in Dulbecco's modified Eagle's medium (DMEM) containing fetal calf serum (10% v/v) for 5–7 h before use. Following the indicated treatments, cells were centrifuged (8,000*g*, 1 min), the

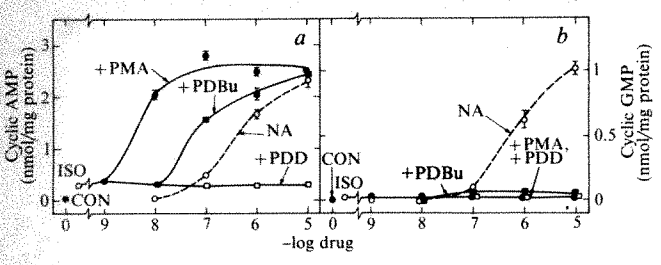

Fig. 1 Potentiation of β-adrenergic cyclic nucleotide responses by phorbol esters (*a*, cyclic AMP; *b*, cyclic GMP). Pinealocytes (10^5 cells per tube) were treated for 15 min with (−)isoprenaline (ISO; 10^{-6} M) either alone or in combination with 4-β-phorbol 12-myristate 13-acetate (PMA), 4-β-phorbol 12,13-dibutyrate (PDBu) or 4-α-phorbol 12,13-didecanoate (PDD). The dose-response curve to (−)noradrenaline (NA) is shown for comparison. Phorbol esters (Sigma) were added as 100 × concentrated solutions in ethanol. All points represent the mean ±s.e.m. of three samples. The lack of error bars indicates that the s.e.m. was less than the area covered by the symbol.

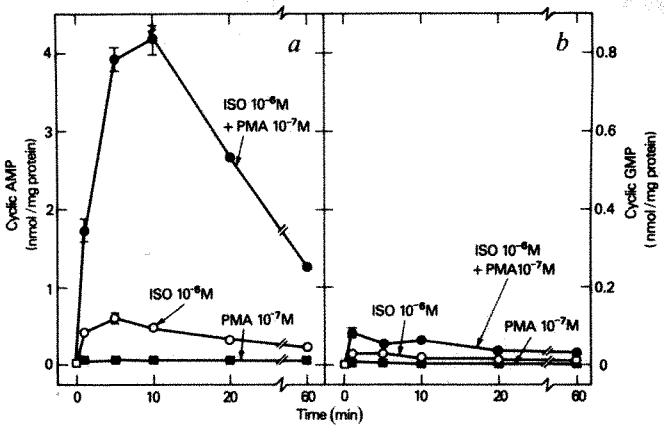

Fig. 2 Time course of PMA potentiation of β-adrenergic cyclic nucleotide response (*a*, cyclic AMP; *b*, cyclic GMP). Pinealocytes (10^5 cells per tube) were treated with PMA (10^{-7} M), (−)isoprenaline (10^{-6} M), or PMA (10^{-7} M) plus (−)isoprenaline (10^{-6} M) for the period indicated. All points represent the mean ±s.e.m. of three samples.

media aspirated and the cell pellet immediately frozen on dry ice. Samples were sonicated in perchloric acid (5%), neutralized, then frozen (−30 °C) until cyclic nucleotide concentrations were determined in duplicate by radioimmunoassay following acetylation[13]. The cross-reactivities of the cyclic AMP and cyclic GMP antisera were 0.07% and 0.53% respectively. Protein was determined by a dye binding assay using bovine serum albumin as the standard[14].

Treatment with isoprenaline (10^{-6} M), a β-adrenergic agonist, produced an eightfold increase in pinealocyte cyclic AMP and a doubling of cyclic GMP. Addition of 4-β-phorbol 12-myristate 13-acetate (PMA) or 4-β-phorbol 12,13-dibutyrate (PDBu), activators of protein kinase C[15], together with isoprenaline, potentiated the cyclic AMP, but not the cyclic GMP, response (Fig. 1). The maximal increase in cyclic AMP was comparable to that seen with noradrenaline, a mixed α- and β-adrenergic agonist. The concentrations of PMA and PDBu producing half-maximal potentiation were approximately 5 and 50 nM respectively. These concentrations are similar to the reported half-maximal concentrations necessary to activate protein kinase C[16]. 4-α-Phorbol 12,13-didecanoate (PDD), which does not activate protein kinase C, had no potentiating effect (Fig. 1). Addition of these phorbol esters alone produced no elevation in cyclic AMP.

An examination of the time course of the cyclic AMP response to isoprenaline (10^{-6}M) or isoprenaline plus PMA (10^{-7} M) indicated that potentiation was present after 1 min, reached a peak by 10 min and was still elevated after 1 h (Fig. 2). The small potentiation of the cyclic GMP response is probably an artefact caused by the cross-reactivity of the cyclic GMP antisera.

Measurement of protein kinase C activity in pinealocytes revealed a very high activity (42,000 pmol ^{32}P incorporated per 3 min per mg protein) when compared with most tissue[17,18] including neural tissues (Table 1). Treatment of cells with either phenylephrine (10^{-6} M) or PMA (10^{-7} M) caused a rapid decrease in cytosolic protein kinase C activity with a corresponding increase in membrane-associated activity. It has been suggested that the redistribution of this protein kinase activity may be an important, early event in the action of phorbol esters, perhaps enabling the enzyme to gain access to physiological substrates[19].

The physiological activator of protein kinase C is thought to be diacylglycerol, which is transiently formed from the breakdown of membrane phosphatidylinositol[20]. Noradrenaline, acting through α_1-adrenoceptors, is known to stimulate this process in the pineal gland[21,22]. A synthetic diacylglycerol analogue, 1-oleoyl 2-acetyl glycerol (OAG), can also activate C kinase[23] and furthermore is able to cross the cell membrane. OAG (12.5–50 μg ml^{-1}) potentiated the stimulation of cyclic AMP produced by isoprenaline (10^{-6} M) (Fig. 3). No effect of OAG alone was observed. A small but significant potentiation of the cyclic GMP response to isoprenaline cannot be completely explained by the cross-reactivity of the cyclic GMP antisera.

These studies clearly show that phorbol esters and OAG, both of which activate protein kinase C, mimic the action of α_1-agonists on pinealocytes and potentiate β-adrenergic stimulation of cyclic AMP content. In addition, protein kinase C is rapidly redistributed from the cytosol into membranes not only in response to PMA[19], but also by treatment of the intact cells with an α_1-agonist, phenylephrine. These findings, together with earlier evidence that postsynaptic α_1-adrenoceptors mediate a rapid increase in membrane phosphatidylinositol turnover in pinealocytes[21,22], suggest that activation of protein kinase C is involved in the α_1-adrenergic amplification of β-adrenergic stimulation of cyclic AMP accumulation in this cell. Presumably, diacylglycerol generated by noradrenaline-mediated phosphatidylinositol turnover interacts with protein kinase C in the

Table 1 Effect of phenylephrine or PMA treatment of pinealocytes on cytosolic and membrane-bound protein kinase C activity

Expt no.	Pretreatment	Protein kinase C activity (pmol ^{32}P incorporated per 3 min per 5×10^6 cells)	
		Cytosol	Membranes
1	Water	13,750	1,000
	Phenylephrine (10^{-6} M)	8,725	5,160
2	Vehicle	13,248	1,395
	PMA (10^{-7} M)	6,286	3,164

Pinealocytes (5×10^6) were treated with phenylephrine (10^{-6} M) for 1 min or with PMA (10^{-7} M) for 15 min. Cells were pelleted (1,000*g*, 1 min), washed, then lysed in water (250 μl) containing $CaCl_2$ (10^{-5} M) by brief (5-s) sonication (expt 1) or by repeated aspiration into a syringe through a fine (27-gauge) needle (expt 2). Membrane and cytosol were separated (12,000*g*, 1 min at 4 °C) and 0.5 ml of buffer A (20 mM Tris-HCl, *p*H 7.5, 2 mM EDTA, 0.5 mM EGTA, 2 mM phenylmethylsulphonyl fluoride) was added to each preparation. Cytosol was applied to a DE-52 cellulose column (0.5 × 1 cm) equilibrated with buffer A. The column was washed with 8 volumes of buffer A, and the enzyme eluted with 0.08 M NaCl in buffer A. Membranes were solubilized with Nonidet P-40 (1%) by gentle mixing for 30 min at 4 °C. The preparation was centrifuged (Beckman Microfuge, 10,000*g*, 2 min at 4 °C) and the detergent-solubilized preparation applied to a DE-52 cellulose column and eluted as described for cytosol. Protein kinase C activity was assayed in triplicate as described previously with 0.75 mM Ca^{2+}, in the presence and absence of 24 μg phosphatidylserine, and 1.6 μg diolein[17,30]. Protein kinase C activity was determined by subtracting the amount of ^{32}P incorporated into histone H1, in the absence of added phospholipids, from the amount incorporated in the presence of phospholipids. Protein kinase C activity is expressed as pmol ^{32}P incorporated per 3 min per total cytosolic and membrane fraction from 5×10^6 cells.

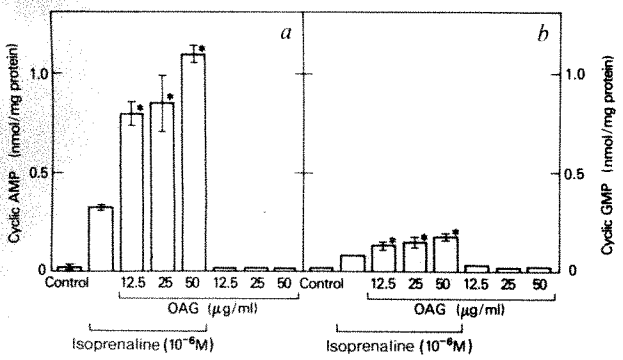

Fig. 3 Potentiation of β-adrenergic cyclic nucleotide responses by 1-oleoyl, 2-acetyl glycerol (OAG). OAG (10 mg ml^{-1} in chloroform) was dried under N_2, then suspended in dimethyl sulphoxide (1%) by brief, vigorous sonication on ice immediately before use. OAG (a gift from Dr Y. Nishizuka) was added as ×25 to ×100 concentrated stock suspension to give the final concentrations indicated. Pinealocytes (10^5 cells per tube) were pelleted (1,000g, 1 min) and resuspended in DMEM without fetal calf serum, then treated for 5 min with OAG alone or in combination with (−)isoprenaline. Each bar represents the mean ±s.e.m. of three samples. * Significantly different from isoprenaline alone, $P < 0.05$ using Duncan's multiple range test.

presence of membrane phospholipids and Ca^{2+} transiently to activate and stabilize the enzyme in association with the membrane. This activation of protein kinase C may result in the rapid phosphorylation of a component of the system synthesizing (β-adrenoceptor, guanine nucleotide binding proteins, adenylate cyclase catalytic subunit ?) or degrading (phosphodiesterase ?) cyclic AMP, an important intracellular messenger.

Apparently a different mechanism mediates the α_1-adrenergic amplification of the β-adrenergic cyclic GMP response. Unlike cyclic AMP, the accumulation of pineal cyclic GMP in response to noradrenaline is Ca^{2+}-dependent[24]. Conceivably the α_1-adrenergic amplification of the cyclic GMP response requires not only protein kinase C activation but also an elevation of intracellular Ca^{2+}. This may explain the significant potentiation of the cyclic GMP response by OAG; OAG would be expected to be rapidly metabolized to the corresponding phosphatidic acid[23], which may then increase intracellular Ca^{2+}. Inositol trisphosphate[25] or phosphatidic acid[26] generated as a result of an increased phosphatidylinositol turnover may be physiological mediators of this action of α_1-adrenoceptor stimulation. Alternatively, guanylate cyclase may be stimulated by arachidonic acid or a metabolite[27].

Finally, these studies are of special interest because, to our knowledge, they are the first to describe a synergistic interaction between these intracellular signalling systems. Previous work has generally suggested that activation of protein kinase C may reduce neurotransmitter or hormone-dependent cyclic AMP signals (for example, see refs 28, 29). Clearly, this is not the case in all cell types.

Human granulocyte–macrophage colony-stimulating factor is a neutrophil activator

Richard H. Weisbart*, David W. Golde†, Steven C. Clark‡, Gordon G. Wong‡ & Judith C. Gasson†

The polymorphonuclear leukocyte (PMN), or neutrophil, is the major host defence cell protecting the body against invasion by bacteria and fungi. Products of oxidative metabolism mediate PMN microbicidal and tumoricidal activity[1] but the mechanisms by which these pathways become activated are not well understood. We have previously described a human granulocyte–macrophage colony-stimulating factor (GM-CSF) of relative molecular mass (M_r) 22,000 that also inhibits neutrophil motility (NIF-T activity)[2]. Because of its direct action on granulocytes, this lymphokine is a candidate for a neutrophil-activating factor. We have studied the effect of GM-CSF/NIF-T on superoxide anion generation in response to the bacterial chemo-attractant *N*-formylmethionyl-leucylphenylalanine (f-MLP)[3], and report here that PMNs preincubated with either purified natural GM-CSF or biosynthetic (recombinant) GM-CSF showed increased (as much as fourfold) superoxide anion production in response to f-MLP. These results indicate that human GM-CSF is a neutrophil-activating factor.

A neutrophil migration-inhibition factor from T lymphocytes (NIF-T) produced by a human T-lymphoblast cell line (Mo) was characterized as an acidic glycoprotein of M_r 22,000 (22K) with specificity for binding PMN plasma membranes[2,4–6]. Purified NIF-T was shown to have colony-stimulating activity, and expression of a cDNA for human GM-CSF demonstrated that the gene product has NIF-T activity[2], confirming the identity of these two proteins.

In the experiments reported here, we examined the effect of GM-CSF on superoxide anion production by neutrophils, measured as superoxide dismutase-inhibitable cytochrome *c* reduction[7]. PMNs incubated with Mo-conditioned medium alone for 2 h did not produce measurable superoxide anion. In 10 separate experiments, a mean (±s.e.m.) of 2.1 ± 0.2 nmol superoxide anion per min per 10^6 PMNs was produced over 4 min in the presence of 10^{-8} M f-MLP. However, when PMNs were preincubated for 2 h with Mo-conditioned medium before addition of f-MLP, superoxide anion production was increased to a mean of 7.0 ± 0.4 nmol per min per 10^6 PMNs measured over 4 min. The results of a representative experiment are shown in Fig. 1.

The degree of enhancement of f-MLP-induced oxidative metabolism was dependent on the length of time for which the PMNs

were incubated with Mo-conditioned medium (Fig. 2). A maximum (fourfold) increase in cytochrome *c* reduction (measured over 5 min) occurred when PMNs were incubated with Mo-conditioned medium for 2 h before addition of f-MLP (Fig. 2).

GM-CSF was isolated sequentially from Mo-conditioned medium by lectin affinity chromatography, gel filtration chromatography and reverse-phase HPLC, with co-purification of GM-CSF[2] and neutrophil-activating factor (NAF) activities (data not shown). GM-CSF isolated by HPLC was subjected to SDS-polyacrylamide gel electrophoresis (SDS-PAGE). Analysis of eluates from gel slices showed CSF and NAF activities corresponding to a 22K protein (Fig. 3). The NH_2-terminal amino-acid sequence of this protein is identical to that predicted by the nucleotide sequence of the human GM-CSF cDNA clone[2].

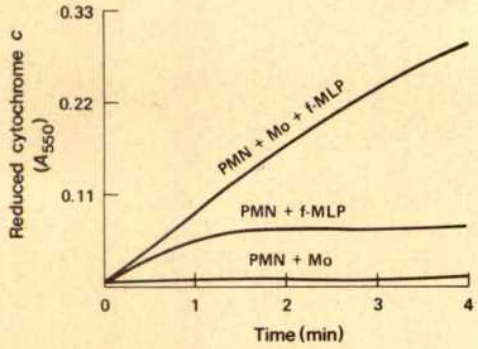

Fig. 1 Effect of Mo-conditioned medium on f-MLP-induced PMN oxidative metabolism.

Methods. PMNs were isolated from peripheral blood of healthy subjects by Ficoll–Hypaque gradient centrifugation, and red blood cells were removed by 6% dextran sedimentation and 30-s hypotonic lysis. PMNs (5×10^6 ml^{-1}) were suspended in Hanks' buffered salt solution (HBSS) (without phenol red) containing 5% fetal calf serum (FCS), and 0.4-ml aliquots containing 2×10^6 PMNs were incubated for 2 h at 37 °C with 0.040 ml of medium with 5% FCS alone or Mo-conditioned medium. After incubation, 2 ml of cytochrome *c* (1.2 mg ml^{-1} in HBSS with 5% FCS) were added to each cell suspension, mixed, and the contents divided equally into two tubes. Superoxide dismutase (0.010 ml of 2 mg ml^{-1}) was added to one of the tubes, and f-MLP was added as 1% of the volume to both tubes at a final concentration of 10^{-8} M. The cell suspensions were transferred immediately to disposable 1-ml cuvettes, and superoxide dismutase-inhibitable cytochrome *c* reduction was measured at 550 nm at 37 °C for 5 min in a Varian DMS 90 dual beam spectrophotometer. Absorbance was recorded every 5 s with a computer-assisted program. The data are expressed as the difference between results for Mo-conditioned medium and for medium alone.

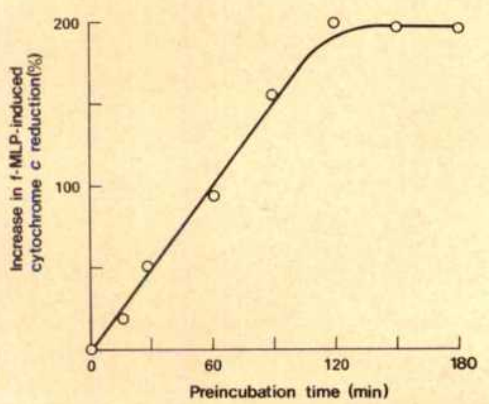

Fig. 2 Effect of length of preincubation with Mo-conditioned medium on f-MLP-induced PMN oxidative metabolism. Methods were the same as for Fig. 1 except that PMNs were preincubated for various periods of time with Mo-conditioned medium that titred 1:200 after 2 h of incubation. The data are expressed as percentage increase in mean A_{550} over 5 min after addition of f-MLP.

GM-CSF has been expressed in COS monkey cells transfected with a molecular clone of the human gene obtained independently from a cDNA expression library prepared from Mo mRNA[2,8]. Such biosynthetic recombinant GM-CSF did not directly increase PMN oxidative metabolism. In 10 separate experiments, PMNs incubated with conditioned medium from mock-transfected COS cells produced a mean (±s.e.m.) of 2.5 ± 0.3 nmol superoxide anion per min per 10^6 PMNs, measured over 4 min, in response to f-MLP. However, an average of 8.4 ± 0.7 nmol superoxide anion per min per 10^6 PMNs was produced over 4 min in response to f-MLP when PMNs were

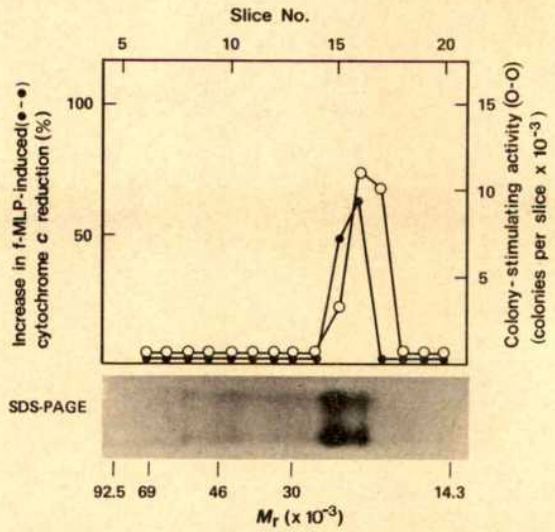

Fig. 3 Analysis of HPLC-purified CSF and NAF by SDS-PAGE. Ten litres of serum-free Mo-conditioned medium were concentrated and processed as described previously[2]. Briefly, the proteins precipitated with 80% ammonium sulphate were dialysed and applied to a lentil lectin–Sepharose 4B column, washed, and eluted with 0.5 M α-methyl-D-mannoside. The eluted glycoproteins were fractionated on an Ultrogel AcA 44 column, and fractions with peak GM-CSF activity were pooled and further fractionated by reverse-phase HPLC using a Vydac C-18 column. Protein was eluted with a gradient of acetonitrile containing 0.1% trifluoroacetic acid. HPLC fractions were evaporated to dryness, reconstituted and assayed for NIF-T, CSF and NAF activities. A fraction previously shown to contain GM-CSF was assayed and found to have NAF activity; this fraction was subjected to SDS-PAGE in a 10% polyacrylamide gel[2]. An aliquot of the sample was iodinated, fractionated with the unlabelled protein as a tracer, then analysed in parallel lanes in the presence and absence of 2-mercaptoethanol. The lane containing the unlabelled protein was sliced, eluted and assayed for NAF activity as well as NIF-T and CSF[2,10,11]. The results obtained for NIF-T and CSF have been published previously[2].

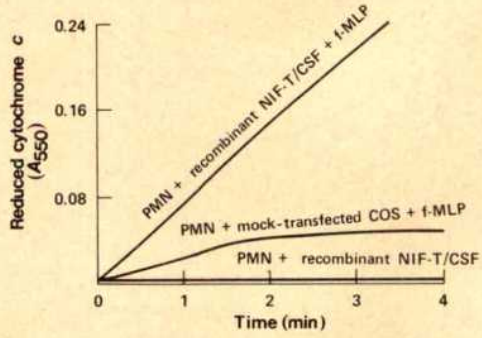

Fig. 4 Effect of biosynthetic recombinant GM-CSF on f-MLP-induced PMN oxidative metabolism. Computer-generated graph of measurements made at 5-s intervals. Methods as for Fig. 1, except that PMNs were preincubated with conditioned medium from monkey COS cells containing GM-CSF cloned[8] in the expression vector p91023(B) and with medium from mock-transfected COS cells.

preincubated with recombinant GM-CSF. (Figure 4 shows the results of a representative experiment.) Furthermore, GM-CSF purified to homogeneity from COS-conditioned medium by gel filtration chromatography and HPLC had neutrophil-activating activity. Control experiments using buffers, medium and conditioned medium from mock-transfected COS cells, and other HPLC fractions, eliminated the possibility that endotoxin contamination was responsible for these results. Also, the titres of NIF-T, CSF and NAF activities were the same in Mo-conditioned medium (1:200) and conditioned medium from COS cells transfected with the cloned GM-CSF gene (1:10,000).

These studies demonstrate that GM-CSF enhances oxidative metabolism of PMNs in response to the chemo-attractant f-MLP. Our results with this human lymphokine appear to correspond to those described for a murine CSF which has been shown to enhance granulocyte antibody-dependent cytotoxicity[9]. T-cell regulation of neutrophil oxidative metabolism by lymphokines may have an important role in neutrophil-mediated microbicidal and tumoricidal activity as well as in the pathogenesis of immune-mediated inflammatory diseases.

Levels of c-*myc* oncogene mRNA are invariant throughout the cell cycle

Craig B. Thompson*, Peter B. Challoner, Paul E. Neiman* & Mark Groudine†

Fred Hutchinson Cancer Research Center, 1124 Columbia Street, Seattle, Washington 98104, and Departments of *Medicine and †Radiation Oncology, University of Washington, Seattle, Washington 98195, USA

The steady-state messenger RNA levels of several genes increase when cells are stimulated to proliferate[1-4]. The transcripts from one such gene, the proto-oncogene c-*myc*, increase approximately 20-fold shortly after cells are stimulated to proliferate and then decline before the onset of DNA synthesis[1,5]. It has been inferred from these data that expression of c-*myc* may be specific to the G_1 portion of the cell cycle[5]. Alternatively, this transient increase in c-*myc* mRNA following the stimulation of quiescent cells could be the result of an activational event that renders the cells competent to enter the cell cycle. To distinguish between these possibilities, we performed experiments to determine whether the amount of c-*myc* mRNA fluctuates during the cell cycle in cells that are under constant stimulation to proliferate. Although c-*myc* mRNA does undergo a transient increase within 2 h of serum stimulation of quiescent serum-deprived cells, our results show that the level of c-*myc* mRNA is constant throughout the cell cycle and does not diminish in density-arrested cells maintained in the presence of serum growth factors. In contrast to c-*myc*, the mRNA levels of two other genes whose expression has been associated with cellular proliferation[6-8] do show consistent variations within the cell cycle. Both thymidine kinase (TK) and histone 2b (H2b) mRNA levels increase during S phase in continuously growing cells and decrease when cell replication ceases in density-arrested cultures. Therefore, the transient increase in c-*myc* transcription following the activation of quiescent cells is not due to the type of cell cycle-dependent regulation characteristic of the TK and H2b genes.

To distinguish events which occur during the activation of quiescent cells to proliferate from events regulated within the cell cycle, we separated cells in exponentially growing cultures by counterflow centrifugation, a technique which fractionates cells primarily on the basis of size[9,10]. Because cells undergo a linear increase in volume as they progress through the cell cycle[9], a non-synchronized population of growing cells can be separated by size into subpopulations representing progressive stages of the cell cycle. This method avoids the perturbations in cellular metabolism which are inherent in experiments involving either chemical arrest or deprivation of essential growth factors[11]. To analyse events within the cell cycle, 10^8 exponentially growing cells were loaded into a counterflow centrifuge and separated into six subpopulations of increasing mean cell volume (Fig. 1). To verify that an effective cell cycle separation had occurred, the cells were stained with propidium iodide and the DNA-staining profile analysed on a fluorescence-activated cell sorter (FACS). The average fluorescence per cell of each fraction was calculated and expressed as a multiple of the diploid cell peak. Each fraction was then assigned an average ploidy value ranging from $2n$ for G_1 cells to $4n$ for G_2/M cells.

Two types of exponentially growing cell cultures were analysed in this way. MSB-1, a transformed chicken T-cell line with structurally normal c-*myc* alleles[12], was grown continuously in suspension culture. Chicken embryo fibroblasts (CEF) were dissected from the developing breast muscle of 11-day-old embryos and grown at low density on plastic Petri dishes[7]. Total RNA from cell cycle-dependent subpopulations was isolated using guanidinium isothiocyanate[13]. Ribosomal RNA increased in direct proportion to cell volume as cells progressed from G_1 to G_2/M; because of this, the levels of ribosomal RNA were equalized (Fig. 2) to avoid the measurement of mRNA variations attributable only to increases in cell volume during growth. Northern blots were prepared from the equalized RNA samples and hybridized sequentially with probes specific for the c-*myc* and TK genes. The blots were also hybridized to probes for the β-actin gene, which encodes an essential structural protein required for cell integrity[14] and therefore should be transcribed in all viable cells, and the gene for H2b, which has been shown previously to be cell cycle-regulated[15]. As shown in Fig. 2, the level of c-*myc* mRNA was equivalent in all of the cell-cycle dependent subpopulations of both CEF and MSB-1 cells. The c-*myc* mRNA levels as measured by scanning densitometry varied <20% between any two fractions in an individual experiment; this was a consistent finding in several experiments involving both cell types. Levels of β-actin mRNA were also constant in all subpopulations. In contrast, although TK mRNA was present throughout the cell cycle during exponential growth, a two- to sixfold increase in the level of this transcript was found in subpopulations enriched for S-phase cells. Similarly, the H2b mRNA level was 5-15 times greater in the subpopulations containing S-phase cells in both cell types. The quantitative variation in the cell-cycle expression of the H2b gene that we observed was comparable to that reported by others[15,16].

As an alternative approach to analysing the association of c-*myc* expression with cell proliferation, the levels of c-*myc* mRNA were examined as cells were shifted between exponential growth and growth arrest (Fig. 3*a*). In the continuous presence of serum growth factors, little difference in the levels of c-*myc* mRNA was observed between cultures in exponential growth and those that had ceased proliferation. This contrasts with a >10-fold reduction of TK mRNA in both CEF and MSB-1 cells as they stopped proliferating. When quiescent cells were

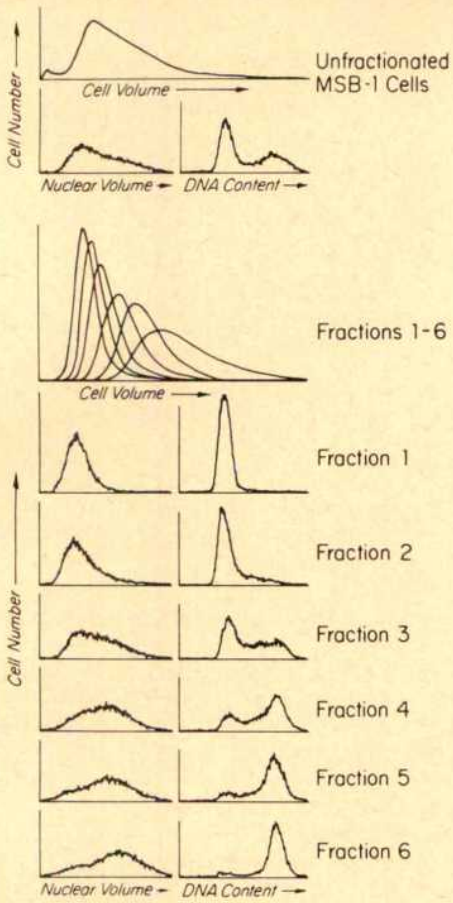

Fig. 1 Representative cell volume, nuclear volume and DNA content analysis of elutriated cell fractions. Exponentially growing MSB-1 cells were separated by counterflow centrifugation (elutriation) into six fractions of increasing cell size which were numbered 1–6 from smallest to largest. The recovery of the unfractionated cells in the six subpopulations was 93%. Cell volume was measured using an electronic cell counter/sizer. Nuclei were prepared by solubilization of cells with 0.5% NP40 in Tris-buffered saline containing 10 mM $MgCl_2$. Nuclear volume was determined by measuring narrow-angle light scatter on a FACS, and the average DNA content of cells from each fraction was determined by FACS analysis after staining of the nuclei with propidium iodide. *n* is the haploid DNA content of MSB-1 cells. Unfractionated cells gave a bimodal DNA curve characteristic of exponentially growing cells[9]. The early fractions from the elutriation contained cells with a 2*n* DNA content characteristic of G_1 cells. As cells of increasing size were recovered, the nuclear volume and average DNA content per cell increased. The final fraction contained almost exclusively cells with 4*n* DNA content, characteristic of G_2/M cells.

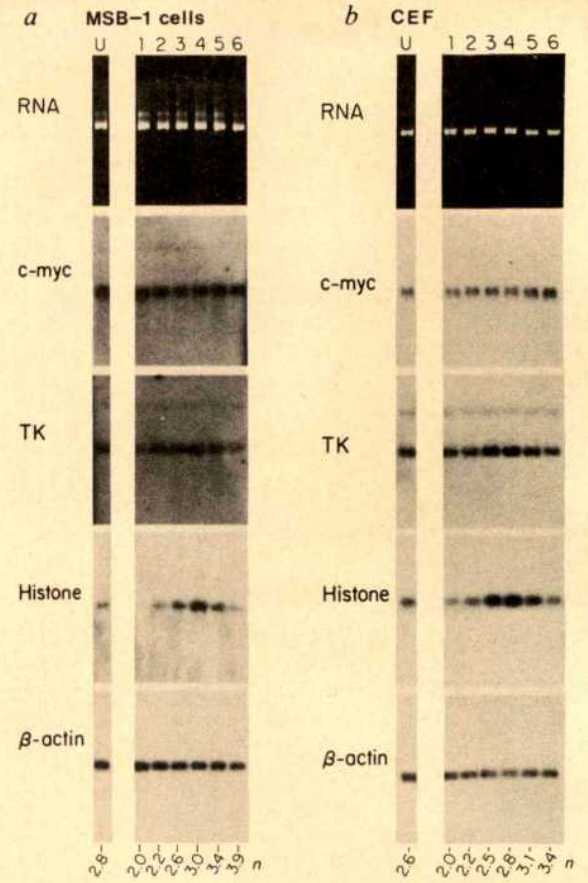

Fig. 2 The c-*myc*, TK, H2b and β-actin mRNA content of cell cycle-separated MSB-1 cells and CEF. Total RNA was prepared from the unfractionated population (U) and each of the subpopulations. The top panels of *a* and *b* show ethidium bromide staining of equal amounts of the RNA samples separated on a non-denaturing 1% agarose gel. These equalized RNA samples (2–5 μg depending on the experiment) were separated on 1% agarose/formaldehyde gels and blotted onto nitrocellulose. Filters were then hybridized with a ^{32}P-labelled 3.2-kilobase (kb) *Sst*I fragment containing the chicken c-*myc* gene[7], a 2.9-kb *Hin*dIII fragment containing a portion of the TK gene[7] (a gift from M. Wigler), a 0.59-kb *Hin*dIII fragment containing the 3′-untranslated region of the β-actin gene[14] (a gift from D. W. Cleveland) or a 2.3-kb *Hin*dIII/*Bam*HI fragment containing the H2b gene[24] (a gift of P. A. Krieg). Each filter was probed sequentially with several of these fragments to ensure that the hybridization observed represented true variations between samples rather than variations in sample preparation. Autoradiograms were exposed for 2–48 h and equivalent exposures compared. Relative molecular masses of the mRNAs that hybridized to each of the probes were similar to those published previously[7,14,24]. The additional band present on some TK and c-*myc* hybridizations was due to nonspecific hybridization to 28S ribosomal RNA and thus provides confirmation that equal amounts of RNA were transferred to the filters. Quantitation was performed by densitometry[1]. Numbers below the autoradiograms represent average haploid DNA content (*n*) of cells in each fraction.

recultured at lower density, both cell types resumed growth and the level of TK mRNA increased, while c-*myc* mRNA remained relatively constant. Again, the H2b mRNA levels paralleled those of TK. Although β-actin mRNA levels were constant in the presence of serum factors in MSB-1 cells, there did seem to be an increase in β-actin mRNA levels during exponential growth of CEF. Similar increases in β-actin mRNA levels have been reported when fibroblasts spread out in subconfluent culture conditions[17].

Figure 3*a* shows that c-*myc* expression is independent of the proliferative state of a cell. Others have shown that before cells can proliferate they must be activated by growth factors to a state where they are competent to enter the cell cycle[18]. Thus, previously described variations in levels of c-*myc* mRNA could be the result of this activation process, rather than the result of regulation during the proliferative cycle. Consistent with the reports of others using murine 3T3 cells[1,2,4], we find that serum-deprived cultures of both CEF and MSB-1 avian cells had lower amounts of steady-state c-*myc* mRNA relative to ribosomal RNA (data not shown). However, the steady-state levels of TK, H2b and β-actin mRNAs also decreased during serum deprivation. Although the cells remained viable and an increase in the levels of c-*myc* was observed on restimulation, it is difficult to be certain that these variations are anything more than a general decrease in steady-state mRNA due to sub-optimal culture conditions. Nevertheless, the response of serum-deprived CEF to the addition of serum growth factors did provide another demonstration of the fact that c-*myc* expression was regulated independently of TK and H2b gene expression. Figure 3*b* shows an experiment in which confluent CEF were serum-deprived for 3 days and then re-exposed to serum while still confluent. c-*myc* mRNA underwent a transient three- to fivefold increase in

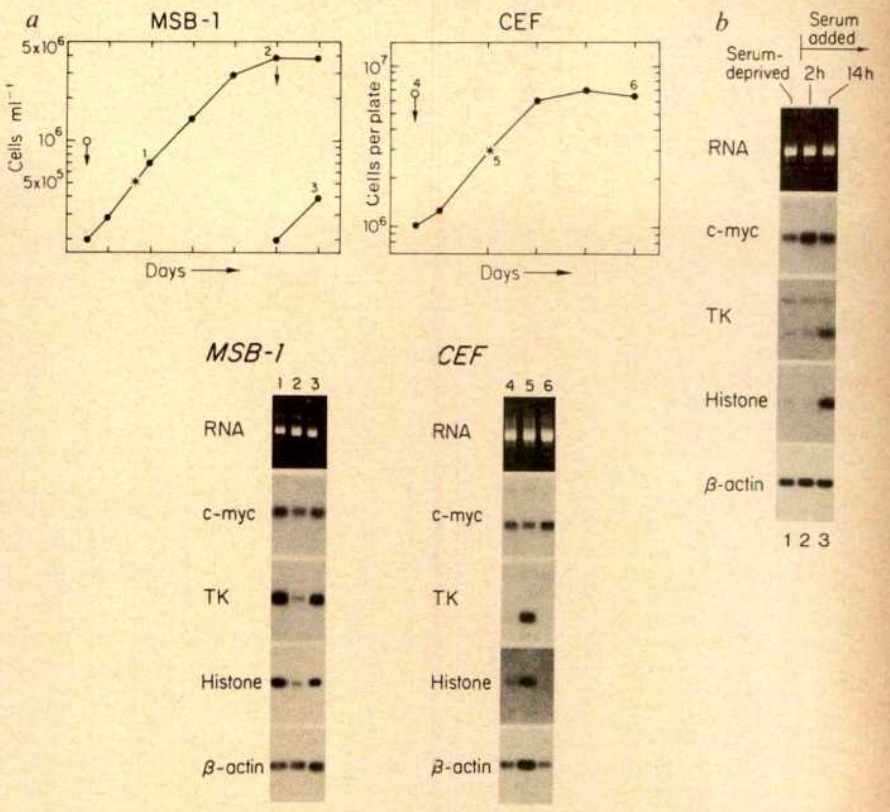

Fig. 3 *a*, Growth curves of MSB-1 cells and CEF. Exponentially growing MSB-1 cells were followed in culture until no further increase in cell number was observed. They were then recultured at a lower density and resumed exponential growth. Confluent CEF were recultured at a density of 1×10^6 per 150-mm plates and followed to confluency. Below the growth curves are autoradiograms of Northern blots prepared with equal amounts of RNA and hybridized with c-*myc*, TK, H2b and β-actin as described in Fig. 2 legend. For MSB-1, lane 1 represents RNA isolated from cells during initial exponential growth; lane 2, RNA from growth-arrested cells; and lane 3, RNA from cells after resumption of exponential growth. For CEF, lane 4 represents RNA isolated from confluent cells; lane 5, RNA from cells in exponential growth; and lane 6, RNA from cells after they have become confluent again. Cell viabilities as measured by trypan blue exclusion were >95% at each of the assay points for both CEF and MSB-1 cells. In both cell types, >40% of the cells were in S or G_2/M phase during exponential growth and <5% had greater than 2*n* DNA content during growth arrest. ↓ Indicates the point at which cells were recultured; * is the point on the growth curve at which cells were used for separation into cell cycle-dependent subpopulations using counterflow centrifugation, shown in Fig. 2. *b*, Effect of 3 days' culture of confluent CEF in the presence of medium containing 0.1% serum, followed by stimulation by addition of 6% serum to the culture. Total RNA was prepared before stimulation and 2 h and 14 h after stimulation. Top panel, ethidium bromide-stained gel showing the ribosomal RNAs after equalization; lower panels, autoradiograms of Northern blots of identical 1% agarose/formaldehyde gels hybridized with c-*myc*, TK, H2b and β-actin genes. In each panel, lane 1 is RNA isolated from cells before serum stimulation; lane 2 is RNA isolated from cells 2 h after stimulation; and lane 3 is RNA isolated from cells 14 h after stimulation.

expression 2 h after serum addition and then fell to near quiescent levels by 14 h. The TK and H2b mRNAs were barely detectable either before the addition of serum or 2 h after serum addition, but increased substantially by 14 h, the approximate time required for quiescent CEF to reach S phase following re-exposure to serum factors[18].

Finally, because the conditions in which cells are maintained *in vitro* may be different from the conditions in which cells proliferate *in vivo*, we examined the expression of c-*myc* and TK genes in cell cycle-dependent subpopulations of thymocytes (Fig. 4). Thymocytes proliferating *in vivo* had a wider size range than exponentially growing cells *in vitro*, and the first several subpopulations eluted from the counterflow centrifuge were made up exclusively of cells with 2*n* DNA. The rest of the subpopulations were composed of cells in progressively later stages of the cell cycle, comparable to the subpopulations obtained from CEF and MSB-1 cells. Figure 4 shows that the level of c-*myc* mRNA was slightly lower in the 2*n* thymocyte subpopulations but was constant in all subsequent fractions. The lower c-*myc* mRNA levels in the smaller 2*n* subpopulations correlated closely with the percentage of cells in these subpopulations which had the surface phenotype of mature T cells as assessed by monoclonal antibodies[19] (up to 30% of the cells in the subpopulation containing the smallest cells). Therefore, the 2*n* subpopulations are composed of both thymocytes in the G_1 phase of the cell cycle and small terminally differentiated T cells destined to leave the thymus[20]. Because terminally differentiated cells have been shown to contain low amounts of c-*myc* mRNA[4,21], the low level of c-*myc* mRNA in the 2*n* subpopulations presumably represents the average c-*myc* content of mature T cells and G_1 thymocytes. In contrast to c-*myc*, genes for H2b and TK were expressed only in the subpopulations containing S-phase cells; β-actin mRNA levels were constant in all fractions. Our results suggest that the *in vivo* expression of c-*myc*, H2b, TK and β-actin genes in proliferating thymocyte cells is similar to their expression in cells proliferating *in vitro*.

Previous reports[1,4,5] have shown that the c-*myc* mRNA levels of murine cells are low in quiescent serum-deprived cells and high in exponentially growing cells. Moreover, growth factors which cause cells to enter the cell cycle have been demonstrated to induce c-*myc* transcription[2]. It has also been shown that following removal of the growth factor responsible for the induction of proliferative competency, the c-*myc* mRNA level rapidly declines, and despite this, cells can proceed through the cell cycle they have already initiated[5]. These results could mean that c-*myc* is a cell-cycle-regulated G_1-specific transcript[5]. However, for the cells we have examined, the level of c-*myc* mRNA is constant throughout the cell cycle in the continuous presence of serum growth factors. This appears to be a general phenomenon, as we have obtained similar results in a variety of cell types in addition to those presented above, including murine BALB/c 3T3 cells[1], human HL60 cells[21] and avian BK25 cells[12] (data not shown). As this constant level of c-*myc* mRNA was seen in RNA samples containing equal amounts of ribosomal RNA, and the amount of ribosomal RNA increases as a function of cellular volume as cells progress though the cell cycle, c-*myc* must be transcribed throughout the cell cycle. In the accompanying paper[22], data are presented which show that c-*myc* protein is also translated as a fixed percentage of total protein synthesis throughout the cell cycle of both avian and human cells. Based on these results, we postulate that c-*myc* expression reflects the competency of cells to enter and progress through the cell cycle. In the presence of the appropriate growth factors, both proliferative competency and c-*myc* expression can be maintained irrespective of position in the cell cycle.

In contrast to our results with c-*myc*, the TK mRNA level did seem to vary within the cell cycle. TK gene expression has been linked previously to S phase by experiments showing an increase in TK enzymatic activity during DNA replication[6,23]. Our data demonstrate a similar association between increased TK mRNA levels and S phase. In a pattern of expression that is similar to that for H2b, TK mRNA levels increased during S phase,

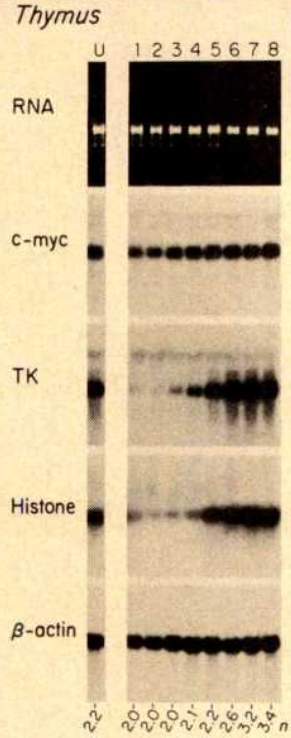

Fig. 4 The c-*myc*, TK, H2b and β-actin mRNA content of cell cycle-separated thymocytes. Numbers at the bottom of the lanes represent the average DNA content per cell (*n*). Thymocytes were prepared by gently teasing apart the thymuses of 6-week-old chickens. and filtering the cell suspension through nylon mesh to remove clumped cells. Contaminating non-lymphoid cells were removed by centrifuging the cell suspension over Ficoll-Hypaque. Greater than 95% of cells prepared in this manner stain positively with monoclonal antibodies specific for thymocyte antigens[19]. Cells were separated into subpopulations and analysed in a manner analogous to that shown in Fig. 1 except that two additional subpopulations were isolated at the beginning of the separations due to the wide distribution in size of thymocytes proliferating *in vivo*. Over 50% of the cells in the unfractionated population were isolated in the first three fractions, all of which were exlusively 2*n* in DNA content. Thereafter, the average DNA content and nuclear volume per cell in each fraction increased, indicating that a separation on the basis of cell cycle had occurred. Total RNA was prepared from the unfractionated thymocytes (U) of each of the subpopulations. Ribosomal RNA concentrations in all fractions were equalized and ethidium bromide staining of the equalized ribosomal RNAs, separated on a 1% agarose gel, is shown in the upper panel. Autoradiograms of Northern blots were prepared and hybridized with c-*myc*, TK, H2b and β-actin as described in Fig. 2 legend.

decreased as the number of replicating cells declined in culture, and was not expressed until 14 h after serum stimulation of quiescent cells. However, the variation of TK mRNA levels within the cell cycle of exponentially growing cells was not as large as the variation of H2b mRNA. There are several possible reasons for this. Unlike the H2b gene, expression of the TK gene may be only partially S-phase-dependent. For example, histone variants have been described in which transcription is induced at the start of DNA synthesis but is not completely repressed following S phase[16]. Alternatively, the half-life of TK mRNA may be greater than that of H2b, possibly because of the lack of polyadenylation of histone mRNA[8].

Taken together, these data define two broad categories of mRNA expression with respect to the cell cycle. Some genes, such as those for TK and H2b, are expressed at specific points in the cell cycle and can be said to be cell-cycle-regulated. A second class of genes, represented by c-*myc*, are expressed in cells capable of proliferating and are transcribed continuously throughout the cell cycle.

We thank our colleagues Kathleen Conklin, William Forrester, Stephen Hann and Robert Eisenman for stimulating discussions and critical comments on the manuscript and Rainer Storb for use of his counterflow centrifugation equipment. c-*myc* oncogene protein synthesis is independent of the cell cycle in human and avian cells

Stephen R. Hann, Craig B. Thompson* & Robert N. Eisenman

Several lines of evidence suggest a role for the *myc* oncogene in cell proliferation.[1–7] Most recently, mitogenic stimulation of quiescent lymphoid, fibroblast and epithelial cells has been demonstrated to lead to a sharp increase in c-*myc* RNA levels[8–10]. To determine how c-*myc* expression is linked to the cell proliferative cycle, we have used centrifugal elutriation to enrich for populations of avian and human cells at different stages of the cell cycle. Centrifugal elutriation is a counterflow centrifugation method that separates cells on the basis of volume, a parameter correlating well with progression through the cell cycle[11–14]. Using *myc*-specific anti-peptide antibodies, we show here that the synthesis, half-life and modification of c-*myc* proteins are constant throughout the cell cycle of normal and transformed cells.

Figure 1*a* (upper panel) shows distributions of cell volume, nuclear volume and DNA content for an exponentially growing population of K562 cells. The K562 line is derived from a human chronic myelogenous leukaemia[15] containing a chromosome 9 translocation involving the c-*abl* oncogene, but does not contain either amplified or translocated *myc* sequences[16]. These cells display the broad range of nuclear and cell volumes expected for an unsynchronized population of growing cells. In addition, the DNA content profile indicates the presence of cells in G_1, S and G_2/M phases of the cell cycle. Using centrifugal elutriation of this population of K562 cells, we have collected six subpopulations differing in cell volume (Fig. 1*a*, lower panel). Flow cytometric analysis of these fractions indicates that fraction 1 has a DNA content characteristic of cells in G_1, fractions 2 and 3 contain cells in G_1 with increasing numbers of S-phase cells, fractions 4 and 5 contain primarily S-phase cells with some G_1 and G_2/M cells, respectively, and fraction 6 contains predominantly G_2/M cells. The increase in nuclear and cellular volume observed during progression through the cell cycle is paralleled by an increase in both the quantity of ribosomal RNA and amino-acid incorporation, to levels in G_2/M cells more than twice those found in G_1 cells (data not shown).

To determine the level of c-*myc*-encoded protein synthesis, K562 cells were pulse-labelled for 20 min with ^{35}S-methionine before elutriation. The labelled cells from each elutriator fraction were lysed and sonicated in buffer containing detergents. Because incorporation of the labelled amino acid increased in direct proportion to cell volume during progression through the

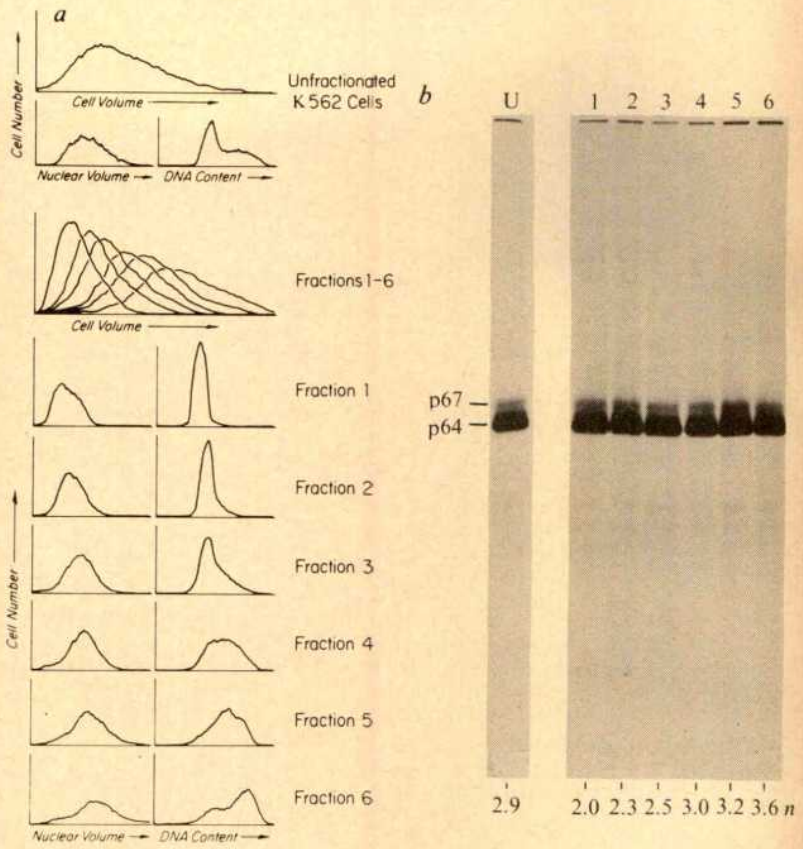

Fig. 1 *a*, Representative cell volume, nuclear volume and DNA content analysis of elutriated cell fractions. *b*, Analysis of c-*myc*-encoded proteins in cell cycle-separated K562 cells. *N* represents the haploid DNA content of K562 cells; U, unfractionated population.

Methods. *a*, An exponentially growing culture of the human chronic myelogenous leukaemia cell line K562 was suspended in Tris-buffered saline with 0.5 mM EDTA, 5% calf serum at 4 °C and separated by counterflow centrifugation into six fractions numbered 1–6 in order of increasing cell size. The recovery of the input unfractionated cells from the six subpopulations was 90%. Cell volume was measured using an electronic cell counter/sizer. Nuclear volume was determined by measuring narrow angle laser light scatter on a fluorescence-activated cell sorter (FACS) after preparation of nuclei by solubilization of cells with 0.5% NP40 in Tris-buffered saline containing 10 mM $MgCl_2$. The average DNA content of cells from each fraction was determined by FACS analysis after staining the nuclei with propidium iodide. *b*, The K562 cells (10^8 cells) shown in the elutriation fractions of *a* were first labelled with 3 mCi ^{35}S-methionine before elutriation. The elutriated subpopulations were lysed in Ab. buffer (0.01 M Tris-Cl *p*H 7.5, 0.05 M NaCl, 0.5% NP40, 0.5% deoxycholate, 0.5% SDS, 0.5% Trasylol, 1 mM phenylmethylsulphonyl fluoride, 10 mM iodoacetamide), followed by 30 s of sonication and centrifugation at 10,000*g* for 10 min. The lysates were adjusted to equal levels of incorporated label and brought to the same volume. Immunoprecipitation was as described previously using anti-hu-*myc* 12C (affinity-purified antibodies prepared against a synthetic peptide whose sequence corresponds to the 12 C-terminal amino acids of the human c-*myc* coding region)[17]. The immunoprecipitate was dissolved by boiling for 3 min in SDS electrophoresis sample buffer (5% SDS, 4% β-mercaptoethanol, 0.08 M Tris-Cl *p*H 6.8, 10% glycerol, 0.002% bromophenol blue) and electrophoresed on a discontinuous 10% SDS-polyacrylamide slab gel. A fluorograph of the dried gel is shown. M_rs were determined as previously described[17]; M_r markers were co-electrophoresed on all gels. Quantitation was carried out by scanning laser densitometry of fluorographs.

cell cycle (data not shown), we adjusted the amounts of lysate to normalize for equal amounts of incorporated label[17]. This allows an analysis of changes in c-*myc* protein levels that are not due simply to changes in cell mass during growth. The c-*myc* proteins were immunoprecipitated with an anti-peptide antibody reactive with the carboxy-terminus of human c-*myc* proteins (anti-hu-*myc* 12C)[17]. Figure 1*b* demonstrates that K562 cells synthesize the major and minor human c-*myc*-specific proteins p64 and p67 (respective relative molecular masses (M_rs) 64,000 and 67,000) as previously observed for cells with unrearranged c-*myc*,[17] and also that the levels of $p64/67^{myc}$ are constant (<25% maximum variation among the fractions) in the six cell fractions derived from different phases of the cell cycle. The short labelling time used in these experiments (20 min) coupled with the rapid elutriation time (45 min) at 4 °C implies that we are measuring primarily the rate of synthesis of *myc* proteins, which have a half-life of ~25 min at 37 °C[17]. Similar results to those shown in Fig. 1*b* were obtained when cell populations were labelled after elutriation (data not shown), indicating that the elutriation procedure is unlikely to be perturbing *myc* protein metabolism.

To find whether production of c-*myc* protein is different in transformed cells containing an altered c-*myc* allele, we also examined Manca, a human Burkitt's lymphoma cell line, which contains a translocation (t(8; 14)) of c-*myc* exons 2 and 3 into the immunoglobulin heavy-chain locus[18,19] and produces only the $p64^{myc}$ protein[17] (see Fig. 2*a*, lane U). When c-*myc* protein synthesis in Manca cells was assayed after fractionation by elutriation into cell cycle stages, as seen with K562 cells, the rate of synthesis of $p64^{myc}$ showed little variation (23% among the average G_1, S and G_2/M subpopulations) throughout the growth cycle when cell extracts were normalized to equal amounts of incorporated label (Fig. 2*a*).

We next attempted to generalize these observations by examining c-*myc* protein synthesis as a function of the cell cycle in normal and transformed avian cells. Accordingly, we labelled with ^{35}S-methionine: (1) secondary quail embryo fibroblast cells (QEF), (2) a Marek's disease virus-transformed chicken thymocyte line (MSB-1 cells) containing unrearranged c-*myc* (ref. 20) and (3) the chicken bursal lymphoma cell line BK25, containing a c-*myc* gene activated by insertion of a long terminal repeat[21]. The labelled cells were fractionated by elutriation, the lysates adjusted to equal amounts of incorporated label and avian c-*myc* proteins identified by immunoprecipitation with anti-peptide antiserum prepared against the carboxy-terminus of the MC29 v-*myc*-encoded protein (anti-v-*myc* 12C)[22]. The QEF (Fig. 2*b*) and MSB-1 cells (Fig. 2*c*) showed the avian $p59/62^{c\text{-}myc}$ proteins characteristic of cells possessing unaltered c-*myc* genes, while the BK25 bursal lymphoma line (Fig. 2*d*) showed high levels of only one of the c-*myc* proteins ($p59^{myc}$), similar to that previously reported for human tumour cells containing c-*myc* alterations[17]. The data again demonstrate no consistent change in the levels of synthesis of these c-*myc*-encoded proteins. A maximum of 20% variation was found among the BK25 fractions, with 30% variation among the MSB-1 fractions.

We also assayed for c-*myc* protein synthesis in a synchronized QEF population at various times after release from a double-thymidine block at the G_1/S boundary. Cells released into serum-containing medium doubled in cell number ~10 h after release, but levels of c-*myc* protein synthesis, except for a transient increase 1 h after release, did not change significantly throughout the 24-h QEF cell cycle (Fig. 2*e*). In addition, the G_1/S-blocked non-proliferating population had levels of c-*myc* protein synthesis equal to that of the mock-treated proliferating cells (compare Fig. 2*e*, lanes 0 and M). In a parallel experiment,

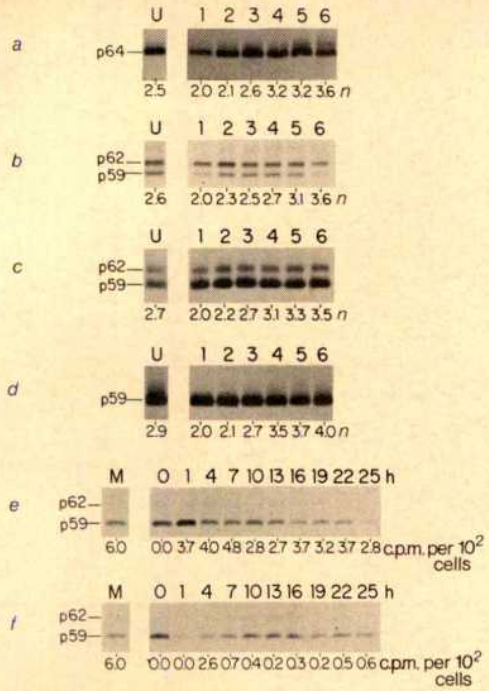

Fig. 2 *a–d*, Synthesis of c-*myc* proteins in human and avian cells separated into cell cycle subpopulations. Exponentially growing cells (10^8) were labelled for 20 min with 1–3 mCi ^{35}S-methionine before elutriation. Lysates from cell cycle subpopulations were adjusted to equal amounts of incorporated label and immunoprecipitated (*a*, anti-hu-*myc* 12C; *b–d*, anti-v-*myc* 12C (ref. 22)) as described in fig. 1 legend. *a*, Manca cell line, a human Burkitt's lymphoma cell line[18,19]; *b*, quail embryo fibroblast cells, secondary culture; *c*, MSB-1 cells, a chicken thymocyte line; *d*, BK25, a chicken cell line derived from a bursal lymphoma. Numbers below the autoradiograms represent average DNA content of cells in each fraction. U, unfractionated cells. *e*, *f*, Synthesis of c-*myc* proteins in chicken embryo fibroblast cells synchronized by double-thymidine block. Secondary cultures of chicken embryo fibroblasts (CEF) were grown in 100-mm dishes to 5×10^6 cells per dish and treated with 25 mM thymidine for 18 h. This was followed by growth in complete medium for 9 h and another 18-h incubation in complete medium containing 25 mM thymidine. Cells were labelled with 500 μCi ^{35}S-methionine per ml for 20 min before removal of the thymidine (0 time point) and at 3-h intervals after removal of the thymidine and incubation in growth medium containing 10% calf serum, 2% chick serum (*e*) or in growth medium lacking serum (*f*). Preparation of lysates and immunoprecipitation with anti-v-*myc* 12C were as described in Fig. 1 legend. Parallel cultures were labelled for 20 min with 5 μCi ^{3}H-thymidine per ml and aliquots of lysates were precipitated with trichloroacetic acid to determine incorporation of label into DNA as denoted by numbers below the lanes. Synchrony induction was confirmed by direct cell counting. Lanes M, mock-treated cultures. Only the relevant portions of the autoradiograms are shown. Lower band intensities in *e* (25 h) and *f* (1 h) lanes were due to sample loss during preparation of immunoprecipitates.

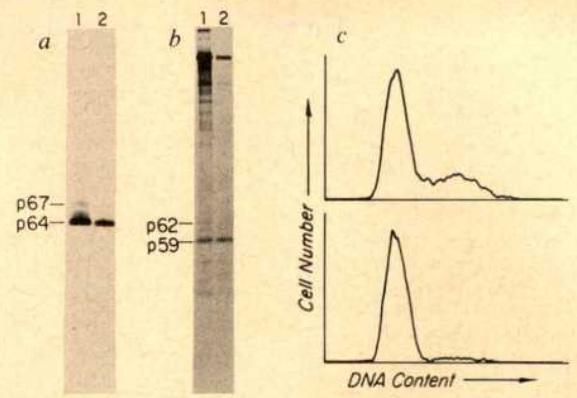

Fig. 3 Synthesis of c-*myc* proteins in quiescent and growing human and avian cells. *a*, K562 cells; *b*, QEF. Lanes 1, exponentially growing cells; lanes 2, quiescent cells. *c*, FACS analysis of the DNA contents of QEF cells in *b*. Upper panel, exponentially growing cells; lower panel, quiescent cells.
Methods. Human K562 cells were grown to saturation (10^6 cells per ml) and tertiary cultures of QEF were grown to confluency (2×10^7 cells per 100-mm dish) and incubated in normal growth medium for an additional 48 h. The cells were then incubated for a further 48 h in medium containing 0.1% serum (quiescent cells) and then labelled for 20 min with 500 μCi ^{35}S-methionine in medium lacking serum. Parallel cultures of non-serum-starved exponentially growing cells (4×10^5 ml^{-1} K562 cells; 10^7 per 100-mm dish QEF) were also maintained and labelled at the same time. FACS analysis indicated the presence of G_1, S and G_2/M cells in the exponentially growing populations. Lysis and immunoprecipitation with anti-v-*myc* 12C were as described in Fig. 1 legend.

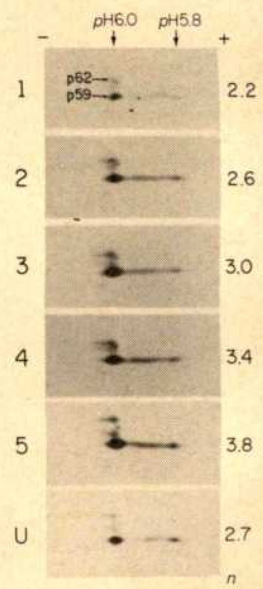

Fig. 4 Two-dimensional gel electrophoretic analysis of c-*myc* proteins synthesized in cell cycle-separated subpopulations of MSB-1 cells. Numbers on the left-hand side refer to the cell fractions; U, unfractionated cells; *n* represents the haploid DNA content.
Methods. Chicken MSB-1 cells (10^8 cells) were labelled for 20 min with 3 mCi ^{34}S-methionine before centrifugal elutriation. The isolated subpopulations were lysed and immunoprecipitated with anti-v-*myc* 12C as previously described except that the final washed immune complex was dissolved by boiling for 1 min in 9.5 M urea, 0.5% SDS, 5% β-mercaptoethanol, 0.2% ampholines *p*H 3.5–10 followed by addition of an equal volume of 9.5 M urea, 2% w/v NP40, 1.6% ampholines *p*H 5.0–7.0, 0.4% ampholines *p*H 3.5–10.0, 5% β-mercaptoethanol and boiling for 1 min. Equilibrium isoelectroc focusing was carried out as described by O'Farrell[25]. Briefly, the solubilized immune complex was applied to a first-dimension equilibrium isoelectric focusing tube gel. Following electrophoresis to equilibrium, the gel was removed, equilibrated in 10% glycerol, 5% β-mercaptoethanol, 2.3% SDS, 62.5 mM Tris-Cl *p*H 6.8, and electrophoresed in the orthogonal direction on 10% SDS-polyacrylamide slab gels. Only the relevant portions of the second-dimension gels are shown. The *p*H gradients in the isoelectric focusing gels were determined by incubating 5-mm slices of a parallel gel in degassed distilled water and measuring the *p*H of the eluted ampholine.

we measured c-*myc* protein synthesis in QEF released from the double-thymidine block into serum-free medium (Fig. 2*f*). In contrast to the cells released into complete medium, these cells showed only a small increase in incorporated ^{3}H-thymidine label at 4 h after release, no cell division up to 25 h after release and a significant decrease in ^{35}S-methionine incorporation. Figure 2*f* shows that these arrested quiescent cells had virtually the same levels of c-*myc* protein synthesis as the actively growing cells released into complete medium throughout most of the 25-h period (compare Fig. 2*e* and *f*). The transient changes in c-*myc* protein synthesis observed 1 h after release would seem to be a serum-dependent effect on synthesis rather than a cell cycle-regulated event.

To relate the levels of c-*myc* protein synthesis observed during the cell cycle of proliferating cells to the levels found in non-proliferating cells arrested in G_1, we sought to determine whether the levels of c-*myc* protein differed between quiescent G_1 cells deprived of serum and cells growing in the presence of serum. To obtain quiescent cells, we grew human K562 cells to saturation, and QEF to confluency, in serum-containing medium for 48 h followed by a further 48-h incubation in medium with 0.1% serum. The serum-starved K562 cells showed a 10-fold less ^{3}H-thymidine uptake than the parallel culture of proliferating cells. Both populations showed substantial c-*myc* protein syn-

thesis, although the proliferating cells had twice the level of c-*myc* protein (Fig. 3*a*). The QEF also showed a decrease in ^{3}H-thymidine incorporation. Cytofluorometric measurement of the DNA content of the serum-starved QEF showed a complete absence of S and G_2/M cells, in contrast to the non-serum-starved cells which showed the expected levels of S and G_2/M cells (Fig. 3*c*). Figure 3*b* shows that there is no significant difference in c-*myc* protein levels in proliferating and non-proliferating QEF.

Although the synthesis of c-*myc* proteins seems not to change significantly during the cell cycle, two other properties relating to c-*myc* proteins, turnover and post-translational modification, could potentially vary in a cell cycle-dependent manner. Pulse-chase experiments indicate an extremely short apparent half-life (20–30 min) for avian v-*myc* and human c-*myc* proteins[17,23]. We therefore used this technique on chicken MSB-1 cells separated by centrifugal elutriation. After a 15-min pulse and a 60-min chase, there was no significant change in apparent turnover of c-*myc* protein as a function of the cell cycle (data not shown).

To examine post-translational modification of c-*myc* protein as a function of the cell cycle, we performed two-dimensional gel electrophoretic analyses. The only known modification of *myc* proteins is phosphorylation[17,22,24]. Changes in the extent of phosphorylation, or some other type of charge modification, would probably produce charge alterations that would be detectable as shifts in isoelectric point[25]. MSB-1 cells labelled with ^{35}S-methionine for 20 min were separated by elutriation, lysed and the anti-v-*myc* 12C immunoprecipitate dissolved and subjected to equilibrium isoelectric focusing in the horizontal dimension and SDS-polyacrylamide gel electrophoresis in the vertical dimension[25]. Figure 4 shows that the avian p59^{myc} protein is resolved into a major spot of *p*I 6.0 which trails into a poorly resolved minor spot of *p*I 5.8. The minor p62^{myc} protein and another faint spot also have *p*Is of 6.0, suggesting that the difference between p59^{myc} and the higher-M_r forms is not due to hyperphosphorylation or other charge-altering modifications. Comparison of the two-dimensional electrophoretic patterns of the c-*myc* proteins in MSB-1 cells separated into different cell cycle subpopulations revealed no alterations in isoelectric point (Fig. 4). Finally, we have also failed to detect differences in ^{32}P-labelling of c-*myc* proteins at different times after release of MSB-1 cells from a G_1/S block (data not shown).

Our results demonstrate that in avian and human cells the rate of synthesis (as a fraction of total cell protein synthesis), turnover and modification of c-*myc* proteins is independent of the cell cycle stage. Several reasons make it unlikely that we did not achieve an effective separation of cells into different cell cycle stages. The increases observed in cell volume, nuclear volume and DNA content (Fig. 1*a*) and in protein synthesis and ribosomal RNA content in our isolated subpopulations all correlate well with progression through the cell cycle[11,12]. Furthermore, the accompanying manuscript shows that the levels of c-*myc* RNA in avian cells are also constant throughout the cell cycle, even though levels of histone 2b and thymidine kinase messenger RNAs vary during the cell cycle in the same cells[26]. Previous reports have indicated that stimulation of quiescent cells with growth factor results in a rapid increase in c-*myc* transcription[8]. One interpretation of these previous findings has been that c-*myc* is 'switched on' during the transition from a G_0 to a proliferating state and that high levels of c-*myc* expression may be needed to traverse each G_1 period[27,28]. However, the data in this and the accompanying paper demonstrate that the levels of c-*myc* expression are essentially the same in all growth phases of proliferating cell populations and in non-proliferating cells arrested in G_1 or G_1/S. We conclude that the characteristic mode of c-*myc* expression is continuous synthesis and rapid turnover throughout the cell cycle in non-terminally differentiated cells and tumour cells. The increase in c-*myc* expression on stimulation of resting cells is only transient, with the elevated levels of both c-*myc* RNA[8,10] and protein[29] falling back to a constant basal level which is then maintained throughout subsequent cell cycles.

We thank Susan Fisher for technical assistance and Mark Groudine, Peter Challoner, Paul Neiman and Maxine Linial for stimulating discussions and critical readings of the manuscript. The striking number of human and murine immunodeficiency disorders which map to the X chromosome (Table 1) suggests that genes localized on this chromosome must have important roles in lymphocyte development. At least seven distinct disorders in the human and two in the mouse disrupt lymphocyte maturation, particularly that of B cells, at characteristic stages[1,2]. As functional genes mapping to the X chromosome in one mammal are found on the X chromosome in all other mammals[3], the same genes regulating lymphocyte development are expected to be found on the X chromosome in mouse and man. Investigations into the possible mechanisms of these X-linked disorders have been hampered by the lack of molecular probes for the genes or gene products affected; because of this, and the possibility of correlating

¶ Present address: Department of Biology, M-001, University of California at San Diego, La Jolla, California 92093, USA.

one or more of the several hundred B- or T-cell-specific genes[4] with a specific mutation, we surveyed 15 different B- and T-cell-specific cDNA clones for localization to the X chromosome. We report here the characterization of one of these murine cDNA clones, which hybridizes with a large, X-linked gene family, designated XLR (X-linked, lymphocyte-regulated). We show that the XLR gene family is closely linked to the X-linked immunodeficiency described in the CBA/N mouse strain (*xid*)[5], by restriction fragment length polymorphism (RFLP) analysis of DNA from mice congeneic for *xid*. This finding, together with data on the expression of the XLR locus in B cells (see accompanying paper[6]), indicates that this gene family either includes the locus defined by the *xid* mutation or is adjacent to it in a gene complex which may be important in lymphocyte differentiation.

The initial cDNA clone, pX310, which identified XLR was obtained by screening a T-cell-specific, selected cDNA library[7] with a T-helper cDNA–T-suppressor mRNA-subtracted cDNA probe. Although pX310 was originally isolated in this manner as a T-cell-specific clone, subsequent analysis shows that mRNAs which cross-hybridize with this cDNA are also expressed in late-stage and secretory B-lymphocyte tumour lines, but not in the original B-cell tumour (BAL 17) used in the subtraction of the T-cell library (see accompanying report[6]). pX310 was one of 15 clones, obtained from T-cell-specific or B-cell-specific libraries, which were analysed by Southern blotting to mouse–hamster somatic cell hybrids[8]. This cDNA clone characteristically hybridizes with 10–14 bands on Southern analysis, consistent with its recognizing a gene family, and *Eco*RI restriction digests of DNAs from the somatic cell hybrid lines indicate that all of the restriction fragments which hybridize to pX310 are found on the mouse X chromosome (Fig. 1). Most useful for such a chromosomal assignment are results obtained from an analysis of the somatic cell hybrids MAE 28, containing the murine chromosomes 12 and X; MAE 32, containing chromosomes 16 and X; and MACH 4A63, containing most of the mouse chromosomes, including chromosomes 12 and 16 but not X (see Fig. 1). DNAs from the former two cell lines hybridize with pX310, while DNA from the latter line does not. None of 14 other cDNA clones obtained from the T- or B-cell-enriched cDNA libraries show evidence of being derived principally from X-chromosomal genes, or of recognizing such a large gene family. That the multiple bands seen with the pX310 probe are not due to 5′- or 3′-untranslated region repeats is indicated by the fact that an internal restriction fragment from an apparently full-length XLR cDNA clone gives an identical pattern on Southern blots (data not shown).

The 10–14 bands seen on Southern analysis of pX310 are comparable to the 15–28 bands seen with murine class I major histocompatibility complex (MHC) gene probes[9,10] (corresponding to ~35 different genes[11]) and to the 8–10 bands seen for α-interferon (IFN-α) corresponding to ~10 distinct genes[12].

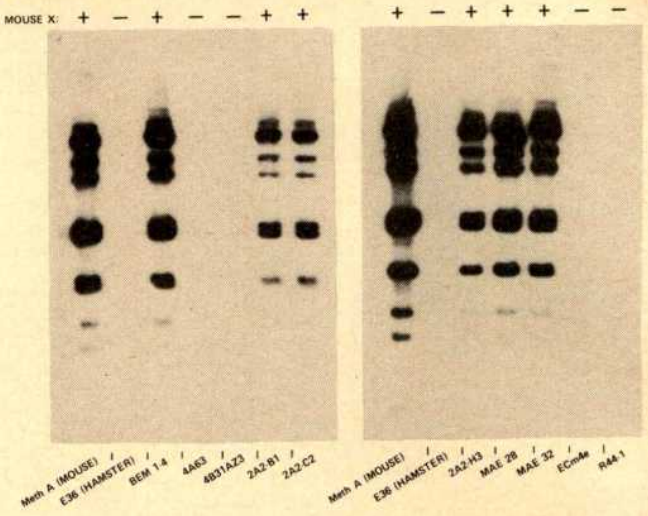

Fig. 1 X-linkage of the XLR gene family. DNAs were isolated from mouse–hamster somatic cell hybrids, digested with the restriction enzyme *Eco*RI, and blotted onto nitrocellulose according to the method of Southern[8]. The insert from XLR cDNA clone pM1 was labelled by nick-translation to 5×10^8 c.p.m. μg^{-1}, blots were hybridized with 10^6 c.p.m. ml^{-1} in 5× SSPE[28], 50% formamide at 42 °C, and washed repeatedly before exposure, the most stringent wash being in 0.2× SSPE at 60 °C. The names of hybrid lines are given at the bottom, and the presence (+) or absence (−) of the mouse X chromosome in each hybrid is indicated above each lane. The chromosomal content of each line has been described elsewhere[29,30], and the copies of mouse chromosome X per hybrid cell are: meth A (2.0), E36 (0), BEM 1-4 (0.87), 4A63 (0), 4B31AZ3 (0), 2A2-B1 (0.35), 2A2-C2 (0.60), 2A2-H3 (0.70), MAE 28 (1.00), MAE 32 (1.00), ECm4e (0), and R44-1 (0).

Similar to the class I MHC genes, there are no apparent dispersed members on other chromosomes. While an XLR probe gives little or no cross-hybridization with hamster DNA in moderately stringent conditions (see Fig. 1 legend), it does hybridize well with DNAs from three distinct wild mouse species and, indeed, shows less polymorphism than another gene family, PGK, for these DNAs (D.I.C. and M.M.D., unpublished data). This is distinctly different from the pattern seen for mobile elements[13]. Both class I MHC and IFN-α genes are genetically linked in a cluster to other very distantly related genes; in the former case, to the class II MHC genes[14], and in the latter case, to β-interferon[15].

One of the most studied X-chromosomal defects is the *xid* lesion[16,17], which causes a recessive B-cell immunodeficiency which appears to disrupt late-stage B-cell functions[18]. The mutation was recognized in a subline of mice, designated CBA/N,

Table 1 X-linked immunodeficiency diseases

Name of defect	Cell types affected	Presumed stage	Functional defect
Human defects (ref. 1)			
Severe combined immunodeficiency	T, B	Stem cell	T-cell immunity (TCI), antibody (Ab)
Wiskott–Aldrich syndrome	T, B, platelets	Haematopoietic	TCI, Ab to polysaccharides, low platelets
Agammaglobulinaemia (Bruton's)	B	Pre-B cell	Ab
Agammaglobulinaemia with growth hormone deficiency	B	Pre-B cell	Ab
Lymphoproliferative syndrome	B	B-cell growth regulation	Lymphomas on Epstein–Barr virus infection
Hyper IgM, reduced IgG and IgA	B	Plasma cells	Low IgG, low IgA
Hyper IgM and IgG, reduced IgA	B	Plasma cells	Low IgA
Murine defects (refs 2, 19, 20)			
CBA/N (*xid*)	B	Mature B cell	Antibody to polysaccharides
DBA/2Ha	B	Mature B cell	Plasma cell differentiation

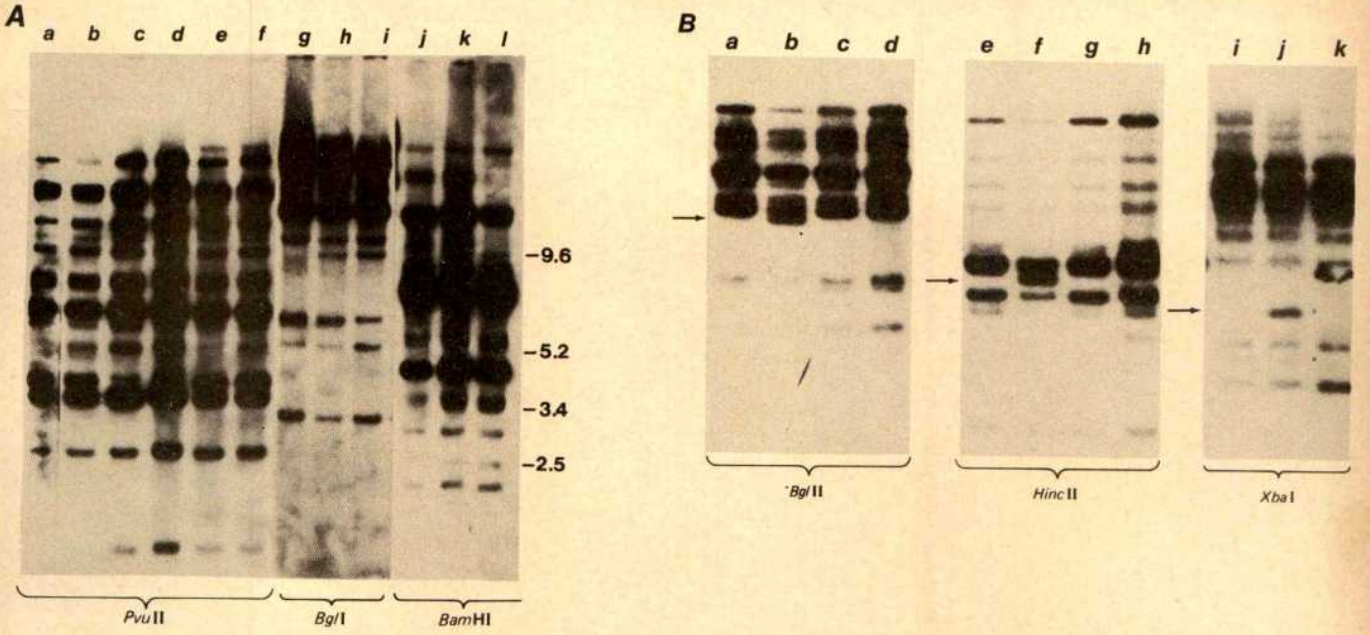

Fig. 2 *A*, Restriction fragment length polymorphism analysis of genomic DNA from MRL (lanes *a*, *g*), CBA/N (*c*, *i*, *l*), CBA/Ca (*d*), BXSB (*e*, *j*), and from the *xid* congeneic strains, MRL *xid* (*b*, *h*) and BXSB *xid* (*f*, *k*). Polymorphisms referred to in the text are labelled by size (in kb) on the right of the figure; restriction enzymes are indicated at the bottom. Blots were probed with the insert from the XLR cDNA clone, pX310. *B*, Southern comparison of genomic DNA from NZB (lanes *a*, *e*, *i*), NZB *xid* (*b*, *f*, *j*), CBA/N (*c*, *g*, *k*) and CBA/Ca (*d*, *h*) congeneic strains hybridized with XLR probe, pM1. Restriction enzymes were *Bgl*II (*a*–*d*), *Hinc*II (*e*–*h*), and *Xba*I (*i*–*k*). Bands unique to NZB *xid* are indicated by arrows. Using the formulation of Klein[14] and the fact that BXSB *xid*, MRL *xid* and NZB *xid* mice had been bred through 9, 12 and 19 potential recombinations, respectively, at the time of analysis, the probability of linkage to within 10 centimorgans is $1-(0.43)(0.31)=87\%$ for the two strains with classic RFLP, and to within 5 centimorgans, 85%, for all three strains.

derived from the normal strain, CBA/Ca. We compared the organization of the XLR locus in genomic DNA from the mutant CBA/N with that from the wild-type CBA/Ca strains, and genomic DNA from a mouse line bearing a distinct X-linked immunodeficiency, DBA/2Ha[19,20], with that from its normal parental line, DBA/2J. These comparisons revealed no obvious reorganizations or deletions in the XLR family in either the CBA/N (Fig. 2*B*, lanes *c*, *g* and *k*) or DBA/2Ha strains (data not shown). However, many eukaryotic mutations are not obvious deletions or translocations and are not directly detectable by Southern analysis[21–23]. It is conceivable that the complexity of the Southern pattern could obscure such a difference, although the patterns given by many different restriction enzymes have been analysed.

Congeneic strains have been bred in which the *xid* mutation, was introduced onto the background of the MRL strain (MRL *xid*[24]), the BXSB strain (BXSB *xid*[25]), and the NZB strain (NZB *xid*[26]); these congeneic lines are useful for determining whether a gene probe such as XLR, recognizes DNA linked to the *xid* mutation. The MRL, BXSB and NZB backgrounds are wild type for the *xid* phenotype. The congeneic mice are bred by backcrossing male offspring, which have been phenotyped for the *xid* trait, to background females, taking resulting F_1 (+/*xid*) females (the only circumstance in which recombination can occur) for crossing to background males, and typing their male offspring for use in continuing the line. This breeding strategy creates a line deriving almost all of its genetic material from the background strain, and only a small fraction of genetic material, almost exclusively surrounding the locus being introduced (*xid*), from the donor strain (see Fig. 2 legend for calculations)[14]. In all cases these mice are statistically expected to derive less than $\frac{1}{8}$ of their X chromosome from the *xid* donor[14]. If the XLR probe recognizes RFLPs derived from the *xid* donor, then some (or all) of the gene family must be linked to *xid*, as any unlinked DNA derived from the CBA/N background has essentially been bred out of the line.

Figure 2*A* shows the Southern blot analysis of male liver DNA prepared from the indicated murine strains, and used in RFLP analysis of the XLR gene family: both MRL *xid* (lane *b*) and BXSB *xid* (lane *f*) congeneic mice possess a 5.2-kilobase (kb) *Pvu*II band of the XLR family characteristic of CBA/N (*xid*) DNA (lane *c*) and unlike the banding pattern of the background strains, MRL (lane *a*) and BXSB (lane *e*). Furthermore, the MRL *xid* mice possess a 9.6-kb *Bgl*I polymorphism (lane *h*), not present in the MRL strain (lane *g*), that is characteristic of *xid* DNA (lane *i*). The BXSB *xid* strain (lane *k*) has inherited two *Bam*HI polymorphisms (at 3.4 and 2.5 kb) from the *xid* background (lane *l*) that are absent from the BXSB (lane *j*). In contrast, BXSB *xid* mice (lane *k*) also have the BXSB (lane *j*) form of a 15-kb *Bam*HI polymorphism, indicating that the BXSB *xid* line has inherited some of its XLR locus from the CBA/N DNAs, and some from the BXSB. If all members of the gene family are tightly clustered, like the MHC genes[11] and most gene families, recombination must have occurred between members of the XLR family. If the family is more dispersed, some members will be linked and more distant members unlinked. In either case, we conclude that one or more members of the XLR gene family are closely linked to *xid*.

Interestingly, in comparing multiple restriction digests from the NZB, NZB *xid* and CBA/N DNAs, rather than observing distinct RFLPs, we found bands unique to the NZB *xid* genome that were not present in either of the parental DNAs (Fig. 2*B*, lanes *b*, *f* and *j*). The 5.5-kb *Bgl*II, 3.6-kb *Hinc*II and 2.9-kb *Xba*I restriction fragments unique to the NZB *xid* strain are indicated by arrows (Fig. 2*B*). This observation suggests that during the breedng of the NZB *xid* line, meiotic rearrangement of the XLR locus occurred. The fact that this distinct pattern has been perpetuated for three subsequent generations, and not lost in backcrossing (D.I.C., A.D.S. and M.M.D., unpublished observation), also argues for linkage of XLR to the *xid* phenotype in this congeneic strain. Although these findings cannot be unambiguously interpreted, they may represent the result of an inversion or unequal recombination between distinct members of the gene family during the breeding of this strain. In the globin gene family, unequal recombinational events have been associated with gene deletions and reorganizations[27].

The multiple members of the XLR gene family may encode functionally distinct molecules and thus might be responsible for more than one of the X-linked deficiencies noted in Table

1. One such possibility is raised by the fact that the human X-linked Wiskott-Aldrich immunodeficiency causes a B-cell defect very similar to that of the *xid* mouse, but in addition leads to abnormal T cells and platelets[1]. Consistent with this possibility, XLR genes are expressed in both B and T lymphocytes (see accompanying report[6]). The isolation of the XLR probe described here defines a large number of new X-linked genes, at least some of which are linked to a murine immunodeficiency trait and expressed in lymphocytes. Further, it offers an important basis for the analysis of X-linked defects in the mouse and, when human probes become available, in the human equivalents.

Expression of an X-linked gene family (XLR) in late-stage B cells and its alteration by the *xid* mutation

David I. Cohen*†, Alfred D. Steinberg‡, William E. Paul† & Mark M. Davis*†

* Department of Medical Microbiology, Stanford University School of Medicine, Stanford, California 94305, USA
† Laboratory of Immunology, National Institute of Allergy and Infectious Diseases, and ‡ Arthritis and Rheumatism Branch, NIADDK, National Institutes of Health, Bethesda, Maryland 20205, USA

One of the most extensively studied X-linked immunodeficiency disorder is the *xid* mutation of the mouse strain CBA/N (reviewed in ref. 1). This mutation may involve a maturational defect as *xid* animals are unable to raise antibodies to soluble polysaccharide antigens, a function normally attributed to late-stage B cells[2,3]. Moreover, studies using monoclonal antibodies have defined a B-cell surface antigen (BLA-2 or 14G8) that is expressed on most or all immature B lymphocytes, but not on a subpopulation of mature splenic B lymphocytes[4,5]; this late-stage, 14G8 antigen-negative splenic B-cell subpopulation is apparently absent from mice bearing the *xid* defect[5]. In the accompanying paper[6] we describe the isolation of a cDNA clone recognizing a family of genes on the X chromosome, at least some of whose members are closely linked to the *xid* trait. We report here that this gene family, XLR, is transcribed in certain B- and T-cell lineage tumours, but not in macrophage tumours, or liver or kidney cells. We show that it is transcribed principally in late-stage, 14G8-negative B-cell tumours and plasmacytomas, but not in immature B-cell or pre-B-cell tumours. We are able to detect transcription in all of 12 plasmacytomas (secretory B-cell tumours) derived from mice with normal X chromosomes, but not in three plasmacytomas carrying the *xid* mutation. These data, combined with the restriction fragment length polymorphism analysis linking the XLR gene family to the *xid* mutation[6], suggests that the *xid* defect occurs within a member of this gene family.

We analysed RNA expression from the XLR gene family in several B-cell tumours and other tissues, by Northern analysis and, in some cases, primer extension studies. Expression of XLR occurs in only certain B-cell tumours (Figs 1, 2); it is also transcribed in a wide variety of functional T-cell hybridomas,

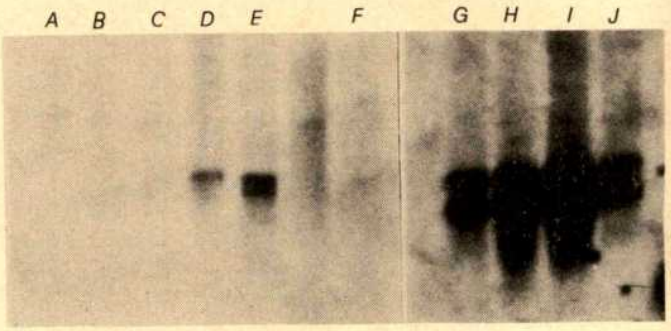

Fig. 1 Northern analysis of 5 μg poly(A)$^+$ RNA electrophoresed through 5 mm MeHgOH and 1.5% agarose, as described elsewhere[30]. Lanes *A–F* were probed with pX310, a cDNA clone recognizing the XLR gene family; lanes *G–J* were probed with a β_2-microglobulin cDNA cones[31]. The RNA samples were from kidney (*A*, *G*), liver (*B*, *H*), BCL1 (*C*, *I*), M315P (non-secretory surface IgA$^+$ lymphoma, *D*), M315J (secretory IgA plasmacytoma, *E*, and 2043-1 (*F*, *J*). In all cases blots were probed with an XLR clone, then with a β_2-microglobulin clone to ensure that each RNA was intact and hybridizable.

of both helper and suppressor phenotype, and in other T-cell tumours. In contrast, liver cells, kidney cells (Fig. 1*A*, *B*) and the macrophage tumour lines J774 (ref. 7) and P338D1 (ref. 8) (data not shown) produced no detectable XLR transcripts. We detected transcription in normal lymphoid tissue by Northern analysis of splenocytes (Fig. 2*E*) and thymocytes, or by primer extension studies of purified B cells[9] (data not shown). We conclude that XLR is expressed in some B- and T-cell lymphomas, and in normal lymphocytes, but not in several kinds of non-lymphoid cells; the specificity of this expression during B-cell ontogeny is discussed below.

The level of transcription of XLR genes is ~5–10 copies per cell for XLR-expressing B-cell tumours. This measurement reflects both the frequency of positively hybridizing clones from a plasmacytoma cDNA library (1 clone per 50,000 colonies) and the ratio of XLR to μ (heavy chain) RNA in the presecretory B lymphoma L10A, which is 1/50 as assayed by cytoplasmic RNA titration[10]. This level of expression makes it rare[11], and it is one of several rare lymphocyte-specific cDNA clones which we have isolated using subtracted cDNA probes[12,13]. Interestingly, XLR expression seems to be even lower in normal cell populations (Fig. 2, compare lanes *B–D* with *E*)[14]. Scanning

Fig. 2 Northern analysis of total RNA electrophoresed through 1M formaldehyde, 1.5% agarose and blotted onto nitrocellulose, as described elsewhere[32]. The probe is pM1, a full-length XLR cDNA clone. RNAs in lane *A* (10 μg) and *B*–*D* (20 μg) were from NZB plasmacytomas (2154 (*A*), 2454 (*B*), 2880 (*C*) and 2997 (*D*) from M. Weigart); *E*, whole NZB splenocyte RNA (25 μg). The results are from the same blot and probe but lane *E* (21-day exposure) was exposed seven times longer than lanes *A*–*D* (3-day exposure).

densitometry establishes that the most weakly hybridizing NZB plasmacytoma produces a signal 25-fold more intense than NZB splenocytes in equivalent assay conditions; this relationship remains unchanged when polyadenylated RNAs are compared (data not shown).

As XLR expression is observed in only some B-cell tumours, we attempted to determine whether the types of B-cell tumours expressing XLR RNA represent a specific stage of B-cell differentiation. We addressed this question by analysing an extensive panel of B-cell tumours (Table 1), because such tumours have been an effective model for normal B-cell maturation in many systems[15,16]. The earliest identifiable normal B-cell precursor is the pre-B cell[17]. As shown in Table 1, only one of nine Abelson pre-B-cell tumours[16] expresses XLR. Immature B cells, such as those found in neonatal or *xid* mutant mice, possess large amounts of surface IgM[18] and typically express the 14G8 determinant[4,5]; neither of the two early-stage B-cell tumours assayed here transcribes XLR. More mature B cells express δ (heavy chain)[19] and many do not express 14G8 (refs 5, 7). Furthermore, as a requirement for immunoglobulin secretion, presecretory B cells must activate the gene encoding the J-chain protein because this protein is necessary for assembling the secreted, multimeric forms of IgM and IgA[20]; therefore, activation of the J-chain gene provides an independent means of assessing B-cell maturity[21]. Of six B-cell lymphomas analysed which possess a mature surface immunoglobulin phenotype, three are relatively more mature in that they express little or no 14G8, and in that they have activated the J-chain gene as demonstrated by either demethylation (L10A)[21] or actual transcription (Fig. 3*C*, lanes *e* and *g*). Of this group of six lymphomas, only the three more mature, presecretory B-cell-stage tumours transcribe XLR. The final stage of B-cell differentiation is immunoglobin secretion and all of 12 secretory-stage tumours (plasmacytomas) transcribe XLR. The pattern of XLR transcription differs between plasmacytomas, which produce two principal transcripts of 1.0 and 1.1 kilobases (kb), and presecretory tumours, which produce one distinguishable transcript of 1.2 kb (Fig. 1*D*, *E*). This finding indicates that either multiple members of the family are activated sequentially or differential splicing occurs during the transition from the presecretory to the secretory stage, as occurs with the μ heavy-chain gene[22]. Even though these stages are probably not absolute, B-cell tumours which transcribe XLR are mature cells at either the presecretory or secretory stage when analysed by multiple criteria (Table 1).

It has been established that a mature subpopulation of splenic B lymphocytes lacking the 14G8 (BLA-2) antigen, and uniquely characterized by a panel of other markers, is absent from mice with the *xid* mutation[5]. Interestingly, the B-cell tumours analysed in the present report, which transcribe XLR, also lack the 14G8 marker. On the basis of this similarity, it is tempting to equate these B-cell tumours expressing XLR with the normal B cells which are absent from *xid* mutant mice. The 'turning-on' of this X-linked gene during the maturation of some B cells coincides with the 'turning-off' of a marker (14G8) which is expressed at an abnormally high frequency in *xid* B cells.

We next asked whether the *xid* mutation directly affects XLR expression. We prepared and analysed mRNA from a pool of three plasmacytomas raised in the NZB *xid* mouse[23], which is an NZB congeneic strain into which the *xid* mutation has been introduced[24], and compared the results with those obtained from plasmacytomas lacking the *xid* mutation, including NZB plasmacytomas. The 12 plasmacytomas lacking the *xid* mutation included cells using the μ, γ or α immunoglobulin heavy chains and κ or λ light chains, and represented tumours expanded either *in vivo* or *in vitro*. All of these 12 plasmacytomas gave essentially similar patterns and amounts of XLR transcription whereas the pool of NZB *xid* plasmacytomas showed no detectable XLR expression (Fig. 3*A*, lane *h*). The most relevant comparison is with the four NZB lines (Fig. 2*A*–*D*). Allowing for the slightly greater amount of RNA loaded for the NZB *xid* pool, and the sensitivity of these Northern blots (see above), we estimate that XLR transcription must be decreased at least 30-fold in the NZB *xid* plasmacytomas, to less than 1 copy per cell; comparative titrations of plasmacytoma RNAs in primer extension experiments support this conclusion (data not shown). Figure 3*C*, lane *j* shows that the same NZB *xid* plasmacytoma RNA contains readily detectable J-chain mRNA, establishing

Table 1 XLR expression in B-cell tumours

Stage	XLR (no. positive/ no. tested)	Phenotype: Immunoglobulin	14G8 staining	J chain	Tumour (XLR expression + or −)
(1) Pre-B	1/9	Cytoplasmic μ	+	−	2043-1, 38B7, ABL5 1, 8, 19, 109, 122, 140 [all (−)] ABLS 5 (+)
(2) Early B	0/2	Surface IgM	+	−	BCL1, W231
(3) Intermediate B	0/3	Surface IgM, IgD	+	−	K46, X16C, BAL17
(4) Presecretory B	3/3	Surface immunoglobulin IgD	−	DM or +	L10A*, 315P, 2PK3
(5) Plasmacytoma	12/12	Secretory immunoglobulin	−	+	V17C, HM14, CPC1, TEPC 1197, CBB22PC3, CBPC112, N2BPC 2154, 2454, 2880, 2993, M315J, M104e

DM, demethylated, not expressed[21]. Data were taken from refs 15, 16, 21, 26–29 and the present study.
We tested all tumours in categories (2), (3) and (4) for 14G8 staining and J expression, but only representative tumours from categories (1) and (5).
* Ref. 21.

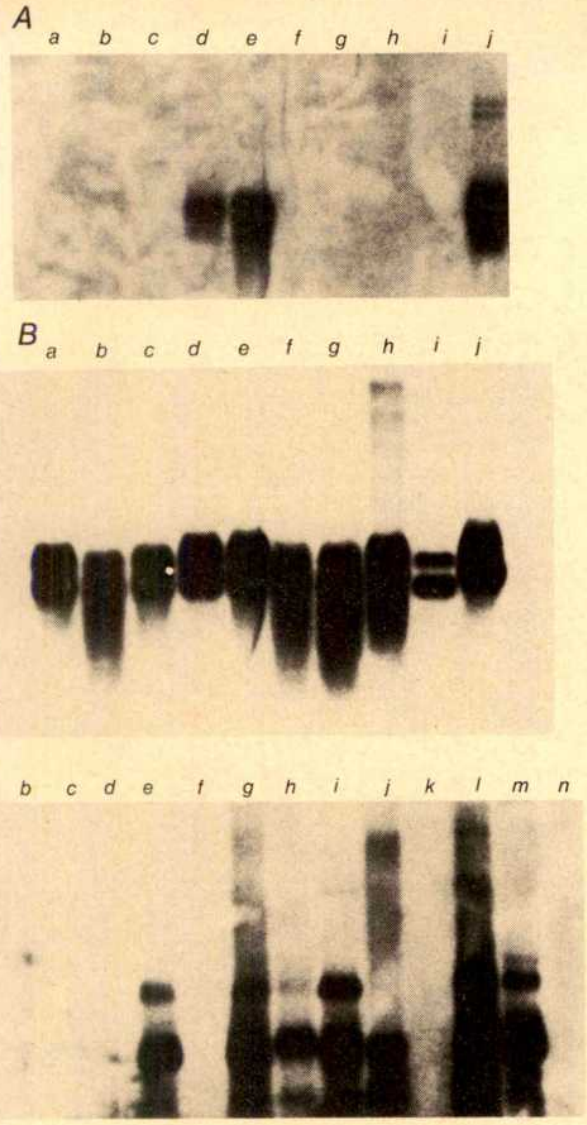

Fig. 3 Northern analysis, as in Fig. 2, using 30 μg of total NZB *xid* plasmacytoma, or 5 μg of poly(A)$^+$ RNA from the other tumours. *A*, Probed with pM1; *B*, the same blot probed with β_2-microglobulin. The RNAs in each lane are: *a*, WEH1 231 (W231); *b*, W231 (different batch); *c*, lipopolysaccharide (LPS)-stimulated W231; *d*, 2PK3; *e*, L10A; *f*, X16C; *g*, K46; *h*, NZB *xid* plasmactyoma; *i*, BAL 17; and *j*, M104e. *C*, RNA probed with a J-chain cDNA clone[15]; *a*, W231; *b*, BAL17; *c*, X16C; *d*, K46; *e*, 2PK3; *f*, L10A; *g*, M315P; *h*, M104e; *i*, M315J; *j*, NZB *xid* plasmacytoma; *k*, T-cell RNA from EL4; *l*, V17C; *m*, HM14; and *n*, LPS-stimulated W231. The NZB *xid* plasmacytoma RNA was extracted from a pool of equal numbers of cells from three independently derived plasmacytomas, in order to have sufficient material for complete analysis. One principal type of antibody produced by these cells is IgA/κ (A.D.S., unpublished data).

that these cells are at the correct stage to transcribe XLR (Table 1), and that the mRNA analysed is intact. We conclude that the *xid* mutation alters the normal expression of XLR.

The experiments described here establish that XLR transcription is characteristic of late-stage B-lymphocyte maturation and that this expression is altered in cells bearing the *xid* mutation. These data indicate that the *xid* mutation disrupts XLR gene expression and, coupled with the linkage data described in the accompanying paper[6], support the notion that the *xid* mutation occurs within a member of the XLR gene family. The mutation may act either directly or indirectly to account for the pattern of expression observed here. In the direct model, the NZB *xid* plasmacytoma cells would normally express XLR but cannot, owing to the *xid* defect. Alternatively, these plasma cells may represent an XLR-nonexpressing class of B cells that are rare in normal animals but common in those carrying the *xid* defect; this rare class would predominate if the XLR-requiring plasma cell fails to mature in the *xid* animals. The latter alternative is more consistent with a dual-pathway model of (late-stage) B-cell maturation[1,5,25].

We thank Dr M. Koshland for the J-chain cDNA clone, Jc-3 used in our study; Dr J. Parnes for the β_2-microglobulin cDNA clone; Dr A. DeFranco for RNA and for critical review of the manuscript; Drs R. Lynch for the M315P and M315J lines, J. F. Mushinski for ABL and plasma cell RNAs, J. Kung and J. Kemp for the cell-surface staining in Table 1; and K. Redman for assistance in the preparation of the manuscript. D.I.C. is a Fellow of the Leukemia Society of America. This work has been supported, in part, by a NIH grant to M.M.D. (AI20320).

An N-terminal peptide from p60^{src} can direct myristylation and plasma membrane localization when fused to heterologous proteins

David Pellman*, Ellen A. Garber, Frederick R. Cross & Hidesaburo Hanafusa

The Rockefeller University, 1230 York Ave, New York, New York 10021, USA

The *src* gene product, p60^{src}, of Rous sarcoma virus (RSV) is a tyrosine-specific protein kinase which is associated with the plasma membrane of infected cells (for review, see ref. 1). Myristic acid is bound in an amide linkage to glycine 2 of p60^{src} (refs 2–6). Of the N-terminal 30 kilodaltons of p60^{src}, only amino acids 1–14 are required for myristylation, and myristylation of p60^{src} may be required for its membrane association, and for cell transformation[4,7]. To test the hypothesis that the first 14 amino acids of p60^{src} contain a recognition sequence for myristylation, we have fused the DNA sequence coding for these amino acids to either the *fps*

* Present address: Division of the Biological Sciences and the Pritzker School of Medicine, University of Chicago, Chicago, Illinois 60637, USA.

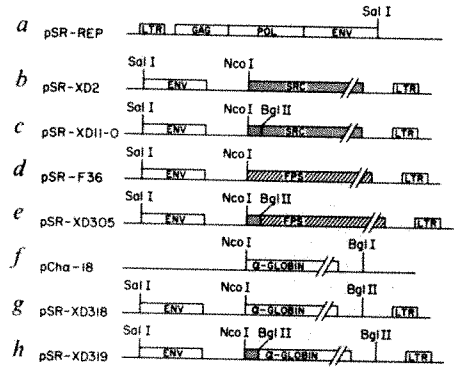

Fig. 1 Structures of the coding sequences of the plasmids used. The shaded boxes indicate portions of the *src* gene; hatched boxes, portions of the *fps* gene; open boxes, chimpanzee α-globin gene. All methods for recombinant DNA manipulations have been described previously[4,26]. All constructions were verified by restriction mapping, and by DNA sequence analysis in the case of pSR-XD305 and pSR-XD319. *a*, pSR-REP contains most of the genes required for replication of RSV (*gag*, *pol* and *env*), and was used in the transfection protocol to produce infectious virus containing the replacements for the *src* gene shown in *b*–*g*, as described elsewhere[26]. *b*, pSR-XD2 contains the wild-type RSV *src* gene[26]. *c*, pSR-XD11-0 is a pSR-XD2 derivative with a *Bgl*II linker inserted into the DNA coding for arginine 15 of p60^{src} (ref. 26). pSR-XD11-4 has a similar structure, except that two more base pairs are inserted into the DNA at the 5′ side of the linker[26]. *d*, pSR-F36 is similar to pSR-XD2, except that the *src* gene is replaced by a transforming fragment of the FSV *fps* gene. The construction and characterization of this clone have been described[9]. *e*, pSR-XD305 encodes a fusion protein between amino acids 1–14 of p60^{src} and amino acids 2–833 of the F36 transforming protein. This clone was constructed by first partially digesting pSR-F36 with *Nco*I, and with S_1 nuclease, followed by *Bgl*II linker (CAGATCTG) insertion. One clone, pF23, had a linker inserted at the remnant of the *Nco*I site which spans the initiation codon of the transforming protein of F36 (ref. 9), with S_1 digestion of only the protruding 5′ end remaining after *Nco*I digestion. This clone was recombined, at its *Bgl*II site, with pSR-XD11-0. *f*, pCh α-18 is a complete cDNA clone of a chimpanzee α-globin gene[10]. *g*, pSR-XD318, a derivative of pSR-XD2 with the pCh α-18 coding sequence substituted for *src*. pCh α-18 was cut with *Bgl*I (which cuts 3′ to the termination codon) followed by S_1 digestion and *Bgl*II linker insertion. This DNA was digested with *Bgl*II and *Nco*I. *Nco*I cuts at the initiation codon for α-globin. pSR-XDR111, a pSR-XD2 derivative with a *Bgl*II linker inserted at the *Rsa*I site 172 nucleotides 3′ to the termination codon of *src* (F.R.C. unpublished data), was digested with *Bgl*II and partially with *Nco*I. The fragment that was digested with *Nco*I only at the *src* initiation codon was ligated to the globin DNA insert to produce pSR-XD318. *h*, pSR-XD319 is a derivative of pSR-XD2 which encodes a fusion between the first 14 amino acids of p60^{src} and all of α-globin. pChα-18 was cut with *Bgl*I and S_1, then with *Nco*I. The *Nco*I site was gap-filled, and *Bgl*II linkers ligated to this insert DNA. pSR-XD321, a pSR-XD2 derivative in which all of *src* except for DNA encoding amino acids 1–14 is deleted (J. Samarut and F.R.C., unpublished), was constructed by recombining pSR-XD11-4 (see description of pSR-XD11-0 above) with pSR-XDR23, a pSR-XD2 derivative with a *Bgl*II linker inserted at an *Rsa*I site 105 nucleotides 3′ to the *src* termination codon (F.R.C., unpublished). After cutting of pSR-XD321 with *Bgl*II, followed by digestion with alkaline phosphatase, the *Bgl*II-ended α-globin insert was ligated into the plasmid.

gene of the F36 derivative of Fujinami sarcoma virus (FSV)[8,9], or to the chimpanzee α-globin gene[10]. We report here that although the fusion proteins were myristylated, the parental proteins were not, and unlike the non-myristylated F36 p91^{fps} which was not bound to the plasma membrane, the myristylated fusion protein was bound, like p60^{src}. We conclude that the first 14 amino acids of p60^{src} contain a sequence which is sufficient for myristylation, and which may direct proteins to the plasma membrane.

The structures of the genes inserted into the RSV genome instead of the *src* gene are shown in Fig. 1. Figure 2 shows the sequences of regions of interest.

Fig. 2 Sequences of the N-terminal portions of the coding sequences in pSR-XD2, pSR-F36, pSR-XD318, pSR-XD305 and pSR-XD319. The pSR-XD2, pSR-F36 and pSR-XD318 sequences are from refs 27, 8 and 10, respectively. DNA derived from *Bgl*II linkers and amino acids encoded by this DNA are shown in brackets. The *src* DNA in pSR-F36 is derived from pSR-XD11-0, and that in pSR-XD319 from pSR-XD11-4 (ref. 26).

The fragment of the *fps* gene expressed following transfection with the pSR-F36 plasmid (nucleotides 1,472–4,162 of the FSV *fps* gene) lacks the *gag* portion, and encodes an 833-amino acid *fps* protein (amino acids 349–1,182 of the FSV *fps* protein), called p91^{fps}. The plasmid pSR-XD305 (Figs 1, 2) contains a recombinant *src*–*fps* gene which encodes a protein consisting of the first 14 amino acids of p60^{src}, followed by Pro-Asp-Leu, then amino acids 2–833 of the F36 *fps* protein[9]. The viruses recovered following transfection with these plasmids are called F36 (ref. 9) and NY305, respectively.

A protein of relative molecular mass (M_r) 93,000 (93K) is specifically immunoprecipitated from extracts of NY305-infected cells by anti-*fps* antiserum (Fig. 3*A*). Proteolytic mapping (data not shown) confirms that this protein is the product of the NY305 *src*–*fps* fusion gene, p93$^{src-fps}$. The F36 p91^{fps} is not detectably labelled with ^{3}H-myristic acid, even after long exposure, whereas both p60^{src} and p93$^{src-fps}$ label well (Fig. 3*A*).

We have compared the subcellular localization of p91^{fps} and p93$^{src-fps}$ by cell fractionation and measurement of immune complex tyrosine kinase activity, as described previously[4,9]. As with the FSV transforming protein p140$^{gag-fps}$ (refs 11–13), the proportion of p91^{fps} found in the crude membrane pellet (P100) was salt-dependent (Fig. 4*A*). In contrast, 95% of the p93$^{src-fps}$ was found in the crude membrane pellet at both salt concentrations tested. The P100 fractions were floated in discontinuous sucrose gradients. Unlike p60^{src}, which is tightly and specifically associated with the plasma membrane[1], the p91^{fps} kinase activity was not enriched in any membrane fraction. The p93$^{src-fps}$ kinase activity was highly enriched in plasma membranes (Fig. 4*B*). Therefore, the addition of the first 14 amino acids of p60^{src} to p91^{fps} made the subcellular fractionation pattern of the fusion protein indistinguishable from that of p60^{src} (refs 1, 4, 14).

Both F36 and NY305 induce focus formation efficiently, and NY305 induces the same distinctive fusiform morphology as reported for F36, in contrast to the round cell morphology induced by RSV[9] (data not shown). As the RSV p60^{src} and NY305 p93$^{src-fps}$ proteins appear to have a similar subcellular location, transformed cell morphology may reflect the affinity of these enzymes for substrates, rather than the subcellular location of the tyrosine kinase. Like F36, NY305 induces colony formation in soft agar, and both viruses are tumorigenic (data not shown). Thus, the alteration in subcellular location of p91^{fps} by the addition of the first 14 amino acids of p60^{src} did not alter

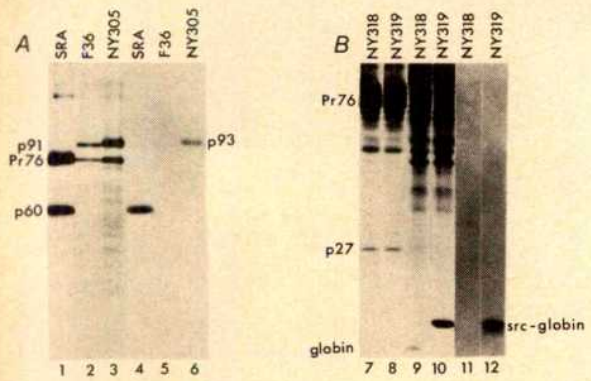

Fig. 3 Myristylation of fusion proteins containing the N-terminal 14 amino acids of p60^{src}. Infected chick embryo fibroblasts (CEF) were labelled for 4 h with ^{3}H-leucine or ^{3}H-myristic acid, and cell lysates were immunoprecipitated with saturating amounts of antiserum as described previously[4]. *A*, Infected cells were labelled with ^{3}H-leucine (lanes 1-3) or ^{3}H-myristic acid (lanes 4–6), and immunoprecipitated proteins were separated by electrophoresis on a 9% SDS-polyacrylamide gel. Proteins from cells infected with the Schmidt–Ruppin subgroup A strain of RSV (SRA; lanes 1, 4) were immunoprecipitated by tumour-bearing rabbit (TBR) serum[4]. Proteins from F36- (lanes 2, 5) or NY305-infected cells (lanes 3, 6) were immunoprecipitated by FSV-specific regressing-tumour antiserum (anti-FST; refs 9, 28). Exposure of the fluorographed gel for 2 days yielded lanes 1–3; exposure for 12 days lanes 4–6. *B*, Infected cells were labelled with ^{3}H-leucine for 0.5 h (lanes 7–10) or with ^{3}H-myristic acid for 2 h (lanes 11, 12), and immunoprecipitated proteins were analysed by electrophoresis on a 12.5% SDS-polyacrylamide gel. Proteins were immunoprecipitated with TBR serum (lanes 7,8) or with rabbit anti-human haemoglobin serum (Cappel Laboratories) (lanes 9–12). The fluorographed gel was exposed for 12 (lanes 7–10) or 16 (lanes 11, 12) days.

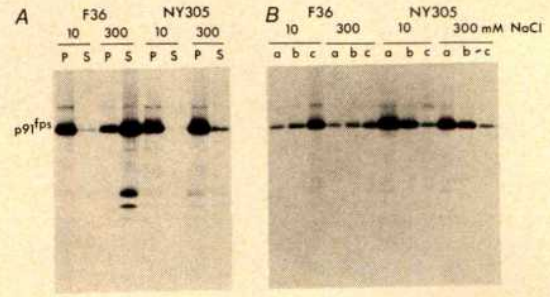

Fig. 4 Salt-independent plasma membrane association of a fusion protein containing the N-terminal 14 amino acids of p60^{src}. *A*, Infected cells labelled for 4 h with ^{3}H-leucine were fractionated into crude membrane (P) and cytosolic (S) fractions as described previously[4], except that the salt concentration of the postnuclear supernatant was adjusted to 10 mM or 300 mM as indicated. Kinase activity was assayed in immune complexes formed by immunoprecipitation with anti-FST serum as described previously[9,28]. Immunoprecipitates were analysed on a 9% polyacrylamide gel. Autophosphorylated bands were excised from the gel shown in Fig. 3*A*, and ^{32}P radioactivity quantitated by Cerenkov counting. The percentage radioactivity found in the P100, assuming 100% recovery, was as follows: for F36 p91^{fps}, 94% and 15% at 10 and 300 mM NaCl, respectively; for NY305 p93$^{src-fps}$, 96% and 93%, respectively. *B*, Crude membrane fractions prepared in *A* were fractionated on a discontinuous sucrose gradient as described previously[4], except that the gradient contained fewer steps: the P100 fraction was resuspended in 40% sucrose, underlaid with 50% sucrose, and overlaid with 35% and 20% sucrose in buffer. Lanes *a–c* represent membrane fractions collected from the gradient interfaces: *a*, 20/35% sucrose interface, which is enriched for plasma membranes; *b*, 35/40% sucrose interface; *c*, 40/50% sucrose interface, which is enriched for rough endoplasmic reticulum, Golgi and mitochondrial membranes[14]. Kinase activity was assayed in immune complexes formed by immunoprecipitation with anti-FST serum and analysed by electrophoresis on a 9% SDS-polyacrylamide gel. The radioactivity in the autophosphorylated bands was quantitated, and the specific activity of kinase activity in each fraction quantitated with reference to the total protein content, as described elsewhere[4]. p91^{fps} distributed essentially in parallel with the total protein of the fractions. p93$^{src-fps}$ showed an approximately 100-fold enrichment in the 20/35% fraction relative to that in the 40/50% fraction.

biological activity; this is in contrast to the requirement for myristylation and membrane association of p60^{src} for cell transformation[4,7], and demonstrates a biological difference between p60^{src} and p91^{fps}. Although recent reports suggest that FSV p140$^{gag-fps}$ is loosely associated with the plasma membrane[12,13], we have not observed this for p91^{fps} in our conditions for cell fractionation (Fig. 4*B*).

As p60^{src} and p91^{fps} are partially homologous[8], we wanted to test the effect of the first 14 amino acids of p60^{src} on an unrelated protein. We constructed RSV genomes in which the *src* gene is replaced by the gene for chimpanzee α-globin[10], or by a fusion of the sequence coding for the first 14 amino acids of p60^{src} and the α-globin gene (the structures of these recombinants are shown in Figs 1, 2). Cells transfected with these DNAs were labelled with ^{3}H-leucine or ^{3}H-myristic acid. Figure 3*B* shows the proteins immunoprecipitated from these cells with anti-α-globin antiserum. Cells transfected with pSR-XD318, the plasmid encoding α-globin, produce a 15K protein, approximately the expected size[10]. Cells transfected with pSR-XD319, the plasmid encoding the *src*–globin fusion protein, produce a 17 K protein. Both of these bands are specific to the DNA used for transfection, and are not seen in immunoprecipitates with normal serum, therefore they probably represent α-globin and the *src*–globin fusion protein, respectively. Only the *src*–globin fusion protein is labelled with ^{3}H-myristic acid.

Peptide sequences that direct post-translational modifications have been described elsewhere[15]. It is probable that the first 14 amino acids of p60^{src} contain a signal for N-myristylation. However, there is no obvious sequence homology between the N-terminal portions of other myristylated proteins[16–19] and that of p60^{src}.

The α-globin protein, and to a lesser extent the *src*–globin fusion protein, are quite unstable in chicken embryo fibroblasts (data not shown), and are therefore difficult to label efficiently with ^{3}H-leucine. We have been unable, therefore, to determine the subcellular localization of the α-globin protein. However, the *src*–globin fusion protein is found primarily in a crude membrane pellet after extraction of cells in isotonic salt (data not shown), which is consistent with the p60^{src} N-terminus having a similar effect on α-globin as it has on p91^{fps} with respect to subcellular localization.

The Harvey sarcoma virus transforming protein, p21^{ras}, is covalently modified with palmitic acid[2], a modification which requires a short C-terminal sequence and correlates with p21 membrane association[20]. Short sequences which target proteins to their appropriate subcellular locations have been described for secreted proteins, mitochondrial proteins, integral membrane proteins, and nuclear proteins[21–25]. The results presented here show that the myristylated N-terminal 14 amino acids of p60^{src} contain a sequence which is sufficient for myristylation, and which may direct p60^{src} and p93$^{src-fps}$ (and possibly the *src*–globin fusion protein) to the plasma membrane.

We thank D. Foster for the gift of pSR-F36 plasmid and anti-FST antiserum; Stephen A. Liebhaber for the gift of pCHα-18 α-globin cDNA; Janice E. Buss for communicating results before publication; and S. Sugano, D. Foster and A. Dutta for comments on the manuscript. This work was supported by USPHS grant CA14935 from the NCI, and by grant MV128B from the American Cancer Society. E.A.G. was supported by a Merck fellowship. F.R.C. was supported by NI training grant AI07233.

Specific expression of a foreign β-globin gene in erythroid cells of transgenic mice

Kiran Chada, Jeanne Magram, Kathryn Raphael*, Glenn Radice, Elizabeth Lacy* & Frank Costantini

Department of Human Genetics and Development, College of Physicians and Surgeons, Columbia University, 701 W. 168th Street, New York, New York 10032, USA

The globin gene family represents an attractive system for the study of gene regulation during mammalian development, as its expression is subject to both tissue-specific and temporal regulation. While many aspects of globin gene structure and expression have been described extensively[1], relatively little is known about the *cis*-acting DNA sequences involved in the developmental regulation of globin gene expression. To begin to experimentally define these regulatory sequences, we have taken the approach of introducing cloned globin genes into the mouse germ line and examining their expression in the resulting transgenic animals[2,3]. Here we describe a series of transgenic mice carrying a hybrid mouse/human adult β-globin gene, several of which express the gene exclusively or predominantly in erythroid tissues. These studies demonstrate that regulatory sequences closely linked to the β-globin gene are sufficient to specify a correct pattern of tissue-specific expression in a developing mouse, when the gene is integrated at a subset of foreign chromosomal positions.

Figure 1 shows a restriction map of the hybrid β-globin gene[4] used in these experiments. A portion of the mouse β-major globin gene and 5′-flanking DNA was included to ensure that any regulatory sequences within this region would be compatible with regulatory factors in mouse erythroid cells, and to thus circumvent possible species-specific differences in globin gene regulation. The 3′ end of the gene was derived from the human β-globin gene, allowing the hybrid gene and its mRNA to be distinguished from the endogenous β-globin genes and their

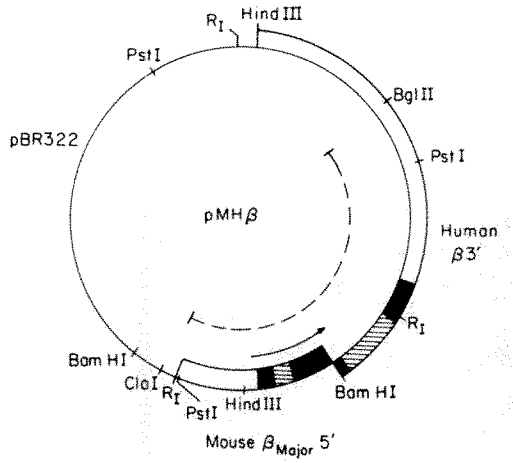

Fig. 1 Restriction map of plasmid pMHβ, containing a hybrid mouse/human β-globin gene. This plasmid was provided by P. Mellon and T. Maniatis, and its construction is described in ref. 4. The plasmid contains the 5′ portion of the mouse β-major globin gene and the 3′ portion of the human β-globin gene, fused at a conserved *Bam*HI site in the second exon of both genes. The clone also includes 1.2 kb of 5′-flanking mouse DNA and 3.8 kb of 3′-flanking human DNA. Solid bars represent exons, hatched bars represent introns, and open bars flanking mouse or human DNA. The broken line indicates the 5.0-kb *Cla*I–*Bgl*II fragment used for microinjection in some experiments.

mRNAs. Mouse zygotes were microinjected[2,5–7] with either the intact circular plasmid pMHβ, or a linear 5.0-kilobase (kb) *Cla*I–*Bgl*II fragment containing the entire gene and 5′-flanking mouse DNA segment, 1.9 kb of 3′ flanking human DNA, and only 350 base pairs (bp) of plasmid DNA (Fig. 1). Ten transgenic mice were produced, three carrying the entire plasmid and seven carrying the *Cla*I–*Bgl*II fragment (Table 1). When mated with normal mice, each of these transgenic mice transmitted the foreign DNA to a fraction of its progeny, and 10 transgenic lines were established. Southern blot analysis (data not shown) revealed that each line carries one or more copies of a 3.4-kb *Pst*I fragment including the β-globin gene, nearly all of the 5′-flanking mouse DNA and 0.5 kb of the 3′-flanking human DNA (Fig. 1, Table 1).

To determine the pattern of expression of the foreign β-globin gene in each transgenic line, we performed a quantitative S_1 nuclease protection assay[8,9] on RNA samples isolated from erythroid and non-erythroid mouse tissues. Mice in four of the lines (46, 49, 75A and 77) were found to express the gene predominantly or exclusively in erythroid tissues; see Fig. 2*a*. The hybridization probe used here derives from the 3′ end of the human β-globin gene, and a 212-nucleotide fragment is protected from S_1 nuclease digestion by either correctly terminated mRNA encoded by the hybrid β-globin gene, or by human β-globin mRNA[4]. For purposes of comparison, only the 212-nucleotide band obtained with each RNA sample is shown (this was the only reproducible band observed). It can be seen that the highest levels of mRNA derived from the hybrid β-globin gene are found in bone marrow and blood cells.

To confirm that the hybrid β-globin mRNA detected in total blood and bone marrow RNA preparations represented expression in erythroid cells, we analysed RNAs from the tissues of several mice that had been injected with phenylhydrazine, a treatment which causes the spleen to become a major site of erythropoiesis[10]. As demonstrated in Fig. 2*b* for mice in lines 77 and 46, the level of hybrid β-globin mRNA in the spleen after phenylhydrazine treatment was equivalent to that in the bone marrow, while in untreated mice (for example, Fig. 2*a*) the level in spleen was much lower.

In some animals, relatively low levels of hybrid β-globin mRNA were detected in RNAs from certain non-erythroid tissues, particularly heart, lung and kidney (Fig. 2*a*, *b*). We

Present addresses: CSIRO, Division of Animal Production, Ian Clunies Ross Animal Research Laboratory, Great Western Highway, Prospect, New South Wales, Australia (K.R.); Memorial Sloan-Kettering Cancer Center, 1275 York Avenue, New York, New York 10021, USA (E.L.).

suspected that much of this mRNA might have derived from blood cells contaminating these tissues rather than from actual transcription of the foreign β-globin gene in non-erythroid cells; this was confirmed by measuring the amount of endogenous β-globin mRNA contaminating different non-erythroid tissues. In general, those non-erythroid tissues containing the highest levels of hybrid β-globin mRNA also contained the highest levels of endogenous mouse β-globin mRNA (an example is shown in Fig. 2*c*). There were a few non-erythroid tissues (testes of a line 49 mouse and heart and kidney of line 75A mice; Fig. 2*a*) in which hybrid β-globin mRNA appeared to result from inappropriate expression of the foreign globin gene at a very low level (less than one mRNA molecule per cell).

The steady-state level of hybrid β-globin mRNA in each mouse RNA sample was estimated by comparing the observed hybridization signals with those obtained using known amounts of human β-globin mRNA (Fig. 2, Table 1). The mRNA levels in erythroid tissues were highest in mice of lines 46 and 49, where they corresponded to 1–2% of the level of endogenous β-globin mRNA (or ~700 molecules of hybrid β-globin mRNA per reticulocyte). Because these mice contained only one gene copy per diploid genome, the level of expression per gene copy was 2–4% of the normal level. Erythroid tissues from mice of lines 75A and 77 contained considerably lower levels of hybrid β-globin mRNA (Table 1).

The transcripts synthesized from the hybrid β-globin gene in erythroid cells of the transgenic mice were found, by primer extension analysis, to be correctly initiated and spliced. A short, ^{32}P-labelled primer from the third exon of the human β-globin gene was annealed to blood RNA from mice in lines 46 and 77, as well as to human β-globin mRNA. When the hybridized primer was extended with reverse transcriptase and dNTPs, the major primer extension products obtained with blood samples from transgenic mice and with human cord blood were indistinguishable in size (Fig. 3).

Gene transfer studies with murine erythroleukaemia (MEL) cells have led to the conclusion that DNA sequences closely linked to, and perhaps within, the β-globin gene are sufficient for the activation of a transfected gene during the terminal events of erythroid cell differentiation[4,11–13]. Our results allow this statement to be extended to include any additional *cis*-acting regulatory sequences which may be needed to activate the gene specifically in the erythroid cells of a developing transgenic mouse. This conclusion must, however, be qualified in several ways. First, maximal transcription of the β-globin gene may require additional regulatory sequences not included on the DNA fragment used in our experiments. The steady-state concentration of the hybrid mRNA in transgenic mouse erythroid cells was no more than a few per cent of the level of endogenous β-globin mRNA, suggesting that the foreign gene was transcribed at a relatively low rate (although an alternative interpretation—a relatively low stability of the hybrid message—has not been eliminated). The highest mRNA levels observed were similar to the mRNA levels (per gene copy) observed when cloned β-globin genes were introduced into MEL cells[4,11–13].

Second, although it seems that the β-globin gene need not be in its normal chromosomal locus to be expressed and regulated, its expression may depend on integration at a specific subset of the available chromosomal positions. Several of the transgenic lines analysed do not express the hybrid β-globin genes in either erythroid or non-erythroid tissues, although they contain at least one intact copy of the gene (Table 1; data not shown). The β-globin gene is not unique in this regard, as several other genes, including metallothionein fusion genes[7,14] and a mouse α-fetoprotein gene[15], are expressed in only a subset of transgenic mouse lines. Occasional cases of low-level expression in inappropriate tissues (for example, mouse lines 15, 49 and 75A; refs 3, 14, 16, 17) may be another consequence of the integration of microinjected genes at abnormal chromosomal positions.

Given the present results, it is surprising that many other cloned α- and β-globin genes are not expressed in erythroid tissues when introduced into the mouse germ line (refs 3, 18, 19; T. Townes *et al.*, personal communication; S. Rusconi,

Table 1 Transgenic mouse lines

Mouse line	DNA injected	Gene copy no.*	Hybrid β-globin mRNA in erythroid tissues: Tissue	(No. of mice analysed)	RNA fraction‡	% Of total β-globin mRNA§
46	5-kb *Cla*I–*Bgl*II fragment	1	Blood	(1)	8×10^{-5}	1.6
			Bone marrow	(3)	5×10^{-6}	0.6

16	Plasmid pMHβ	180				
15	Plasmid pMHβ	3	Very low expression ($<10^{-7}$) in all tissues			

Approximately 400–800 circular dimers of the entire plasmid, or 10–30 linear molecules of the *Cla*I–*Bgl*II fragment, were microinjected into the pronuclei of (C57BL/6J×CBA/J) F_2 mouse zygotes. All animals examined were transgenic progeny hemizygous for the hybrid β-globin gene.

* Number of copies of the 3.4-kb *Pst*I fragment per diploid genome in transgenic progeny, determined by densitometry of an autoradiogram of a Southern blot (not shown).

† Animals were treated with phenylhydrazine to induce splenic erythropoiesis, as described previously[3,10].

‡ Fraction of total RNA consisting of hybrid β-globin mRNA, determined by 3′ S_1 nuclease analysis of mouse tissue RNAs, using human cord blood RNA containing a known concentration of human β-globin mRNA as a standard (see, for example, Fig. 2).

§ RNA fraction as a percentage of endogenous mouse β-globin RNA fraction in the same tissue. Values used for mouse β-globin RNA fractions were: blood, 5×10^{-3}; bone marrow, and spleen of phenylhydrazine-treated mice, 9×10^{-4}. These values were determined by RNA titration analysis using a single-stranded probe of known specific activity[25].

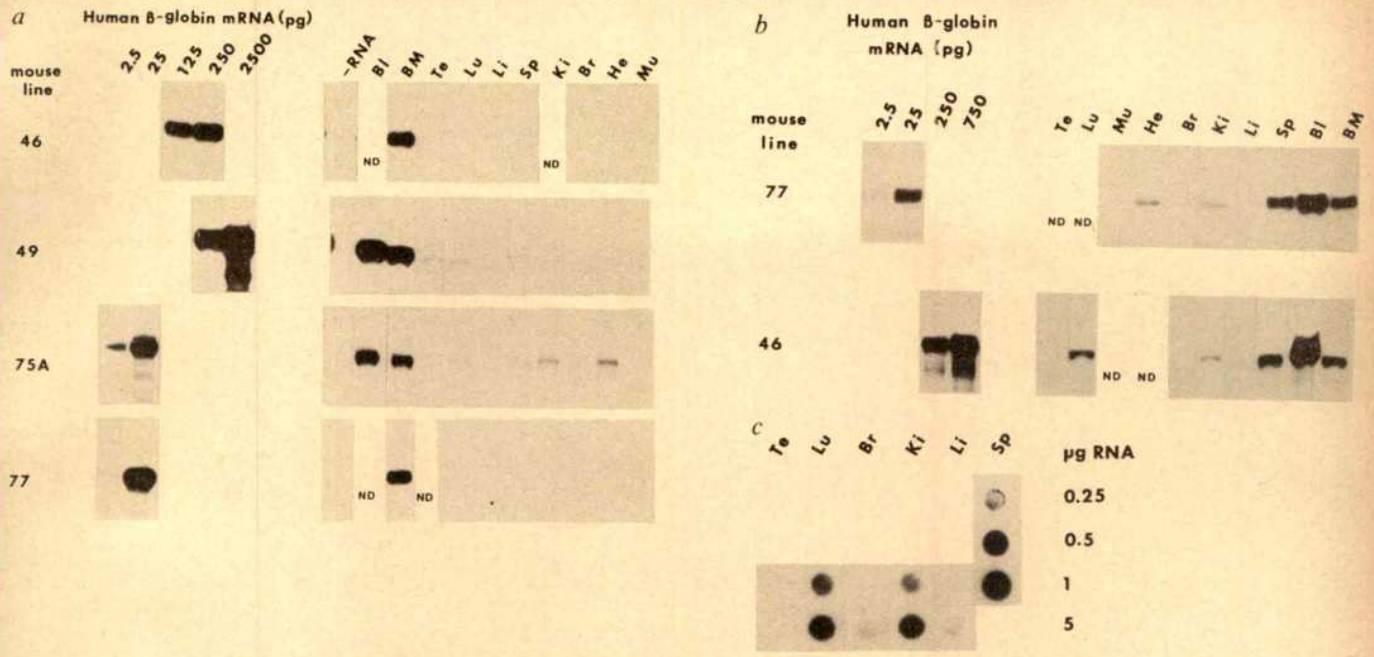

Fig. 2 Specific expression of the hybrid mouse/human β-globin gene in erythroid tissues. *a*, S_1 nuclease analysis of hybrid β-globin mRNA in mouse lines 46, 49, 75A and 77. Total RNA samples from the indicated tissues of a second- or third-generation mouse in each line were analysed by hybridization with a 3′-end-labelled probe derived from the 3′ end of the human β-globin gene, as described elsewhere[4]. For comparison, hybridizations were also performed with human cord blood RNA containing a known amount of human β-globin mRNA. The hybrids were digested with S_1 nuclease and the products fractionated on a 6% polyacrylamide gel containing 7 M urea. Only those regions of the autoradiograms showing the 212-nucleotide probe fragment protected by hybrid mouse/human β-globin mRNA or human β-globin mRNA are shown. The intensities of hybridization signals from the four mice cannot be compared directly because the autoradiograms were exposed for different lengths of time. −RNA, hybridization with only yeast RNA carrier (25 μg); Bl, blood; BM, bone marrow; Te, testis; Lu, lung; Li, liver; Sp, spleen; Ki, Kidney; Br, brain; He, heart; Mu, skeletal muscle. 10 μg of RNA from blood and 25 μg of RNA from all other tissues were used for each hybridization reaction. ND, not determined for the animal whose analysis is shown here. The human 3′ probe does not cross-hybridize with endogenous mouse β-globin mRNA in the conditions used (data not shown). *b*, S_1 nuclease analysis of hybrid β-globin mRNA in tissues of mice treated with phenylhydrazine. A mouse from line 46 and one from line 77 were treated with phenylhydrazine to induce anaemia. Total RNA (25 μg) from each of the indicated tissues was used for hybridization and S_1 nuclease analysis. The specific hybridization signal (212-nucleotide protected fragment) obtained with RNA from each tissue is shown as in *a*. Note the greatly increased level of hybrid mouse/human β-globin mRNA in the spleen RNAs, compared with spleen RNAs from mice in lines 46 and 47 which were not treated with phenylhydrazine. *c*, Dot-blot analysis of endogenous β-globin mRNA contamination in non-erythroid tissues. To estimate the relative degree of blood contamination in non-erythroid tissues, endogenous β-globin mRNA was measured in RNA samples from a phenylhydrazine-treated mouse in line 46 (the same mouse as analysed in *b*). RNAs from the indicated tissues were denatured with formaldehyde, spotted onto a nitrocellulose filter[26], and the filter was hybridized with a ^{32}P-labelled mouse β-major cDNA clone[27]. The two non-erythroid tissues with the highest level of blood contamination (lung and kidney) are the same two tissues that contain the most hybrid β-globin mRNA (*b*).

Methods: Mice were killed by cervical dislocation, organs were dissected and total RNA was isolated as described previously[3,28]. Blood was obtained by heart puncture, and cells were washed once in cold phosphate-buffered saline containing 10 U ml^{-1} heparin before isolation of total RNA. The 0.75-kb *Eco*RI–*Pst*I fragment of the human β-globin gene was 3′-end-labelled with ^{32}P, and strand-separated on a polyacrylamide gel[29] as described[3,4]. The specific activity of the probe was $2–4 \times 10^7$ c.p.m. μg^{-1}, and 4 ng of probe were used for each hybridization reaction. In these conditions of probe excess, the hybridization signal observed (212-nucleotide protected fragment) is proportional to the β-globin mRNA concentration in each reaction. Hybridization was performed at 45 °C for 12–16 h, in 80% formamide, 0.4 M NaCl, 0.04 M PIPES, *p*H 6.8, 1 mM EDTA. Hybrids were mixed with denatured salmon sperm DNA (50 μg ml^{-1}) and digested with 400 U ml^{-1} S_1 nuclease (Sigma) at 15 °C for 1 h. The concentration of β-globin mRNA in the human cord blood RNA was determined (by R_0t analysis; data not shown) to be 1%, in agreement with published estimates of the globin mRNA content of reticulocytes[30].

personal communication). There are several factors that may be responsible for the successful expression of the hybrid β-globin gene in our experiments. First, it is possible that the use of mouse DNA sequences in the hybrid gene construct provided an essential regulatory element that is absent or divergent in the mammalian globin genes used previously. Second, the two transgenic lines which express the hybrid β-globin gene at the highest levels contain a single copy of the gene, rather than the multiple, tandem copies usually observed. The arrangement of exogenous globin genes in tandem arrays may provide an inferior substrate for transcriptional regulation. A different explanation, which we favour, is that plasmid or bacteriophage λ sequences may have an inhibitory effect on β-globin gene expression in transgenic mice; this interpretation is suggested by the fact that all four mouse lines which showed tissue-specific expression contained the hybrid β-globin gene with most of the plasmid sequences removed (Table 1). Furthermore, most of the cloned globin genes that were not expressed in previous experiments were introduced together with prokaryotic vector sequences. This hypothesis remains to be tested definitively.

The results presented here, as well as recent studies demonstrating tissue-specific expression of other microinjected genes[15,16,20–23], indicate that the transgenic mouse system will be useful for elucidating the mechanisms by which genes are activated in specific cell types during development. One important aspect of globin gene regulation which this technique should allow us to study experimentally is the switch from embryonic to adult haemoglobin synthesis during mouse embryogenesis[24]. An analysis of the timing of expression of the mouse/human hybrid β-globin gene has shown that the gene is turned on at the appropriate stage of development for an adult β-globin gene in the mouse (J.M., K.C. and F.C., in preparation). Experiments with additional cloned globin genes, such as embryonic genes or embryonic/adult fusion genes, may allow us to identify *cis*-acting DNA sequences involved in the control of haemoglobin switching.

Fig. 3 Analysis of the 5′ terminus of mouse/human hybrid β-globin mRNA by primer extension. A ^{32}P-labelled single-stranded primer, consisting of a 48-nucleotide *Bst*NI–*Eco*RI fragment from the third exon of the human β-globin gene, was hybridized with human cord blood RNA or blood RNA from transgenic or control mice. The primer was extended with reverse transcriptase and the products denatured and analysed by electrophoresis on a 6% polyacrylamide gel containing 7 M urea. ***a***, Autoradiogram showing analysis of the following RNA samples: Hβ400 and Hβ40, human cord blood RNA containing 400 pg and 40 pg, respectively, of β-globin mRNA; m, molecular weight markers (φX174 DNA digested with *Hin*fI); −RNA, yeast RNA carrier alone (25 μg); 46, total blood RNA (25 μg) from a mouse in line 46; 77, total blood RNA (25 μg) from a mouse in line 77; control, total blood RNA (25 μg) from a mouse not carrying the hybrid mouse/human β-globin gene. The position of the major reverse transcription products expected (418 nucleotides for human β-globin mRNA and 421 nucleotides for the hybrid β-globin mRNA) is indicated by the arrow. No signal was observed when the same reaction was performed with normal mouse blood RNA, showing that the primer is detecting hybrid mouse/human β-globin mRNA rather than endogenous β-globin mRNA in transgenic mouse blood. ***b***, Diagram of the primer extension assay. The heavy line represents the labelled primer and the dotted line the product of reverse transcription after hybridization with human or hybrid mouse/human β-globin mRNA. Preparation of the primer, hybridization and reverse transcription were performed as described in refs 4 and 31, except that 0.4 ng of primer was used for each reaction.

Partial deficiency of erythrocyte spectrin in hereditary spherocytosis

Peter Agre*†, James F. Casella‡, William H. Zinkham‡, Campbell McMillan§ & Vann Bennett†

Departments of *Medicine, †Cell Biology/Anatomy and ‡Pediatrics, Johns Hopkins School of Medicine, Baltimore, Maryland 21205, USA
§ Department of Pediatrics, University of North Carolina School of Medicine, Chapel Hill, North Carolina 27514, USA

Hereditary spherocytosis (HS) is a common, clinically heterogeneous haemolytic anaemia[1,2] in which the primary erythrocyte defect is believed to be some abnormality in the spectrin–actin membrane skeleton[3,4], leading to loss of surface membrane[5]. Recessively inherited spectrin deficiency with extreme erythrocyte fragility and spherocytosis has been identified in certain mutant mice[6,7] and two severely anaemic humans[8]. Although suspected, deficiency of spectrin has not been demonstrated in less severe forms of human HS[9]. We now report the quantitation of erythrocyte spectrin by radioimmunoassay. We found that normal erythrocytes contained 240,000 copies of spectrin heterodimer, whereas erythrocytes from 14 patients with a variety of types of HS were all partially deficient in spectrin (range 74,000–200,000 copies), the magnitude of the deficiency correlating with the severity of the disease. Spectrin deficiency of varying degrees is common in HS and probably represents the principal structural defect leading to loss of surface membrane.

Analysis of Coomassie blue-stained SDS-polyacrylamide electrophoresis (PAGE) gels has revealed deficiencies of specific erythrocyte membrane proteins in certain inherited haemolytic anaemias[10]. We have subsequently found that erythrocytes from humans with mild HS have very subtle reductions in spectrin relative to band 3. Figure 1 shows a Coomassie blue-stained SDS-PAGE slab with erythrocyte membranes prepared from a normal individual and four patients with HS. Determination of relative protein concentrations by the pyridine dye elution method[11] showed the amount of spectrin relative to band 3 to be reduced in the HS samples (Fig. 1 legend). Similar membrane analyses were conducted on erythrocytes from more than 100 individuals, including HS patients from 28 different families. We found that erythrocyte membranes from 39 of 43 HS patients showed small but consistent reductions in spectrin relative to band 3, whereas unaffected relatives, patients with other types of anaemia (including warm-reacting autoimmune haemolytic

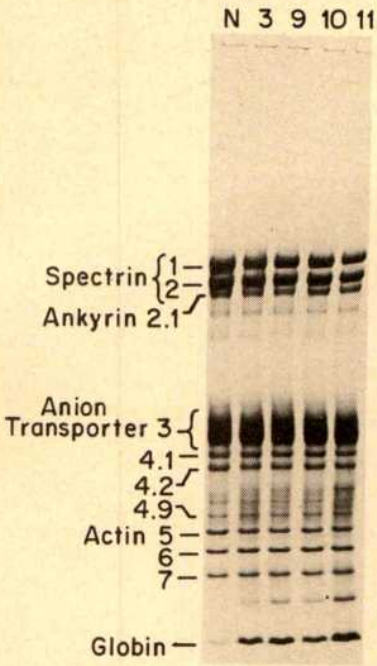

Fig. 1 Coomassie blue-stained SDS-PAGE slab of membranes from a normal individual and four HS patients. Freshly drawn venous blood was washed three times in phosphate-buffered saline (PBS) with removal of the buffy coat. Erythrocytes were lysed and washed repetitively at 0 °C with 7.5 mM sodium phosphate, 1 mM Na-EDTA, 0.2 mM phenylmethylsulphonyl fluoride as described previously[27]. Approximately 25 μg of membrane protein from samples obtained from each of several patients and a control was applied to the top of a 3.5-17% exponential gradient polyacrylamide slab gel and electrophoresed for 3 h at 240 V (ref. 28). Membranes in lane N are from a normal individual and membranes in the other lanes are from patients listed in Table 1. Relative protein concentrations in the spectrin regions of each lane were compared with that in the band 3 region by the pyridine dye elution method[11] and were analysed as the ratios of absorbance at 605 nm of spectrin and band 3: normal = 1.12; patients: 3 = 0.74; 9 = 0.84; 10 = 0.84; 11 = 0.65.

anaemia) and other controls showed no such reduction. Although these analyses indicate that a relative spectrin deficiency commonly exists in HS, they are only semi-quantitative, as this method does not allow determination of the actual number of copies of spectrin per erythrocyte.

We therefore developed a radioimmunoassay to quantify the number of copies of spectrin per erythrocyte. This assay is performed on washed erythrocytes using purified control spectrin as a standard and ^{125}I-labelled pure spectrin as a probe (Fig. 2). Incubation of a known number of washed erythrocytes in 1% SDS at 60 °C results in complete unfolding of membrane proteins, allowing accurate measurement of the actual number of copies per cell by radioimmunoassay[12]. The SDS-lysed erythrocytes were diluted into buffer containing Triton X-100 and albumin to quench the denaturing effect of SDS. Spectrin in these lysates and purified spectrin each competed with ^{125}I-labelled spectrin for binding to immobilized anti-spectrin antibodies, and the profiles of displacement by erythrocyte lysates and by pure spectrin were virtually parallel (Fig. 2). The concentration of purified spectrin and the number of erythrocytes producing 50% displacement of ^{125}I-labelled spectrin were determined by measurements on erythrocytes from each of three normal adults on multiple occasions, and an average of 240,000 copies of spectrin heterodimer per normal erythrocyte was calculated (range 225,000-258,000), reasonably close to the 216,000 copies estimated from Coomassie blue-stained SDS-PAGE gels[13].

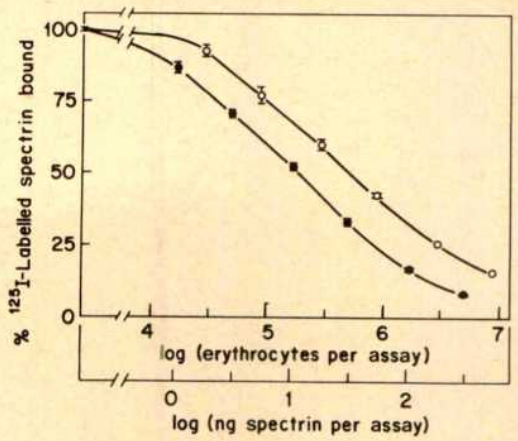

Fig. 2 Radioimmunoassay using ^{125}I-labelled spectrin which is displaced from anti-spectrin antibodies adsorbed onto protein A-bearing staphylococci by spectrin purified from normal erythrocytes (○) or by detergent-solubilized erythrocytes (●).
Methods. Spectrin was purified from normal erythrocytes[27], and the precise protein content was determined from the ultraviolet absorbance spectrum and the extinction coefficient (ref. 29), $E^{1\%}_{1cm}$ 10.7. Pure spectrin was radiolabelled with Na^{125}I to a specific activity of 2×10^7 c.p.m. per μg as described by Hunter and Greenwood[30] and stored at 0 °C at a concentration of 13 μg ml^{-1} in radioimmunoassay buffer (150 mM NaCl, 10 mM sodium phosphate, 1 mM EDTA, 1 mM NaN_3, 1% (v/v) Triton X-100, *p*H 7.5, also containing 1 mg ml^{-1} bovine serum albumin and 5 μg ml^{-1} pancreatic trypsin inhibitor). The immunoadsorbent was prepared from washed protein A-bearing staphylococci and serum from rabbits immunized with human spectrin as described elsewhere[31]. Erythrocytes were washed three times in PBS with removal of the buffy coat and suspended to a haematocrit of 10%. Aliquots of this suspension were removed and counted with a Coulter model B instrument. Aliquots of the erythrocyte suspensions, pure spectrin and ^{125}I-labelled spectrin were separately dissolved and incubated at 60 °C for 10 min in PBS containing 1% (w/v) SDS and then diluted at least 40-fold into radioimmunoassay buffer. The assay was performed in 12×75-mm polystyrene tubes containing 0.2 ml of radioimmunoassay buffer with ~100,000 c.p.m. of ^{125}I-spectrin, varying dilutions of erythrocyte lysate or pure spectrin and a 0.5% (v/v) suspension of antispectrin-staphylococci (diluted ~1:9 with washed staphylococci to reduce the capacity of the immunoadsorbent to precipitate only 40% of the total ^{125}I-spectrin). Samples were shaken gently overnight at 4 °C, then washed with 4 ml of 2 M urea, 1% (v/v) Triton X-100, 0.1 M glycine and the pellets were collected by centrifugation (20 min at 3,500*g*) and analysed for ^{125}I. The final SDS concentration was never more than 0.025% (w/v) and, in the presence of 1% (v/v) Triton X-100, did not interfere with ^{125}I-spectrin binding. Binding of ^{125}I-spectrin to control immunoadsorbents, prepared from preimmune rabbit serum and staphycocci, was negligible and therefore not subtracted. Points represent means ±s.e.m. for triplicates. The content of spectrin in solubilized erythrocytes was determined by calculating the number of cells and the quantity of pure spectrin producing 50% inhibition of ^{125}I-spectrin binding by linear regression of data points in the linear portions of the profiles. A radioimmunoassay using ^{125}I-labelled 43,000-M_r cytoplasmic fragment of band 3, prepared as described by Bennett[27], and immunoadsorbent, prepared from affinity-purified anti-43,000-M_r fragment IgG and protein A-bearing staphylococci, was performed similarly.

The radioimmunoassay can also be modified to measure band 3 content. However, purified band 3 is extremely hydrophobic and unstable, and therefore is neither a good protein to label with ^{125}I nor a stable source of protein standard. Therefore, it was necessary to use an ^{125}I-labelled cytoplasmic fragment of band 3 (relative molecular mass (M_r) 43,000) as a stable, water-soluble probe[14] and normal control erythrocytes as a standard for comparison with HS erythrocytes.

Spectrin and band 3 radioimmunoassays were performed in parallel on erythrocytes from multiple controls as well as HS

patients. The band 3 radioimmunoassay was used, as band 3 is an integral membrane protein, 60–80% of which is not linked directly to the membrane skeleton via ankyrin[15], and it was expected that the unlinked fraction would be relatively preserved even in membranes deficient in membrane skeleton proteins. Table 1 shows the results of these analyses. It is clear that normal individuals of different ages, individuals who had undergone splenectomy for reasons other than anaemia, and patients without HS who had microcytosis and reticulocytosis all had a similar number of copies of spectrin per erythrocyte. Of 14 HS patients studied who had dominant or non-dominant patterns of inheritance and clinical severities ranging from mild to nearly lethal, all had significant reductions in the number of copies of spectrin per erythrocyte. The reductions varied between patients but correlated with the clinical estimation of disease severity, ranging from 200,000 copies per erythrocyte for the least affected to only 74,000 for the most seriously affected. The reduction in the number of copies of spectrin was highly reproducible when measured on multiple occasions on erythrocytes from the same HS patients (interassay variability $<\pm 4\%$). Erythrocyte spectrin content was also found to be similar within families when members with anaemias of comparable clinical severity were compared (members of families B, D and H). Note that the splenectomized member of family D and the relative who had a spleen had erythrocytes with similar spectrin contents. Members within families A and E who had anaemias of different clinical severities were found to have correspondingly different spectrin contents which reflected clinical severity.

Increased sensitivity to hypotonic lysis indicates a relative decrease in surface area to volume[16] and is helpful in establishing diagnosis in HS[1]. Blood samples from the patients listed in Table 1 were quantitatively analysed for shifts in hypotonic lysis profile, and this reflected both spectrin content and disease severity (Fig. 3). Although band 3 content was usually slightly reduced, it was generally less reduced than the spectrin content and was much more variable. It is probable that band 3 content is somewhat more reduced before splenectomy because of the selective removal of certain regions of the membrane by the spleen, possibly related to the process referred to as splenic 'conditioning'. This idea is supported in family D, where the patient without a spleen had significantly more band 3, and higher band 3 contents were also noted in splenectomized non-anaemic individuals. Because of reductions in band 3, the apparent reduction in spectrin relative to band 3 determined from Coomassie blue-stained SDS-PAGE gels always underestimated the true corpuscular spectrin deficiency as measured by radioimmunoassay. The ratio of spectrin to band 3 determined from SDS-PAGE gels (see Fig. 1 legend) is similar to the quotient of the spectrin and band 3 radioimmunoassays (Table 1).

Erythrocytes from patients with all types of HS were found to be deficient in spectrin to varying degrees, whereas erythrocytes from several controls and patients with other types of anaemias were not. A common underlying defect such as partial spectrin deficiency provides a logical explanation for a clinically heterogeneous anaemia in which a reduction in membrane surface area is a recognized common feature. Several observations indicate that the deficiency of spectrin is a primary factor in the pathogenesis of spherocytes. To date, no case of spectrin deficiency has been reported without spherocytes being found in the peripheral blood. Furthermore, when spectrin and actin are stripped from normal erythrocyte membranes, the structure spontaneously disintegrates into tiny vesicles. A partial deficiency in spectrin may result in an underlying membrane skeleton which may not support adequately all regions of the lipid bilayer, leading to loss of small areas of unsupported lipid and untethered integral membrane proteins. If the fragility of HS membranes results primarily from deficiency of spectrin, it might be corrected by addition of spectrin; incorporation of spectrin into erythrocytes of the spectrin-deficient *sph/sph* mutant mice by exchange haemolysis led to partial correction

Table 1 Radioimmunoassay of spectrin and band 3 in erythrocytes

Control individuals					Radioimmunoassay Spectrin Copies per cell	Spectrin % Of control	Band 3 % Of control
Normal adults, 3 persons					240,000	100	100
Normal child					235,000	98	102
Splenectomy without anaemia, 2 persons					241,000	100	119
Hypoplastic anaemia with ovalocytes					250,000	104	
Microcytic anaemia (iron deficiency)					238,000	99	
Microcytosis with reticulocytosis (Hb SC)					255,000	106	108
Patients with hereditary spherocytosis							
Family	Inheritance pattern*	Patient	Clinical severity†	Splenectomy			
A	Dominant	1	Mild		200,000	84	108
		2	Moderate	+	140,000	58	88
		3	Severe	+	122,000	51	86
B	Dominant	4	Mild		192,000	80	69
		5	Mild		187,000	78	69
C	Dominant	6	Mild	+	182,000	76	
D	Dominant	7	Moderate		166,000	69	87
		8	Moderate	+	168,000	70	104
E	Recessive	9	Severe	+	128,000	53	94
		10	Nearly lethal	+	108,000	45	79
F	Non-dominant	11	Nearly lethal	+	80,200	33	68
G	Non-dominant	12	Nearly lethal	+	75,800	32	66
H	Recessive	13‡	Nearly lethal	+	81,600	34	62
		14‡	Nearly lethal	+	74,400	31	69

* Dominant: one affected parent. Non-dominant: both parents clinically normal with no apparent consanguinity. Recessive: both parents clinically normal with known consanguinity.

† Mild: subclinically affected, no anaemia, reticulocytosis ≤2%, splenectomy considered optional. Moderate: anaemia compensated by reticulocytosis before splenectomy which was performed before age 10 yr, no anaemia or reticulocytosis post-splenectomy. Severe: incompletely compensated haemolytic anaemia requiring occasional transfusions before splenectomy performed before age 3 yr, reticulocytosis >2% post-splenectomy. Nearly lethal: dependent on regular transfusions to maintain haematocrit >14% before splenectomy performed in infancy, post-splenectomy reticulocytes 4–10% with haematocrit ~30% in patients 11–14.

‡ Previous evaluations of these patients have been reported.

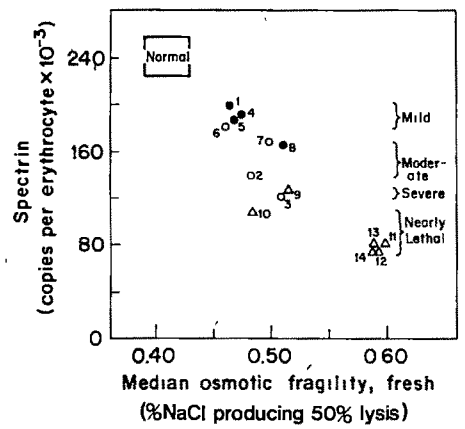

Fig. 3 Correlation of erythrocyte spectrin content and sensitivity to hypotonic lysis. Erythrocyte spectrin content was estimated by radioimmunoassay for each patient and is listed in Table 1 ○, ●, dominant inheritance; △, non-dominant or recessive inheritance; ○, △, previous splenectomy The sensitivity to hypotonic lysis (osmotic fragility) was conducted on fresh blood samples mixed with PBS of concentrations ranging from 0.9% NaCl to distilled water[1]. Median lysis was measured by interpolating between points to estimate the concentration of NaCl at which 50% of cells had lysed. The box at the upper left indicates the range of spectrin determinations on erythrocytes from multiple individuals (Table 1) and the range of median lysis as determined on erythrocytes from multiple normal adults and children

of the mechanical fragility[17]. Reductions in other proteins that bind to spectrin would be expected secondary to deficiency in spectrin, and small but variable reductions in band 3 content were noted by radioimmunoassay as well as small reductions in ankyrin, band 4.1 and actin by analysis of SDS-PAGE gels[8] (for example, Fig. 1). Band 3 deficiency is unlikely to be the primary defect in HS, as this correlated neither with clinical severity nor with osmotic fragility. Small reductions in ankyrin probably result from early degradation of uncomplexed ankyrin, although primary ankyrin defects or deficiencies may exist in certain HS families. A small reduction in band 4.1 is also unlikely to be a primary structural defect in HS, as a 50% deficiency in band 4.1 results, not in HS but in a subclinical form of ovalocytosis[18,19].

The spectrin deficiency in human HS probably results from many genetic defects, with each kindred carrying a different mutation. Probable abnormalities are likely to fall into two groups, a reduced spectrin synthesis due to abnormal gene regulation or unstable mRNA, and inherent protein defects in α- or β-spectrin subunits or ankyrin, leading to defective protein–protein associations, intracellular precipitation or increased susceptibility to proteolysis Bodine and colleagues found spectrin-deficient spherocytic mouse mutants lacking ankyrin (*nb/nb*), with reduced spectrin α-subunit synthesis (*sph/sph*), synthesis of apparently unstable α-subunits (sph^{ha}/sph^{ha}) and reduced spectrin β-subunit synthesis (*ja/ja*)[20]. Erythrocytes from three human families with dominantly inherited spherocytosis have been shown to possess two populations of spectrin, a normal population and a variant population binding defectively to band 4.1 (refs 21, 22). Members of the latter family have been found recently to have a reduction in spectrin relative to band 3 on SDS-PAGE gels (P. Becker and S. Lux, unpublished). The defect in the spectrin-4.1 interaction may result either in reduced spectrin incorporation into the membrane or increased degradation of membrane spectrin, and as expected, it was the variant population that was quantitatively reduced[21,22]. Hereditary pyropoikilocytosis is a rare anaemia[23–25] in which an inherent spectrin defect probably contributes directly to membrane instability[10] but may also lead to secondary spectrin deficiency, while reduced binding of spectrin to ankyrin is another mechanism which could lead to reductions in membrane spectrin (for example, ref. 26). Thus, it is likely that a large number of human genetic defects, although variable in degree, will have the common result of an overall deficiency in spectrin. The studies reported here indicate that spectrin deficiency, from whatever cause, will result in a haemolytic, spherocytic anaemia if the erythrocytes contain less than 200,000 copies of spectrin.

We thank the patients and their families for their generous and enthusiastic participation in this study. The work was supported by grants from the NIH: 1-R01-AM29808-04 to V.B., Clinical Investigator Awards to P.A. and J.F.C. and Research Career Development Award to V.B.

Corrigendum

High rates of *in vitro* synthesis of 1,4-β-D-glucan in cell-free preparations from *Phaseolus aureus*

T. Callaghan & M. Benziman
Nature **311**, 165–167 (1984)

This letter described conditions for high rates of *in vitro* synthesis of 1,4-β-glucan in membrane preparations derived from *Phaseolus aureus*. This was achieved with extracts prepared in polyethylene glycol 4000 and assayed in the presence of Mg^{2+}, Ca^{2+} and cellobiose. The 24% KOH-insoluble glucan product, formed from UDP ^{14}C-glucose, has been characterized as 1,4-β-D-glucan by several criteria, including digestion by purified exocellobiohydrolase and endo-1,4-β-glucanase, methylation analysis and periodate oxidation.

During further studies on the role of cellobiose in this *in vitro* system, more recent analyses of the product (in collaboration with Dr D. P. Delmer) have now revealed largely the formation of 1,3-glucan from UDP-glucose. This finding is puzzling and it is not yet clear why, in our early studies, 1,4-linked glucan was produced, whereas later, under the same conditions, the product was found to contain only 1,3 linkages.

Work is in progress to clarify exactly what conditions are required to obtain reproducible synthesis of cellulose *in vitro* with plant systems.

Pheromone-processing protease of the yeast *Saccharomyces cerevisiae*

A RECENT paper by Mizuno and Matsuo[1] reports the purification from the yeast *Saccharomyces cerevisiae* of a protease with specificity for cleaving at a pair of basic residues within several peptide substrates. The potential importance of such a finding stems from the fact that virtually all eukaryotic peptide hormones and neurosecretory peptides are released from their precursor polypeptides by scission at pairs of basic residues that flank the mature hormone sequences[2]. Indeed, even in a simple eukaryotic microbe like yeast, secreted biologically active peptides, like the mating pheromone α-factor[3-5] and killer toxin[6,7], are excised from their precursors by initial cleavages at pairs of basic residues, namely Lys-Arg.

The activity characterized by Mizuno and Matsuo[1] is soluble and produces Tyr-Gly-Gly-Phe-Leu-Arg (abbreviated leu-enkephalin-Arg) from a larger synthetic substrate (leu-eukephalin-Arg-Arg-Phe-Ala-NH_2). On the basis of this finding, but with no results relevant to the biology of yeast, Mizuno and Matsuo termed this enzyme 'pro-pheromone-convertase Y' and implied that it may be involved in proteolytic maturation of yeast pheromone precursors[1].

We find this reasoning and methodology to be flawed. Recently, we described a mutation (*kex*2) which blocks the proteolytic processing of both prepro-α-factor and prepro-killer toxin and have isolated the normal *KEX*2 gene by recombinant DNA methodology[8]. We demonstrated that *kex*2 mutants lack a membrane-associated protease with specificity for cleaving on the carboxyl side of a pair of basic residues (not between them). Furthermore, cells carrying the *KEX*2 gene on a multi-copy plasmid greatly overproduce this protease. We have observed (ref. 8 and R. Fuller, unpublished results) that the *KEX*2 protease has a strictly neutral *p*H optimum, is completely Ca^{2+}-dependent, is inhibited by heavy metals (for example, Zn^{2+}, Cu^{2+} and Cd^{2+}), by thiol-modifying reagents and leupeptin, but is not sensitive to inactivation by serine protease inhibitors (for example, phenylmethylsulphonyl fluoride, PMSF). In contrast, the activity described by Mizuno and Matsuo has a broad *p*H optimum, is insensitive to chelators, resistant to sulphhydryl-directed reagents and unaffected by leupeptin, but is inhibited by several classical serine protease inhibitors (including PMSF)[1]. Finally, the DNA sequence of the *KEX*2 gene (A. Brake, unpublished results) predicts a polypeptide of relative molecular mass (M_r) 90,000 with a single, striking, membrane-spanning domain; the protein purified by Mizuno and Matsuo[1] was reported to be of M_r ~43,000. Clearly, the *KEX*2 protease and the protein described by Mizuno and Matuo[1] are quite different enzymes

The yield and specific activity of the preparation obtained by Mizuno and Matsuo were not given in their report. As best as can be calculated from the data provided, the final yield was only 2% or less of the initial activity. Given that one of the major neutral PMSF-sensitive vacuole-associated proteases of yeast, proteinase B, has been obtained as a soluble polypeptide of M_r ~41,000 when no precautions were taken to prevent proteolysis during purification[9] (Mizuno and Matsuo added no protease inhibitors to their buffers for obvious reasons), and considering that purified proteinase B will cleave a synthetic substrate, Leu-Trp-Met-Arg-Phe-Ala (somewhat similar to that used by Mizuno and Matsuo), between the Arg and Phe[10], it is possible that the activity described by Mizuno and Matsuo is a proteolytic fragment of proteinase B. This possibility is testable readily because there are available both antibodies directed against proteinase B[11] and mutations in its structural gene (*PRB*1)[12]. Also, it should be noted that Mizuno and Matsuo generated cell homogenates by lysing whole cells with Zymolyase 60,000, a commercial preparation of secreted hydrolytic enzymes from the bacterium *Oerskovia xanthineolytica* (formerly classified as *Arthobacter luteus*). Hence, the activity described by Mizuno and Matsuo and attributed to yeast could actually result from contamination by the PMSF-sensitive bacterial protease known to be present in preparations of Zymolyase[13,14] Again, this possibility could have been eliminated if the Zymolyase treatment had been performed in osmotically stabilizing medium to generate spheroplasts and if the spheroplasts had been washed thoroughly before cell lysis.

MIZUNO AND MATSUO REPLY—As observed in three distinct precursors of enkephalin, pro-opiocortin and pro-enkephalin A and B, the enkephalin units to be processed are flanked by paired basic residues such as Lys-Lys, Lys-Arg, Arg-Arg and Arg-Lys, which are thought to be a typical processing signal. This suggests strongly that proteases specific to paired basic residues may be involved in enkephalin processing. Our knowledge of the processing events from the precursor to the mature peptides, however, is limited and so far, candidate enzymes have not been identified[1,2]. Hence, the suggestion that the proteolytic processing at the paired basic signals in the precursors occurs by sequential actions of trypsin-like and carboxypeptidase B-like proteases is only tentative.

S. cerevisiae α-cells synthesize and secrete α-mating factor, which, when processed from a larger precursor, involves cleavage at a paired basic signal, that is, Lys-Arg. Therefore, we have chosen these cells as a simple model system for the study of enkephalin processing and have identified in the cell lysates a novel protease which recognizes specifically and cleaves the peptide bond between paired basic residues[3]. The enzyme, of M_r~43,000, cleaves various substrates related to pro-enkephalins between paired basic residues, but not at single basic residues. Its unique substrate specificity suggests that the enzyme is involved in pro-pheromone processing[3]. In order to clarify the processing mechanism, it is important that the candidate proteases be characterized in the various peptide-hormone-producing cells, even though it is unknown whether the enzyme really participates in the processing. Several investigators including us have looked for pro-hormone-converting enzymes in the secretory granules from anglerfish pancreatic islets[4], rat neurointermediate lobe[5] and bovine adrenomedullary gland[6,7]. Protease activities converting pro-insulin, pro-glucagon, pro-somatostatin and pro-opiocortin to the corresponding mature hormones were found. Our enzyme purified from yeast, however, is the only protease with specificity for a paired basic signal that has ever been isolated to homogeneity. We are convinced that our approach, which is distinct from Thorner's[8], is necessary for elucidating the as yet unknown mechanism of pro-hormone processing.

We believe that our enzyme is neither a proteolytic fragment of proteinase B nor a contaminant from Zymolyase. Proteinase B is inhibited by 90% by thiol reagent, *p*-chloromercuribenzoic acid (pCMB), at 0.93 μM, hydrolyses the peptide Leu-Trp-Met-Arg-Phe-Ala at the Arg-Phe bond and shows both chymotrypsin-like and trypsin-like specificity[9]. In contrast, our enzyme is not inhibited by

pCMB at 1 mM and does not cleave the peptides at the sites of single basic residues (for example, Tyr-Gly-Gly-Phe-Met-Arg-Phe-NH_2)[3], indicating that our enzyme is not related to proteinase B. The fact that our enzyme was identified also in cell extracts prepared mechanically by Dyno-Mill treatment (not enzymatically with Zymolyase) excludes the possibility that our enzyme resulted from contamination of the Zymolyase preparation by the bacterial protease.

At present, nobody has a clear idea of how many different enzymes are involved in the processing, whether each hormone system has its own unique enzymes, or whether several generic enzymes accomplish most of the known cleavages. Therefore, identification of the enzyme candidates participating in the processing is important, and our pro-pheromone convertase Y should be compared directly with Thorner's enzyme.

Water in the hydrocarbon core of micelles

ARE water molecules excluded from the hydrocarbon core of surfactant micelles, or can they penetrate in-between hydrocarbon chains? Dill *et al.*[1] give an answer based on the contrast variation method in neutron scattering. This method measures the zero-angle limit of the scattered intensity as a function of the scattering length density of the solvent. If their point of view is correct, it provides an important and general technique for studying the hydration and porosity of all colloidal particles. Unfortunately, their claim is based on a misinterpretation of the contrast variation method.

Indeed, for solutions of non-interacting particles, the zero-angle limit of the intensity is a purely thermodynamic quantity, related only to the mass of the dry particle, and contains no information on the arrangement of the constituents within the particle. Formally, it integrates the 'excess' scattering length density with respect to the solvent[2,3], $I(q\to 0) = AN(\Sigma b_i - \rho_s V)^2$, where A is an instrumental constant, N the number of particles, Σb_i the sum of the scattering lengths of all nuclei 'chosen' as belonging to the particle, V the corresponding volume of the particle and ρ_s the scattering length density of the solvent and q the scattering vector. If solvent molecules are included in the particle, they will contribute equally to Σb_i and to $\rho_s V$, unless their specific volume differs substantially from the bulk solvent, which would be extraordinary. Thus, their net effect on the intensity will be zero.

An equivalent formulation calculates the intensity from the 'average' scattering length density $\bar{\rho}$ of the particle; $I = AN(\bar{\rho}V - \rho_s V)^2$ with $\bar{\rho} = (\rho_p v_p + \rho_s v_s)/(v_p + v_s)$ and $V = v_p + v_s$, where v_p is the volume of the dry particle and v_s is that of the solvent included in it. Through simple algebra, this reduces to $I = AN[(\rho_p - \rho_s)v_p]^2$. Hence only the parameters v_p and ρ_p of the dry particle can be measured.

This formalism also applies to the contrast variation method, where the scattering density of the particle is matched by that of the solvent; the matching point will always be obtained for $\rho_s = \rho_p$. Hence, for micelles, it is the scattering density ρ_p of the dry micelle that is measured; solvent molecules in the micelle are not seen by this method.

We know only two ways of measuring solvent penetration in micelles through neutron scattering: one is to go to large scattering vectors (0.6 $Å^{-1}$), where the structure of the micelle can be resolved[4]; the other is to use concentrated solutions of strongly interacting micelles[5], for then the hydration water increases the effective volume fraction, which becomes a thermodynamic quantity measured through $I(0)$. The general conclusion is that bound water is important (eight per headgroup) but is excluded from the core.

Thus, we believe that the author's conclusion is correct for reasons other than those given in their letter; their method does not, however, prove the point. This was also overlooked by others[6], who have concluded that water is excluded from near the ionic headgroups of micelles. If this method was taken at face value for other colloidal systems it could lead to misleading results.

CHEN AND DILL REPLY—We agree with Cabane's point regarding the contrast variation technique, mentioned in the first paragraph on page 44 of our article[1]. But we must emphasize that the original paper by Bendedouch *et al.*[2] did contain firm evidence that there is little penetration of water into the micellar core and that substantial hydration occurs at the outer layer of the micelle where the headgroups of the surfactant molecules reside.

Quoting the analysis procedure used in ref. 2, the differential scattering cross-section per unit volume, for a nearly mono-dispersed and nearly spherical system of micelles isotropically dispersed in solution, is

$$\frac{d\Sigma}{d\Omega}(q) = n_p P(q) S(q\sigma) \qquad (1)$$

where n_p is the number of micelles per unit volume calculable from the surfactant concentration and the aggregation number, $P(q)$ the particle structure factor and $S(q\sigma)$ the interparticle structure factor. The information on micellar structure, aggregation number and hydration comes from both factors $P(q)$ and $S(q\sigma)$. $(d\Sigma/d\Omega)(q)$ is the differential cross-section per unit volume.

For experiments that measure the cross-section at 'zero' q and, for small q (such that $q \times \text{size} < 1$), one can write

$$P(q) = P(0)\exp(-q^2 R_g^2/3) \qquad (2)$$

$$P(0) = \int_V d^3 r(\rho(r) - \rho_s) \qquad (3)$$

and

$$R_g^2 = (P(0))^{-1} \int_V d^3 r\, r^2(\rho(r) - \rho_s) \qquad (4)$$

Using standard notation.

The contrast variation technique which is based on measurements of the zero angle intensity, $P(0)$, indeed contains no information on the solvent (water) penetration and the hydration, because in equation (3) the integration over the volume of the micelle (V) involves the difference of scattering length densities of the micelle and the solvent. Analysis of our 'internal contrast variation' data, more accurate than the 'external contrast variation' data, gives an aggregation number $\bar{n} = 78$ and a dry volume per monomer $V_m = 402$ $Å^3$ (refs 2, 3).

The analysis of the finite q data gives, from equation (2), the radius of gyration, R_g, which, by definition in equation (4), is related to the actual volume V of the micelle (as opposed to the dry volume) and hence would give information on the solvent penetration and hydration. Guinier plots of small q data[2] give the same value of $R_g = 15.4$ Å, independently of the degree of deuteration of the tail groups, which means that the scattering of neutrons is dominated by the hydrophobic tail part of LDS (lithium dodecyl sulphate) monomers forming the core of the micelle. If one assumes that the tails form a close-packed ellipsoidal core with

a semi-minor axis, b, equal to the fully stretched tail length, 16.7 Å, the semi-major axis, a, is then determined to be 23.4 Å using 350 Å^3 as the steric volume of the hydrocarbon tail. The dry head group of the monomer would then occupy a volume equal to $V_H = 402 - 350 = 52$ Å^3, which corresponds to a sphere of diameter $l = 4.6$ Å. Thus, the outer layer of the micelle can be assumed to be a shell of thickness l, consisting of 78 head groups plus solvent molecules. Such a model would predict that there are ~9 water molecules in the outer layer for every one of the head group. The radius of gyration calculated from this model is $R_g = 15.2 \pm 0.2$ Å, in agreement with the experimental value. If we now allow for one solvent molecule per monomer in the core, then, taking the volume of the water molecule to be 30 Å^3, a similar calculation would give $R_g = 15.8$ Å, which disagrees with the experimental value[2].

Finally, systematic measurement of the cross-section in concentrated LDS solution[4] allowed us to fit our model equation (1) consistently well. $S(q\sigma)$, thus extracted, unambiguously gives $\sigma = 2(R + l)$, where R is calculated from the volume of a close-packed dry core and l can be anywhere in the range 4.6–5.6 Å, depending on slight variations of the micellar surface charges.

Species variation in sensitivity of general anaesthesia to high pressure

BASED largely on the coincidence in crustacea of lack of pressure reversal of anaesthesia, insensitivity to strychnine and absence of glycine, and on similarities between strychnine- and high pressure-induced convulsions, Smith *et al.*[1] have proposed a hypothesis of general anaesthesia related to glycine receptors Such an interpretation can be challenged on several grounds.

First, the authors' work[1] shows that the relative potencies of a series of general anaesthetics remain constant across a number of species, whether or not they have glycine receptors. Second, binding of strychnine at the glycine receptor in the mammalian central nervous system is unaffected by general anaesthetics[2]. Third, there is abundant neurophysiological data on the lack of interaction between anaesthetics and glycine. Short-latency, glycine-mediated synaptic inhibitions are not enhanced by general anaesthetics, whereas long-latency γ-aminobutyric acid (GABA)-mediated inhibitions are increased in both amplitude and duration[3]. In a variety of *in vivo* and *in vitro* experimental protocols, the inhibitory effects of glycine are not affected by anaesthetic doses that enhance GABA actions[4-6].

As most of the above experiments have concentrated on barbiturates, we have recently examined the effects of two other clinically useful anaesthetics on the mammalian CNS[7,8]. We found no evidence to support the view that perturbation of the glycine system is a common property of general anaesthetics. The dissociative anaesthetic ketamine did not affect responses of neurones to glycine or GABA but did selectively block activation of the neurones by the glutamate analogue, *N*-methylaspartate[7]; correlated with this, ketamine had no clear effect on synaptic inhibitions but did reduce polysynaptic reflexes[8]. When tested on spinal reflexes and inhibitions in decerebrate cats[8], the steroid anaesthetic, alphaxalone, clearly enhanced long-latency GABA-mediated inhibitions but had no effect on short-latency inhibitions, thought on other grounds to be mediated by glycine[9].

It seems, therefore, that general anaesthetics do not influence the operation of glycinergic synapses. It remains possible that an action on the glycine system underlies the effects of high pressure on vertebrates. The absence of pressure-induced hyperactivity in crustacea[1], presumably an evolutionary advantage to subaquatic species, might support this view. In this case, the present models, which assume that pressure and anaesthetics act at the same site, would need to be re-appraised.

SMITH *ET AL* REPLY—The eloquent points raised by Lodge are both valid and stimulating. As stated in our paper[1], the finding that the pressure reversal of anaesthesia appears to be linked to strychnine sensitivity can be interpreted in more than one way.

If the extended unitary hypothesis (which presupposes that pressure and all general anaesthetics share a common mechanism) is accepted[2], our observations point to strychnine-sensitive processes as an important element in the 'loss of consciousness' in vertebrates. The most widely accepted view would then implicate glycinergic processes. Implicit in this view is that the loss of swimming activity in shrimps, at comparable anaesthetic doses, must arise via a different mechanism. Indeed, our additional finding that shrimps appear to have a dose-response curve that is less steep than that observed for anaesthesia in vertebrates would be consistent with this view.

However, we cannot exclude the possibility that the pressure reversal of anaesthesia could arise from an independent action of pressure resulting in a physiological rather than a pharmacological antagonism of anaesthesia; this is compatible with the view of Lodge, who quite rightly points out that there is no direct evidence that general anaesthetics potentiate the action of glycine-mediated inhibition, although it has been demonstrated that the anaesthetics ketamine and althesin confer substantial protection against strychnine[3]. However, if Lodge's work, at the level of the spinal cord, is considered relevant to loss of consciousness which results from the action of anaesthetics at higher levels within the neuro-axis, then the striking diversity of responses to different agents must lead to a rejection of the unitary hypothesis. This implies that different anaesthetics can act by different mechanisms. Any rejection of such a powerful generalization—the unitary hypothesis—that has provided the key to interpreting the common effects of a disparate group of anaesthetic substances, will require an unequivocal body of evidence.

Whichever interpretation of our results is correct, both are incompatible with present thinking—that general anaesthetics act by inducing a general perturbation of cellular membranes—and we believe that models involving more specific molecular interactions are more appropriate.

nature is keeping ahead.

Are you being left behind?

New research results, the very latest international science news, key papers by the world's leading scientists and speed of publication ensure *Nature* remains one of the foremost weekly scientific journals in the world.

But if you're tied in to a circulation list at work, all this vital weekly information will undoubtedly reach you late, often incomplete and sometimes not at all.

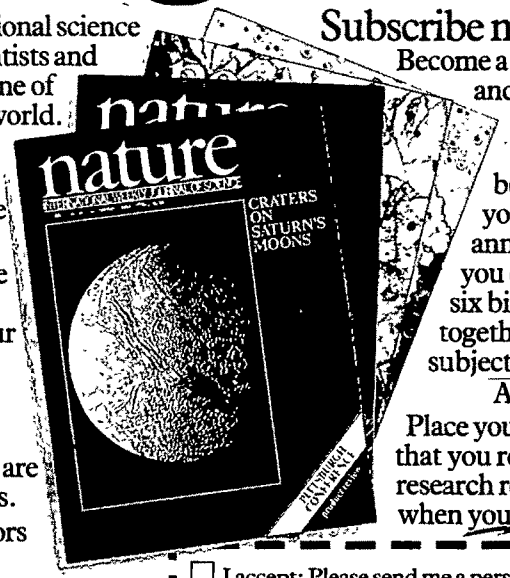
With your own personal copy, you solve the problem. Every week you'll have all the latest research results and science news in your hands within days of publication:

News reports from throughout the world of science and technology.

A **News and Views** section, where new ideas are analysed and discussed by leading researchers.

Articles and Letters in which key investigators disclose their work for the first time.

Book Reviews – Eminent figures offer expert judgments on a wide variety of recent publications.



Special Issues providing an in-depth treatment of topics of importance.

Product Reviews – Detailed descriptions of laboratory equipment newly available.

Classified Advertisements for a wide variety of positions all over the world.

You will no longer be dependent upon other people passing down the 'list' copy, and because you will automatically receive every issue, you won't risk missing a single copy through absence from work. Moreover, you keep all this key information for permanent reference.

Through your door every week

Subscribe now – at Half Price

Become a personal subscriber now and you will receive a discount of 50% off the full rate.

All 51 weekly issues will be delivered to the address of your choice. You can start your annual subscription with any issue you choose. And you will receive six bi-monthly author indexes, together with the annual index of subject and author.

All this for just 96p a week.

Place your order now and make certain that you receive the scientific news and research results crucial to your work when you want them.

☐ I accept: Please send me a personal subscription to *Nature* for one year (51 issues) at the special half-price rate of £49.00.

☐ I enclose my personal cheque for £49.00 made payable to *Nature*. (Note: Institutional cheques cannot be accepted at this special rate).

☐ Please charge to my credit card account.

ACADEMIC PRESS

METHODS IN MICROBIOLOGY

Plasmid Technology

Edited by P. M. BENNETT and J. GRINSTED,
University of Bristol Medical School, England

ISBN: 0-12-521517-7/December 1984 336 pp., $35.00/£25.00

The ability to isolate and manipulate bacterial plasmids has contributed much to the explosive growth of molecular genetics. This volume provides a valuable introduction to the techniques used in plasmid biology. A brief description of plasmids and their importance to bacteria is presented in the first chapter. Subsequent contributions consider experimental approaches to the assignment of genes to plasmids, the transfer of plasmids from one cell to another, the isolation of plasmid DNA, and the physical and genetic characterisation of plasmids. The final chapter discusses one method of DNA sequencing. This work will be vital to all those wishing to exploit plasmid techniques. Experienced workers will also find much of interest.

.....

REPAIRABLE LESIONS IN MICROORGANISMS

Edited by Dr. A. Hurst and Dr. A. Nasim
1985, 352pp., $55.00/£38.00 (UK only), ISBN 0.12.362690.0

This book presents a comprehensive account of the complexities of DNA lesions caused by a wide variety of specific environmental agents.

CONTENTS: *Introduction: Environmentally Induced DNA Lesions and Their Biological Consequences,* **M.C. Paterson and N.E. Gentner.** *Damage and Repair from Ionizing Radiation,* **N.E. Gentner and M.C. Paterson.** *Damage and Repair from Non-Ionizing Radiations,* **R. Tyrrell.** *Repair Mechanisms and Mutagenesis in Microorganisms,* **M.A. Hannan and A. GENETICS OF BACTERIA

Edited by J.G. Scaife, D. Leach and A. Galizzi
1985, 272pp., $59.00/£45.00 (UK only), ISBN 0.12.621180.9

The book covers all the major genetic aspects of bacteria, their plasmids, and phages mutation: gene transfer and recombination, the transposition of genetic elements, and the mechanism and control of gene expression. Special emphasis is placed on *Escherichia coli.* In addition, *Bacillus subtilis,* a Gram-positive organism which has unique features as a genetic system, is introduced. For those wishing to study other bacteria a list of helpful references is provided at the end of Chapter One.

A Volume in the Society for General Microbiology Special Publication Series No.13

THE VIRULENCE OF ESCHERICHIA COLI:

Reviews and Methods
Edited by Professor Max Sussman

1985, 473pp., $75.00/£60.00 (UK only), ISBN: 0.12.677520.6

The first part of this book reviews current notions about the virulence determinants and mechanisms of pathogenesis of diseases due to *E. coli.* The genetics of virulence, immunological reactions and the potential of vaccines are also discussed. The second part of the book consists of seventeen chapters that describe methods, otherwise widely dispersed in the literature, for the study of *E. coli* virulence factors.

Fundamental developments

R.H. Dalitz

Constructing Quarks: A Sociological History of Particle Physics.
By Andrew Pickering.
Edinburgh University Press/University of Chicago Press: 1984. Pp.468. £20, $30.

THE first curious thing about this book is its title. The jacket makes its meaning clear: "scientists are not passive observers . . . of nature, but active constructors of the world of natural phenomena . . .". The second curious thing is that there is nothing inside the book which justifies this conclusion.

The author has a background in theoretical particle physics but is now working as a sociologist of science. His account of the history of experiment and theory in particle physics is both succinct and accurate, and while the book is not written in a popular style it is also not technical; any interested science undergraduate could read it with considerable understanding. One of its threads is to relate the approach and contribution of each of the theoreticians centrally involved to his educational background and previous research experience. These short biographies are factual and interesting; the reader is left to draw his own conclusions. The main theme, however, is that implied by the book's title, as I shall discuss below.

Through the past decade there has been a shift of emphasis in fundamental physics, from hadrons (mesons and baryons) to quarks, largely triggered by the startling discovery of the J/ψ particle in November 1974, although already implicit in our knowledge of hadron spectroscopy (discussed here in Chapter 4) and of deep inelastic scattering of leptons by protons and neutrons (presented in Chapter 5) more than five years earlier. Early in 1974, theoreticians had already predicted from the empirical absence of neutral weak currents involving strangeness change that there should exist a fourth quark c (c = "charm", the first three quarks being u = "up", d = "down" and s = "strange"), estimating its mass to be about 1.5 GeV. The empirical mass for J/ψ was 3.1 GeV and J/ψ soon became understood as a bound state of c with its antiparticle $\bar{c}$, and so provided us with our first "hydrogen atom of quark physics". Particles with non-zero charm, for example mesons with quark structure $(\bar{c}u)$, $(\bar{c}d)$ or $(\bar{c}s)$, were empirically elusive, but the theoreticians insisted on them. The experimenters then worked hard to find them, and their search reached success in 1976, after they adopted a more sophisticated analysis procedure. Chapter 9 gives a good account of these charm discoveries. A fifth quark (b = "bottom") was established in 1977, through the discovery of the Υ (upsilon) particle, and current experiments suggest the existence of a sixth quark (perhaps t = "top"). The masses of these quarks range from several MeV for u and d, to 4.5 GeV for b and about 40 GeV for t.

A deep, elegant and essentially unique theory of the strong interactions of quarks has been developed as a gauge theory based on a symmetry already indicated by the data when we knew only the quarks (u,d,s), a symmetry involving a new degree of freedom for quarks, expressible in terms of a three-dimensional space whose axes are whimsically specified by colours. This theory, discussed in some detail in Chapter 7, is now known as quantum chromodynamics (QCD) and the symmetry as $SU(3)_C$. The gauge field is vector and its quanta are termed gluons. QCD appears to imply that quarks and gluons can only exist within bound states which have no net colour, a constraint known as quark confinement. Since quarks have fractional charge values, they would be readily apparent in the free state, whereas no such objects have yet been established.

Another fundamental step forward was the unification of electromagnetic and weak interactions of quarks and leptons as the electroweak theory, which takes the form of a spontaneously-broken gauge theory based on an SU(2)xU(1) symmetry. This theory was first laid out in 1967 and was proved acceptably finite in 1971. Now known as the Standard Model, in its simplest form it required the existence of some very massive weak bosons ($W^{\pm}$ and Z^0), conceptually partners to the photon, which couple with electromagnetic strength to quark pairs as well as to lepton pairs. This theory also predicted neutral weak currents with no strangeness change; at the prompting of theoreticians (but after a period of uncertainty), the experimenters established the existence of these currents in 1974. The history of gauge theories and electroweak unification is given here at length in Chapter 6; the Standard Model is covered in Chapter 10. The $W^{\pm}$ and Z^0 bosons were identified and measured in 1983, just as this book was going to press, and show excellent accord with the Standard Model.

Although quarks and gluons are confined, quark–quark collisions with high energy- and momentum-transfer occur in very high energy collisions between hadrons. Each secondary quark generates a jet of hadrons which carry its momentum, and the characteristics of quark–quark scattering can be deduced from statistics on these jets. For example, quark–quark scattering is now known to follow Rutherford's Law for spin-½ fermions. Again, weak bosons can decay to a quark–antiquark pair, each generating a quark jet, so leading to phenomena involving correlated jets. In a hadron containing a heavy quark, this quark may transform to a lighter quark with the emission of a pair of leptons, the secondary quark generating a jet of hadrons. There are many possible situations for study in this new area of heavy quark processes.

After reviewing at length the historical development of particle physics, as well as the present scene, the author becomes much exercised by the "incommensurability" of "old physics" and "new physics". The former, typical of the pre-1974 era, is better termed "hadron physics", being the study of the interactions of mesons and baryons, now recognized as "colour-less" composite particles made up of quarks and antiquarks interacting through the gluon field. The latter is better named "quark–lepton physics", where experimental observations are interpreted directly in terms of the fundamental quark–gluon, quark–boson and boson–lepton interactions. This transition to quark–lepton physics has been possible largely because these basic entities appear point-like, so that hard collisions occur at a measurable rate. A similar change of emphasis took place around 1950, when the forefront of fundamental physics moved from nuclear phenomena (the interactions between systems of nucleons) to hadron phenomena (starting with meson–proton scattering), and the accelerators for its study had to be built on the energy scale 1,000 MeV rather than 10 MeV. The simpler phenomena in the physics of hadrons — their detailed spectroscopy, their electromagnetic properties and their interactions at moderate energy — have now been accounted for in considerable detail on the basis of QCD and it is generally anticipated that all of hadron physics, up to moderate energies (say, 10 to 20 GeV), will ultimately be understood in this way, if sufficient theoretical calculation is carried out. For the present, however, we must get on with the study of quark–lepton physics, where the phenomena are much simpler and can teach us more directly about the fundamental interactions.

The author is puzzled at the lack of controversy among physicists about this transition from the study of hadron physics to the study of quark–gluon physics. In the final chapter, entitled "Producing a World", he states: "The history of HEP [high energy physics] can be understood as a communal search for a congenial world: a world which made social sense and in which practice could be socially organised". He concludes that this transition has been a matter of tacit choice, that particle physics today is essentially the result of a conspiracy between experimenters and theoreticians. The theoreticians demand certain phenomena, for their own reasons,

and the experimenters then build equipment sensitive only to those phenomena. As Pickering puts it: "detectors are [now] designed to optimize new physics and to exclude old physics. So specialized have they become that their sole use lies in the investigation of rare phenomena". The experimenters establish what has been required of them, and the theoreticians move on to further demands, in "a social symbiosis of experimental and theoretical practice".

Of course, it must be said here that the theoreticians have had a very good run since about 1970. The gauge principle has proved extraordinarily successful in providing theories which are not *ad hoc* but rooted in deep symmetry principles. But while it is also true that the experimenters have made mistakes, and have had to learn how to deal with background effects which can fog their data on the phenomena they seek to explore, they are not subservient to the theoreticians. In reality, experimenters are cussed individuals, eager to prove the theoreticians wrong whenever possible. In any event, what the author has overlooked is that the experimenters will not be able to find what the theoreticians desire of them, when the theory concerned does not correspond to the real world. Experimenters have the capability of disproving theories, that is the strength of their position, and of course most theories are wrong.

The very direct relationship of the phenomena now seen in the regime of large energy- and momentum-transfer with the underlying theoretical entities and the interactions between them, suggests that particle physics may now have reached a regime of simplicity, as so often hoped for in the past although in a different form. There is no compelling reason why any asymptotic regime of simplicity should exist, of course. This regime stands out only because of the point-like character of the quarks and leptons, relative to the size of about 10^{-13} cm typical for hadrons. As things are, events in this regime are quite rare and it would not have been possible to find them at all amidst the background of events arising from the processes of hadronic physics, if the quark and lepton interactions were suppressed by form factors associated with finite size.

There is, of course, a problem in the minds of many concerning the confinement of quarks and gluons. However, the interpretation of phenomena in terms of entities which we cannot exhibit at the time is not a new situation in physics. The atomic theory of gases was used fruitfully for some decades before a single atom was identified. What *is* new is that the fundamental entities within hadrons are quarks which we cannot hope *ever* to exhibit individually. Are quarks real, in this situation? This is a nice point for philosophical discussion, but in the laboratory there is no doubt at all. Quarks allow us to interpret in simple terms what we see in experiments in this regime. Calculations based on them and their interactions fit the data. They allow us to design new experiments and to decide which measurements are likely to be the most informative. After quite a short period, the active physicist treats them, and thinks of them, as real objects. They have an operational reality for him. On the other hand, these quarks, leptons and bosons are still not necessarily fundamental particles, and the future course of quark–lepton physics is uncertain. Will history run through another cycle and lead us to find that these particles are themselves composite? We see no clear indication for compositeness at present, although there are recent reports of rare anomalous processes in quark–lepton physics for which we have no explanation to hand.

The strange thing about this book is that it is mostly rather good, well-written and engaging, until the author goes off the rails with the idea that the experimenters and theoreticians are making up a world to suit themselves. He is obviously upset that the kind of physics that he learned, "hadron physics", is being ignored in today's experimentation, which does indeed endeavour to eliminate as much of its effects as possible in order to get down to the underlying fundamental physics. Pickering does not seem to have understood the transition which he has been observing, nor to realize that this has happened time and again in the course of physics. However, the sceptical reader will find the book quite rewarding, provided he skips the first and last chapters or takes due warning to read them with caution. □

Channels defined

Charles F. Stevens

Ionic Channels of Excitable Membranes.
By Bertil Hille.
Sinauer/Blackwell Scientific: 1984. Pp. 426. $32.50, £29.50.

NEUROBIOLOGY has made great strides in the past decade or two, and progress in understanding neuronal electrical activity has been particularly impressive. Bertil Hille's new book provides us with an elegant and lucid account of these recent advances in knowledge about electrical excitability.

What is a channel? When Hodgkin and Huxley showed how the nerve impulse arises from increases in the neuronal membrane's permeability to sodium and to potassium ions, these ions were generally viewed as passing through tiny membrane pores that open in response to changes in the transmembrane voltage. In recognition of the hypothetical nature of these rather mysterious "pores", however, the term "channel" soon came into use; "pore" connotes physical characteristics that the vaguer term "channel" does not and, in the early days when we had no way of directly studying the microscopic processes of ion permeation, the less committal name seemed safer. Over the past ten years, we have discovered that channels are integral membrane proteins in which a microscopic pore opens and closes to regulate the flow of ions across the membrane.

In the old days, two questions about channels were clear. How is gating achieved? And how can a channel select between different ionic species? That is, by what mechanism does a channel open and close its pore, and how can that pore — in a potassium selective channel, for example — let potassium ions (crystal radius = 0.133 nm) pass through while excluding sodium ions (crystal radius = 0.095 nm)? Hille's book gives the modern answers to these classical questions and also deals with more recent issues. What is the structure of channel proteins? How are they synthesized and inserted in the right membranes? How did channels evolve? In what ways are various channel types different and what properties do they share? More specialized sections survey our understanding of chemical and toxin modification of channel gating and of the way in which small molecules of the right shape and size can block pores. Introductory sections cover the required background of physical and chemical principles, and also the classical descriptions of channel behaviour such as the Hodgkin-Huxley model.

The book is written in a clear and crisp style with excellent illustrations and a lot of references (about a thousand of them), ranging from work done in the nineteenth century to articles published in the past five years (about a third of the citations). Chapters are relatively independent, are designed for skipping around in and between, and are arranged in short sections with headlines ("Channels are Needed for Excitation"); "'Hydrated Radius' is a Fuzzy Concept"; "Channel Evolution is Slow").

Not only does Hille's book present information clearly, but it fills an important void: no other systematic and modern treatment of this material is available. And while it is not a Sunday-afternoon-learn-a-bit-about-the-brain book, it does make the modern view of channels available to all neuroscientists — advanced undergraduates, graduate students and scientists who need to know what we understand about channels. Hille has been a leading contributor to research on channels, and has brought the expert's insight, together with the master teacher's skill, to the job of explaining what is known about the basis of neuronal electrical activity.

Charles F. Stevens is a Professor of Physiology at Yale University School of Medicine.

The changing face of the Earth

Robert P. Beckinsale

A Short History of Geomorphology.
By Keith J. Tinkler.
Croom Helm/Littlefield, Adams: 1985. Pp.317. £19.95, $25.

THE compilation of a short, comprehensive and readable history of the study of landforms calls for selective wisdom of the highest class. Keith Tinkler's book has all those virtues, even though nearly one-quarter of it is given over to an excellent bibliography and a rather simple index. The dominant method used is to illustrate particular themes by studying influential publications in some depth to convey an overall view of the subject without sacrificing attention to detail. Necessarily, where possible, the focus falls upon form and process as viewed over time.

The reader is assumed to have at least a nodding acquaintance with geomorphology and its terminology, but these prerequisite demands are small and undergraduates are encouraged also by a brief historical *caveat*. The account moves quickly through classical authors to the Italian Renaissance and so to the long period when the earth sciences, with rare exceptions, were constrained by biblical notions. This period merged into the age of James Hutton and John Playfair who believed that "in nature we have no deficiency of time" and whose thoughts were as complementary as their styles were disparate.

There followed the effect of the Industrial Revolution on scientific thinking, which fostered Charles Lyell, the great uniformitarian, who used existing phenomena as a complete basis for his conclusions on processes (and not surprisingly sometimes showed an unfortunate bias). Before his death in 1875, fluvialism had become more positive and the reality of a recent Ice Age generally accepted, thanks to "a blend of factual investigation and imaginative insight... unparalleled in the history of geomorphology up to that point"(p.119).

Most of the remainder of the text covers geomorphology since the 1880s rightly emphasizing the influence of Eduard Suess who postulated a periodic movement of sea-level, diastrophically controlled and globally synchronous, and of William Morris Davis who popularized stages in river courses and cycles in the development of a variety of landforms. During and after the Second World War allegiance to marine planation and cyclic aspects faded in face of improved technologies and heightened interest in climato-genetic geomorphology and in details of fluvial, coastal and tropical landforms. Since 1960 the shift towards quantification and process studies has quickened and progress has been made in, for example, the understanding of slope development, river flow, ice-sheet dynamics and the significance of physical thresholds. Conceptual and theoretical advances have included the systems theory with its concern with a stable, though not static, equilibrium state.

In the final chapter Tinkler tries to assess future trends, a task which some readers may consider regrettable as this space could have been more profitably devoted to ocean-floor spreading, plate subduction, vulcanism and orogenesis, topics which are almost ignored. But anyone interested in the study of landforms will find this a competent summary which manages to sustain a stimulating commentary throughout its commendably short course. □

Robert P. Beckinsale was formerly a Lecturer in Geography at the University of Oxford.

A chip off the old block

Living Fossils.
Edited by Niles Eldredge and Steven M. Stanley.
Springer-Verlag: 1984. Pp.291. DM138, $54.10.

IN SOME groups of animals and plants the rate of evolutionary change is exceedingly slow, and their modern representatives hardly differ structurally from the earliest members to appear in the fossil record. G.G. Simpson referred to such slow evolution and abnormally long survivorship as bradytely, distinguishing it qualitatively from horotelic (normal) or tachytelic (very rapid) evolutionary change. The survivors of such bradytelic lines are "living fossils", conceived as either specifically adapted to particular niches within a more or less permanent environment or as more than usually tolerant of fluctuating conditions. Lineages which become bradytelic might be "advanced" on their first appearance but lack of environmental stimulus for change would enable them to survive indefinitely.

How valid are Simpson's concepts in the light of the current developments in patterns and processes of macroevolution? Is there anything special about such arrested evolution or is bradytely simply the "slow end" of a normal distribution of evolutionary events?

Eldredge and Stanley, in trying to come to terms with these and related questions, solicited specialist contributions to obtain data on groups which might be, or have been, regarded as living fossils. They requested, for example, information on anatomical similarity of modern forms to their ancient relatives, the time scale involved, ecological specializations, diversity and so on. In other words, how good are the examples of living fossils and in evolutionary terms what does it all mean?

There are 30 separate papers in this collection and two concluding summaries, one by each editor. Over half of the papers are devoted to vertebrates — various mammals, coelacanths, *Amia* and *Polypterus* (though not *Sphenodon*). The interesting question is asked (and answered) as to whether there are any anthropoid living fossils. A great variety of invertebrates are discussed, among them *Neotrigonia*, *Peripatus* and limulines (though not *Lingula*), but also bryozoans, and cephalocarids as living fossils lacking a fossil record. There are, however, no plants, not even *Ginkgo*.

Some authors have given a largely anatomical account of their group, but have usually tried to assess whether the surviving representatives are or are not "good" living fossils. Others have also advanced concepts and theory, often thought provoking. It is, of course, easier to categorize as a living fossil an animal whose similar forebears appeared 500 million years ago, than a type which originated more recently. Even then it may not be easy, for, as Ward, for example, acknowledges in his excellent paper on *Nautilus*, the apparent stasis may only be a factor of low morphological complexity. And again Fisher points out that the sparse fossil record of limulines virtually precludes their evaluation as "good" living fossils. In spite of the very different ways in which the various authors have approached their groups, this volume is a really valuable source of well researched information.

Having collected the evidence, to what conclusions do the editors come as to the reality of bradytely as categorically distinct from other rate-phenomena? Eldredge concludes that there is no strong evidence for bradytely as a separate kind of evolutionary mode. Likewise Stanley suggests that Simpson's three classes, including bradytely (originally developed within a gradualistic framework) tend to lose their value as separate categories when seen from a punctuationist standpoint. Does this imply that, after all, one's own point of view may still be the ultimate determinant, and the question should be left open? Possibly, but few could take exception to the concept that living fossils are simply survivors of long-lived groups which have continued, for a variety of reasons, including those Simpson proposed. □

NATURE VOL 314 11 APRIL 1985

Schools for another century

The British government is rightly seeking to improve the quality of school education. It must first win back the confidence of teachers and then act generously.

How should young people be prepared for life in the brave new world thought likely to begin in 2000 or thereabouts? That question preoccupies educationists in industrialized countries as different as the United States and Japan. Most of the recipes emerging from this introspection entail the assumption that the next century will make greater demands on the numeracy of the general population, which is a fair guess. Governments in the industrialized countries are also conscious that their survivial in recent years has hung on economic competition in the design and manufacture of the products of technological innovation, whence the general objective that educational systems must produce many more young people qualified to engage in this competition. That, too, is a reasonable proposition. The difficulty, as all reformers have discovered, is that it is much easier to specify what the future will require of schools and universities than to arrange matters so that these consequences obtain.

This is the test that must be applied to the torrent of proposals for educational reform now flowing from the British government's Department of Education and Science. Last week, Sir Keith Joseph, the minister in charge, published a policy statement called *Better Schools* whose proposals would transform the way in which schools are organized. This has been quickly followed by a set of detailed proposals for a new public examination to be taken by all British sixteen-year-olds that will break new ground in at least two important ways — the General Certificate of Secondary Education is meant to be a measure of educational attainment for students whose ability spans the whole spectrum, while the grades awarded under the new system will be determined by standards supposed to be objective (and not, as with existing school-level examinations, by competition for a fixed quota of the higher grades). For good measure, the government has also published a policy statement on science education urging that all students should follow science courses from the ages of 5 to 16. Objectively, the new proposals are both enlightened and courageous. But ironically, they have appeared at a time when the British government is in dispute with school teachers over pay. So Sir Keith's rush at reform has won him more enemies than friends. He should not be too surprised.

Improvements

Part of the difficulty is that the minister, like the government of which he is a member, has plainly been forced by the realities of the educational system to abandon some of the prejudices with which it came to office in 1979. British schools were then still adjusting in the wake of the upheavals of earlier decades — the reorganization of secondary schools to provide a comprehensive education within their catchment areas, and the wave of curriculum development that enlivened much teaching but which also threw a disconcerting light on the poverty of the rest. In retrospect, the comprehensive reorganization, socially and even administratively a necessity, was forced through too quickly, with the result that the performance of both teachers and students fell below par. The present goverment's first instinct was to unscramble the reorganization, but by 1979, the omlette was indissoluble. So attention turned to the improvement of educational standards within the publicly supported schools. That is the starting point for *Better Schools*.

There are some things to boast about. The proportions of students leaving secondary schools with qualifications in public examinations have risen over the past two decades, if slowly. The government is able to claim that three-quarters of school-leavers now have graded examination results in at least five subjects. The other side of that coin is that only just over a quarter of them perform creditably, well enough to be able to use their qualifications in persuading employers to offer them jobs. Some of the reasons are spelled out in *Better Schools*. In secondary schools, the planning of the curriculum is too often left to chance. Language-learning is almost universally undervalued. Too many teachers are required to perform beyond the levels for which their training and capacity have equipped them. And so on.

Changes

Complaints such as these have been familiar in British education, as in educational systems elsewhere, for decades. The underlying difficulty centres on the sociology of the school. As in other kinds of educational institutions (universities, for example — see below) the polite conventions of academic life conspire to allow teachers the freedom to teach badly if that is their inclination. In the long run, the only remedy is that schools should become more coherent institutions, places in which professional teachers are involved both with the determination of a school's objectives and with the planning of how flesh should be put on these bones. Too often, in the past, bureaucratic interference from outside, or the waywardness of those in charge of schools, has had the effect of giving teachers the impression that they are merely hired functionaries. One of Sir Keith Joseph's more courageous ambitions is to change all this. Among other things, he plans that professional training courses should be more thorough, that the performance of teachers in posts should be regularly assessed, and that teachers' pay should be linked to performance. Nobody disagrees with these objectives. Why have they landed the minister in hot water?

The most obvious difficulty is that the talk of teacher assessment which has been buzzing about for more than a year has not yet been embodied in a set of tangible proposals that teachers trust. Who will carry out the assessment, and by what criteria? Teachers may be forgiven for asking that these questions should be answered before they entrust their careers to such an innovation, however desirable its effects may be. Yet even now, in last week's flurry of documents on educational policy, it is clear that the government has not made up its mind. There is talk of assessment by local education authorities (which employ teachers) and of the possibility that there may have to be some national scheme backed up by a statutory definition of a teacher's responsibility. But the only level at which the assessment of a teacher's performance can be undertaken sensitively is that of the school. The British government would find its ambitions more easily attainable if schools were given a greater degree of autonomy than they enjoy at present, for then professional teachers would more easily sense the connection there must be between performance, success and security.

Another source of difficulty is that the British government's financial support for schools has become ungenerous. As with British universities, British schools are now kept on tight budgets. The government can claim (as it does in *Better Schools*) that school budgets have not declined as quickly as have school

enrolments, but there are still far too many schools short of resources that they must look to parents for essential provisions of cash. And teachers, unassessed though they may be, are badly paid on rigid salary scales allowing for very little variation in the way in which outstanding members of the profession may be rewarded. The government now seems to be saying that it will devise more imaginative ways of rewarding teachers only when the profession has accepted the need for assessment (and has also swallowed this year's offer on pay). That is too wooden a posture. The government would be better advised to take a more active role in persuading teachers to its convictions. One of the essential ingredients of this process should be an undertaking that the resources spent on school education will be substantially increased as the years go by.

For that, in the long run, is the only way in which the government's ambitions to improve educational standards can be attained. The objective should be that the quality of the publicly supported schools should be comparable with that of the private schools, whose performance is a galling reminder to the public sector of how much improvement there is to make. By comparison, reform of the examinations system cannot contribute as much as would a few tangible demonstrations that it is possible radically to improve the quality of education with Britain's impoverished public sector. For Sir Keith Joseph, the implications should be plain. He cannot hope to bring about his reforms without the willing collaboration of a teaching force whose confidence he has lost. The remedy, painful though it may be, is that he must win them round, chiefly by talk but partly by means of some simple demonstrations of the improvements he rightly wants to see. He may have thought his rash of policy documents would tidy up this important enterprise, but it is only a beginning. □

University business

British universities should seize an opportunity for reform.

THE report of the Jarrett committee on the efficiency of British universities has turned out not to be the fearsome document that some academics had expected. But that does not imply that its modest and sensible proposals will be adopted without difficulty or, for that matter, ignored. The essence of the argument now advanced (see p.394) is that, in spite of the distinctiveness of their social function, there is no reason why universities should not be managed as are other complicated institutions, by the self-conscious planning of their own development and by repeated re-examination of the match (or mismatch) between their resources and their ambitions. On that point, the Jarrett committee is on entirely sure ground. The practical difficulty, during the past four years but probably for some time to come, is that individual universities must draw up strategic plans in ignorance of the resources they will have at their disposal in the future. Crisis management has been the game since the budget cuts of 1981. Planning for uncertainty is now the order of the day.

Come what may, British universities cannot emerge qualitatively unchanged from this period of upheaval, for which Jarrett is merely the latest stimulus. The issue that confronts them is simple, even stark. Faced with shrinking resources, the University Grants Committee, British universities' paymaster, has been compelled to plan to distribute what funds there are in a discriminatory fashion. Something like two-thirds of its pot of gold will be used for the support of teaching, the rest for providing the infrastructure for research. The first task may in due course be done by means of formulae, but the second will entail some necessarily invidious judgements on whether this or that research is academically more interesting, or otherwise more deserving. People (*Nature* included) will be watching the grants committee like hawks to ensure that it does not sacrifice quality in the face of claims (from the government, perhaps) that second-rate work may be more useful, but universities cannot hope to succeed in this environment if they are not equipped to be internally discriminatory (between the good and the less good). That, briefly, is all that Jarrett recommends.

The objections are easily anticipated. Universities everywhere, jealous though they are of their constitutional autonomy, have traditionally shrunk from suggestions that they should apply yardsticks to the quality of the work their people do. It is a painful process, but also one in danger of being corrupted by the special influence of powerful members of a faculty, more able to fight for their own corners than they deserve to be. There will also be cries that attempts to discriminate between different fields of research by the allocation of resources will be an offence against academic freedom, which is a beguiling half-truth. For academic freedom implies merely that an academic should be free to pursue the goals he judges to be worthwhile, not that he should be equipped to do so on some standard scale. Yet in practice, the difficulties of deciding these contentious questions within an exclusively academic body are so great that academics should themselves recognize that it will be simplest if the responsibility can be shared with the university's governing body. That is the logic of the Jarrett recommendation. Nobody should think that it will be easily effected.

Much the same is true of the proposal that members of academic staffs at British universities should be regularly subjected to formal appraisal of performance as are, for example, people who work in business or in the civil service. The Jarrett report remarks that appraisal of a person's performance in academic life now happens only accidentally, perhaps at the end of a probationary period or at promotion or relocation. (It might have added that the criteria used on these occasions are often too narrow, or too unambitious.) Again there will be fears that a formal requirement that senior academics should tell their junior colleagues how they rate will interfere with academic freedom, but this is also mistaken. Jarrett might have made more of the positive benefits of sensitive assessment. As things are, too many British universities wedded to the notion that young academics will either sink or swim are allowing their indifference to the careers of new recruits to become a means of wasting talent.

Most British universities will no doubt read the writing on the wall, and bite the bullets Jarrett offers. What, however, will happen to those that are constitutionally incapable of responding? Oxford and Cambridge, which are not merely autonomous but which are self-governing to an embarrassing degree, may find themselves having to vote away some fo their high-level mob rule. The University of London, by any standards the largest in the United Kingdom, will be in greater difficulties. With its federal structure, the obvious danger is that the central administration will blunt the efforts of its constituent parts to improve their capacity to make decisions. The simplest solution is to allow these parts, all of them now larger than many other British universities, to deal directly with the grants committee. Jarrett's management principles require no less.

Whether reforms along these lines will serve the intended purpose does not, unfortunately, rest with the universities, or even with the grants committee. Increasingly, it is the government that determines policy, but on a short-term basis. The first round of budget cuts decreed in 1980 was based on the doctrine that higher education must bear its share of the general reduction of public expenditure then planned; in the event, it cost the government an unplanned £80 million to send 5,000 academics into early retirement. Now there are budget numbers for the three years ahead, but nobody has explained how the university system is to manage the further contraction they imply. And the government is still silent on the issue of how many students should be admitted to British universities, for what purposes and with what support. The general exhortation that universities and industry should work more closely together is known to have financial implications still undefined. All these questions were supposed by now to have been clarified in a policy paper from the British government, whose publication has been imminent for nearly a year. Sir Keith Joseph, the minister responsible, may have had other things on his mind (see above), but his apparently endless delay in saying what he wants of universities is also bad management of a kind. □

US universities

Now even the Texans are short of cash

Austin, Texas

TEXAN ambition is legendary, and the state's two major campuses, the University of Texas (UT) at Austin and Texas A & M University at College Station, certainly fit into that mould. Both aspire to be counted among the country's top research institutions before the end of the century, and both can point to impressive steps already taken towards that goal, including the well-publicised poaching of academic superstars from better-known and more widely celebrated institutions. But a state budget crisis is casting a shadow over the universities' finances — both are state supported — and faculty recruitment and teaching programmes may suffer as a result.

The Texan economy has been built on oil. Since oil prices started to fall two years ago there have been growing numbers of business failures, and property prices have fallen, sometimes dramatically. State tax revenues have also fallen, and because the state legislature is constitutionally prevented from running a budget deficit it now has to find ways of reducing spending by almost $1,000 million (the alternative, raising tax rates, seems too unpopular even to contemplate in Texas). The first proposal for achieving this saving, drafted against a deadline and hardly intended to be taken seriously, would have done so entirely by reducing the state's higher education budget by a startling 29 per cent. The most recent proposals are more moderate — it seems to be agreed that the 1986 higher education appropriation should not be less than 96 per cent of that for 1985 — but the state House of Representatives appropriations committee has nevertheless approved a plan to close down the UT Permian Basin campus and the A & M campus at Galveston. While this will not be the last word on the plan, it indicates how seriously the crisis is now being taken.

Many fear that even small cutbacks will damage the Texas "can do" reputation, which is held to be the major reason why both universities have been so successful in building first class academic departments. Eight UT Austin PhD programmes were ranked among the top ten in the country by a recent national survey, and A & M claims to be among the top 20 US universities in research expenditure. The chancellor of the UT system is on record as saying that support at 96 per cent of 1985 levels will be insufficient to keep academic programmes at their current levels, however, and the university is still pressing for a 4.9 per cent increase. The funding decisions by the legislature are supposed by law to be decided by midnight of 31 May; this year many expect the legislature to resort to the device (used on some previous occasions) of literally turning back the chamber's clock to gain extra time.

The state budget crunch is doubly unfortunate because it comes at the same time as legislative changes that will reduce the benefits accruing to UT Austin and Texas A & M from a massive land endowment granted by the state last century. The 2 million acres of west Texas that were set aside to support scholarship were later found to lie above substantial oil deposits, and it is principally the oil that has supported the extraordinary expansion of both institutions since the 1920s. Royalties are channelled into a Permanent University Fund, now worth around $2,000 million; interest from the permanent fund constitutes the Available University Fund, amounting to about $150 million a year. The universities use the permanent fund to guarantee loans for new building construction, and interest on this bonded indebtedness is the first call made on the available fund.

In a ballot last November, the state increased the number of campuses eligible to use the Permanent University Fund to guarantee loans, to include virtually all UT and A & M campuses; this privilege had previously extended only to a few sites, principally the large College Station and Austin campuses. The result will be that more of the available fund will be tied up servicing debts and so proportionately less will be available for other improvements at the main campuses.

Despite the squeeze, both universities have more to be cheerful about than most: UT's total endowments are by some reckonings worth more even that those of Harvard, generally thought to be the wealthiest university in the country. And the president of Texas A & M, Frank Vandiver, is adamant that state budget problems will not impede plans to recruit top quality faculty: top salaries can be paid to attract the right people (there are two faculty members earning over $100,000 a year) can be paid to attract the right people, and, even more important, the university will provide buildings and equipment beyond the means of many institutions. The success of A & M in becoming the scientific headquarters of the Ocean Drilling Program is ascribed largely to Vandiver's personal commitment to provide $5 million of university funds for a new building for the programme, the first on the university's research park. A & M is also making a strong pitch to attract the proposed Superconducting Supercollider to Texas, to which end it has already devoted $1 million.

At UT Austin, recruitment is now under way to fill 32 new scientific professorial chairs, each carrying an endowment of $1 million. Last year, the university accepted $16 million in private donations for the chairs and was able to match this sum from the Available University Fund; the first appointments have now been announced. The 32 chairs will be in natural sciences and engineering, with a strong emphasis on molecular biology and materials sciences, reflecting the university's desire to serve the economic needs of society, according to Austin Gleeson, dean of the college of natural sciences. Some faculties outside the favoured areas are resentful of what they see as a lack of consultation by the university on where the money should be spent. But Gerhard Fonken, Dean of academic affairs, argues that when a single gift of $8 million is being discussed it is well to bear the donor's wishes in mind. The first of the 32 appointments have recently been announced, but already there are worrying signs that some scientists who have been approached are being deterred by reports about the state legislature's early proposals for higher education spending. The view at Austin is still firmly optimistic; talk of faculty lay-offs is dismissed as scaremongering. **Tim Beardsley**

Perils of secrecy

Washington

THE Office of Technology Assesment (OTA), which exists to advise Congress on technical matters, has discovered one of the pitfalls of working with classified documents. The office was recently commissioned by a congressional committee to prepare a report on "C³I" — command, control, communications and intelligence of nuclear forces. OTA's researcher was provided with the appropriate security clearances; the final report was to be classified.

After poring over Department of Defense (DoD) documents, OTA's researcher wrote his report and submitted it to DoD for security review. DoD promptly slapped on it a classification even higher than the level for which the researcher had had clearance. The classification is also higher than congressmen are ever allowed. So now neither OTA nor the committee that commissioned the study is allowed to read it.

The explanation is that the OTA researcher apparently pulled together enough top secret and "compartmentalized" data (one step above top secret — those with access to any given compartment are not given access to any others or even permitted to know what other compartments exist) to reproduce some of DoD's most secret data on nuclear war-fighting plans, which have a security classification all their own.

OTA officials have suggested outfitting their researcher with a blindfold to allow him to remove the offending passages.

Stephen Budiansky

British universities

Better management demanded

BRITISH universities are in for another shake-up, this time a revolution engendered from within. So much is clear from the report published earlier this week of the committee under Sir Alex Jarrett set up a year ago to give the Committee of Vice-Chancellors and Principals advice on the effective management of universities.

The study now completed has been an unusual exercise, in which individual academics collaborated with professional management consultants and firms of auditors to look into the efficiency of six institutions (the universities of Edinburgh, Essex, Loughborough, Nottingham, Sheffield and University College, London). The report now published is that of the steering committee for the separate studies, and seeks to emphasize some general conclusions reached.

The report seems to accept that the financial deprivation of the British university system will continue, and perhaps even intensify. The committee notes that the hope that the severe cuts of 1981 (effectively a reduction of budgets by 17 per cent over three years) have not been followed by the once-promised "level funding" but by a period during which central government support for universities has been fixed in cash terms that do not adequately compensate for inflation.

The committee notes that, during this period, the British government has also taken steps to influence the pattern of university development, both by the encouragements of some kinds of academic developments and by limitations of student numbers. The report pleads that, in the interests of efficiency, the government should make clear its intentions towards the British university system and that it should look for some way of enabling universities to plan more than one year ahead. Specifically, the committee asks that the government should be prepared to meet the "whole or the greater part" of the cost of such academic redundancy as may be needed in the future.

Starting from the view that change within universities will be further stimulated by the determination of the University Grants Committee to distribute funds more selectively in future, the committee argues for more decisive management within universities. It says that governing bodies (variously called "councils" and "courts" in the British system) should assume responsibility for strategic planning and that vice-chancellors (also called principals) should be recognized as the chief executives as well as academic leaders of institutions (and be given increased powers to do so when necessary).

Ordinarily, the Jarrett report says, there should be a joint committee of the council and the academic senate, with the vice-chancellor as chairman, to superintend planning and the allocation of resources within a university. At the department level, the report says, steps should be taken to see that the performance of individual academics, as teachers and in research, is regularly assessed. In general, the report asks that universities should prune the numbers of committees dealing with other than academic matters, delegating affairs such as the operation of student residences and the maintainance of buildings to university officials.

The report also asks that the grants committee should itself be more active and articulate, and that it should be more vigilant in monitoring promises made by individual universities (as when, in 1981, universities agreed to close some departments and to run others in collaboration with neighbouring institutions). The Jarrett report also says there should be a review of the grants committee itself, in part so as to tell whether it is sufficiently well-provided with resources for the work it has to do. □

Japanese whaling

Hollow victory for United States?

Tokyo

UNSUSPECTING foreigners out in Roppongi, the nightlife centre of Tokyo, are in for a surprise, for there amongst the flashing neon is a large sign in English, paid for by the All Japan Seaman's Union, reading "Continue the whaling on scientific facts". These words, designed to strike at the heart of logically minded Westerners, may be the last from a dying industry.

Scientific facts or no scientific facts, decisions are rapidly being made about the future of whaling in Japan and, despite last-ditch diplomatic efforts by Japan's Fishery Agency, concessions are having to be made that almost certainly spell doom for the offshore whaling industry.

In December last year, the Japanese government filed a formal objection to the 1984-85 International Whaling Commission (IWC) quota for the minke whale catch in the Antarctic Ocean — minke whaling forming the backbone of the Japanese whaling industry. The IWC quota had been set at 4,224 head, 37 per cent down from the previous year, of which 1,941 head were allocated to Japan. By filing the objection, Japan freed itself from the need to observe any quota at all; soon after, however, Japan announced it would "voluntarily" limit Antarctic minke whaling in the November 1984/March 1985 whaling season to the previous season's levels (3,027 head). This, however, did not appease world opinion sufficiently for the United States to withdraw its threat to invoke the Packwood-Magnusson Amendment, a domestic ruling to cut the fishery catch in US waters of any country that defied IWC quotas. This would mean that Japan's huge fishing quota in the US 200-mile fishing zone would be halved in the first year of defiance and reduced to nothing in the second. To buy time for talks, a further compromise was made: the Japanese Antarctic whaling fleet was ordered to stop catching on reaching the new quota set by IWC and return home.

But the move did little to ease US pressure, and a series of talks between the United States and Japan has led to an ultimatum that Japan must withdraw an objection it filed earlier to the IWC complete ban on commercial whaling that is to begin in 1986. Withdrawal of the objection would effectively mean complete defeat: all Japanese commercial whaling would have to end by 1988. All that the Japanese have so far won from the United States is an extra two years' grace — 1988 rather than 1986 — before they must observe the moratorium. Even this gesture was hotly contested in the courts by US environmentalists. A last-minute attempt to gain further concessions from the United States is under way this week, but the Japanese government has already admitted that little can be expected.

The implication of the Seaman's Union poster is that there is actually no clear scientific reason to stop minke whaling. Even IWC's own scientific committee had not claimed that minke stocks were in danger of extinction. Not surprisingly then, the Japanese see their defeat over whaling as a victory for US environmentalists and a view of the morality of the killing of whales they do not share. Strong emotions have been aroused about the way in which foreign pressure has crushed an ancient industry — indeed the Seaman's Union poster carries a different message in Japanese: "Defend our traditional whaling", and has a picture of a traditional craft with rowers clad in loin-cloths to drive home the point.

US environmentalists have recently tried to ease tension by rewarding cases of Japanese kindness to whales. A baby whale that became entangled in a shore net and ended up still alive at a fish market was recently bought by a group of fifteen Odawara fishermen and returned to the sea. Earth Trust, a US environmental group, then gave them a 20,000 yen reward together with a commendation and a whale sculpture. The fishermen, who had been moved to free the whale because "it looked as though it was shedding tears", will donate the money to African refugees.

The whales may be a lot better off for these developments but the United States may well feel a backlash. The Japanese feel they have been forced to concede and the next issue may be that much harder fought.

David D. Swinbanks

Deep-sea drilling

No cut-price membership

Washington

NATIONS participating in the Ocean Drilling Program (ODP) have come down hard against a suggestion from Britain that it might join the project as a part member, perhaps in collaboration with another country, and so save part of the £2.5 million annual membership fee. The executive committee of Joint Oceanographic Institutions Deep Earth Sampling (JOIDES), which manages ODP, has, while urging the United Kingdom to join, passed a resolution that it would be "neither appropriate nor in the best interests of the program or other full members" for Britain to join except as a full member. JOIDES has also instructed planning committees not to guarantee places for British scientists on future research missions of the new ODP drilling ship, the *JOIDES Resolution*.

Britain became a *de facto* non-member of ODP at the end of January when the British Natural Environment Research Council (NERC) failed to raise sufficient funds in time for a deadline. Britain's representative, John Bowman of NERC, had earlier voted in support of the rule that countries that had not paid up by the end of January would no longer be considered members. Efforts are still under way in Britain, however, to secure the amount needed, and JOIDES officials point out that Britain would be able to rejoin in future years if present efforts fail.

The British unwillingness to find the membership fee has annoyed other full members, because the ODP budget had been planned on the assumption that there would be four full members (besides the United States) during 1985. Other full members are France, West Germany and Canada. Japan is committed to join after September this year, but this was also anticipated in budget planning. The programme will be $2.5 million short next year unless another member is found. Already, purchase of some shore-based equipment has had to be deferred, according to Philip Rabinowitz, director of ODP.

ODP scientists say the British scientific contribution to ODP will also be missed. Britain, for its part, would lose its influence on the committees that plan the cruises of *JOIDES Resolution*. This is likely to cause problems for the independent British Antarctic Survey, which has planned its own work on the assumption that Britain would be a member of ODP and so able to participate in an Antarctic drilling cruise in the Weddell Sea.

Despite JOIDES' firm opposition to part membership for Britain, there are hopes that a consortium of European Science Foundation members may join in partnership with Australia. Britain, still out in the cold, has sought temporary observer membership status like that now enjoyed by Japan, and it seems likely that JOIDES will approve this request. But JOIDES is adamant that observer memberships will not be allowed to continue beyond the end of September. **Tim Beardsley**

The sweet smell of success

Tokyo

BIOTECHNOLOGY may not yet be making much of a return for US venture capitalists, but in Japan it is aleady selling cosmetics just as fast as they can be put on the shelves. Recently launched and already a huge success is cosmetic manufacturers Kanebo's "Bio series" of lipsticks, eye shadow, powder and so on.

What puts the "bio" in the series is that the pigment shiokonin used in the cosmetics, is obtained by large-scale plant cell culture. Until now shiokonin has been extracted from the naturally grown roots of the plant gromwell. But in the new process, gromwell root cells are cultured in 750-litre bioreactors and the pigment recovered from solution (see *Nature* 307, 504; 1984). Interestingly, the scientists who developed plant cell culture at Mitsui Petrochemical Industries had not originally been aiming at the cosmetics market at all. Only when they found that they had developed a working system were they forced to try to find a good product to make with it — cosmetics was one of the last things they hit on. Kanebo is now trying to build on this unexpected success

and claims to have succeeded for the first time in culture of tissue from leaves and stems of aromatic geranium. "Bio" perfumes may thus be just around the corner.

The main impetus behind the increased sales of "bio" products — running at three quarters of a million lipsticks a month and outpacing supply — seems to be the allure of "biotechnology" rather than any major improvement in the product. Other Japanese cosmetics manufacturers are now scrambling to join the bandwagon and find their own products. Alun Anderson

Alternative energy

Fuels from the farm

Venice

RESEARCH in the European Community to produce ethanol fuels from biomass is to be stepped up; this may help to solve the problem of agricultural surpluses and the need for a new fuel blend policy as lead is phased out of fuel, and exhaust emissions are further reduced in the European Community (see *Nature* 28 March, p.304).

The problem of surpluses has injected new urgency in the eight-year-old research proposal, which forms part of a broad high-level Commission strategy by farm commissioner Frans Andriessen. According to Dr Strub, general director of the Commission's solar energy division, now there is the political will the research will form an important part of the Community's biomass policy, which has been allocated research funds of 20 million ECU (European Currency Units) for a four-year period.

While farm ministers last week battled over price reductions to stem agricultural overproduction, particularly in cereals, there were signs of a consensus between research, industry and the farm lobby at a European Commission-sponsored meeting on biomass in Venice. According to Madron Seligmann, a British Member of the European Parliament, one hectare of land can produce four tonnes of ethanol and one tonne of biomass each year. The nine million hectares (of the Community's 150 million hectares of agricultural land) that grow surpluses could produce 32 million tonnes of ethanol every year. The 8 million tonnes of cereal surpluses alone represents 2 million tonnes of ethanol or 1.6 million tonnes of butanol-acetone.

The cost of getting rid of Community surpluses is estimated at 7,000 million ECU. According to Professor Andre Giraud (former French industry and energy minister and initiator of the French biomass and nuclear programmes), the Community would actually spend less by encouraging biomass production from surpluses than by subsidizing them, which could be done by a gradually declining system of incentives, and closer cooperation between agriculture and industry.

The need for a new European fuel blend policy has become more pressing as Europe prepares for lead-free petrol distribution in 1989 and stricter vehicle emission controls from 1988 as a result of the decisions by environment ministers on 20 March. Oxygenated products such as ethanol, methanol, acetone and butanol are already used to enhance the octane rating of some 60 per cent of fuel sold in West Germany, which conforms to the stricter Community standard of lead content of 0.15 grams per litre. These fuels may be suitable for the lean-burn engines due shortly. **Anna Lubinska**

Nuclear waste

Dump it here, please

THE British nuclear waste disposal agency, NIREX, is facing vocal opposition almost everywhere in Britain to its search for a new low and intermediate level disposal site. But its French equivalent, ANDRA, has had ten enquiries from the mayors of villages in central France inviting it to put its next site in their backyard.

The only problem is that although the French mayors are keen, for reasons of local development and employment, many of their people are not — for fear of the waste. Thus at one site, the village of Neuvy-le-roi near Tours on the Loire, the mayor was strongly in favour of ANDRA disposing low and intermediate level waste in the clay subsoil nearby, but his 1,000 villagers mounted a campaign against him. The mayor called a referendum: 63 per cent said no, and ANDRA has now dropped Neuvy-le-roi from its list.

However, still on the ANDRA list is Cholet, a town of 60,000 inhabitants south of Nantes and Angers, also near the Loire. Here the mayor is described as "very active" in attracting industry and employment, and the opposition is milder. "The behaviour at Cholet is very different from Neuvy-le-roi" said an ANDRA spokesman. The opponents there "are people you can argue with".

One of the arguments is money. The French government, unlike the British, offers local authorities concerned with potential nuclear sites both cash incentives and cut-price electricity. Thus Cholet stands to gain FF 30 million (£3 million) as a gift for housing and road improvements, and up to FF 1.5 million (£150,000) a year off local electricity bills, if ANDRA chooses it as a disposal site.

In Britain, however, the one named site — at Elstow near Bedford north of London — has met enormous opposition. Bedfordshire County Council has declared the area a "nuclear free zone" and written to the Secretary of State for the Environment, Patrick Jenkin, in strong terms, claiming Elstow "totally unsuitable as a site for a nuclear waste repository". Tempers rose further when the British government decided to allow NIREX to investigate the site by means of a "special development order" — a stratagem which avoids the need for a public inquiry.

The reaction to this British stick was perhaps predictable. The French style, offering a carrot, might have worked better, according to a study made for NIREX by Professor Terrence Lee of the University of Surrey. His survey figures show that 48 per cent of Britons would like monetary compensation (but paid to individuals rather than the council) for the building of a nuclear waste repository nearby, and a further 36 per cent would like compensation paid to the council for community benefit or some similar support — making a total of 84 per cent who say they could be bought off.

Robert Walgate.

Maritime museum plan scuttled

THE *Vityaz*, formerly the pride of the Soviet research fleet, which completed her last voyage in April 1979, is now anchored, a near-derelict with peeling paint and rotting woodwork, off Kaliningrad, *Pravda* reported recently. Plans to turn her into a floating museum have become bogged down in bureaucracy despite backing from ministerial and state bodies.

***Vityaz*, launched in April 1949, and the third Soviet vessel of her name (meaning "hero" or "champion"), spent most of her working life in the Pacific, carrying geological, ichthyological and meteorological expeditions. Her last, 65th voyage, however, ended with a triumphal tour of the major maritime states, including Italy, France, Spain, Portugal, the United Kingdom and Denmark, before she finally dropped anchor in Kaliningrad. It was originally hoped that the ship could go by canal to Moscow and a future as a museum. In the end, however, it was decided to leave her in Kaliningrad, the major fishing and commercial port of the Soviet Baltic coast. There was talk of a "Museum of the World Ocean" in the centre of the city, on the banks of the canal, with *Vityaz* as the prime exhibit.**

But then, in the words of *Pravda*, "it all turned out strangely". *Vityaz*, which had successfully weathered hundreds of thousands of miles of ocean voyaging, somehow became stuck fast when it came to completing the last few metres to her final berth. Now, almost six years after the *Vityaz* dropped anchor in Kaliningrad, only about half the money needed even for the minimum cosmetic refit is available in Kaliningrad. Money has, however, been spent on other things. A special harbour wall for the "memorial ship" has been erected, two smallish pre-war buildings have been renovated for the planned museum, and the surrounding terrain has been artistically laid out. According to the regional Communist Party secretaries, Yu Malakin and P. Kaz'min, public opinion in Kaliningrad still supports the idea of the ship museum, but someone has to make the official decision to build the museum complex. Once it is built, says Mr A. Shkurko, Deputy Minister of Culture of the Russian SFSR, his ministry will be delighted to take it over as a branch of the provincial museum of local history. No one, however, seems willing to assume responsibility for the decision to build.

Vera Rich

Indian science

Gandhi backs research

New Delhi

THE government headed by Rajiv Gandhi, who has pledged to prepare India for the twenty-first century, has allocated the equivalent in rupees of £900 million, or about six per cent of the government's budget for 1985-86, for scientific research and development.

The allocation for science represents only a marginal increase over that for the previous year but it is significant for its emphasis on research and development in non-conventional energy sources, biotechnology, high-power lasers and thermonuclear fusion.

As in earlier years, the lion's share of the budget goes to the Department of Atomic Energy (DAE), which is to set up a new centre for advanced technology at Indore, in Madhya Pradesh. Besides housing a new facility for plasma research, the centre will develop lasers for isotope separation and high power niodymium-glass lasers for laser-induced fusion. DAE also intends to set up a synchrotron radiation source, build superconducting magnets for its heavy-ion accelerator and establish a medical cyclotron for producing short-lived positron-emitting isotopes and radioactively labelled pharmaceutical preparations.

Budget allocations by sector (£ million)

Department of Atomic Energy	£210.0
Space	133.0
Industrial research	114.4
Defence research	104.0
Non-conventional energy	65.0
Agricultural research	55.5
Electronics	78.0
Oceanography	20.7
Meteorology	27.0
Other	93.0
Total	900.6

The Department of Ocean Development (DOD), which has assessed India's ocean thermal energy conversion (OTEC) potential at 50,000 MW, is planning to begin work this year on a 1-MW OTEC plant on the island of Lakshadweep. DOD will also place an order for an ice-breaker, estimated to cost £30 million, for undertaking expeditions to Antarctica. Previous expeditions were made in vessels chartered from Norway.

Electronics and biotechnology have been singled out as frontier areas. The government has abolished excise duty on computers and drastically reduced customs duty on their import. The Department of Electronics will launch this year a project to design a "fifth generation superminicomputer incorporating inference and knowledge based management functions". The Ministry of Science and Technology has earmarked a sum of £5 million for a biotechnology centre in New Delhi, its con-

tribution to the UNIDO plan for twin international centres for genetic engineering and biotechnology at Trieste, Italy and in New Delhi.

The Department of Environment has allocated funds for setting up a chain of botanical gardens for building a germplasm bank of economic plants, and seed and pollen banks for the conservation of threatened species. The department will also initiate this year a five-year £180-million programme to clean up the polluted river Ganges.

The Department of Space, which gets the second biggest share in the budget, plans to set up five regional remote sensing service centres to facilitate use of aircraft and satellite-sensed data and to provide trained manpower. Images received from Landsat will be augmented with data to be obtained from the French SPOT satellite. The space department will also start work on a new launch-pad for orbiting satellites in polar orbits. The polar launch station is expected to become operational in 1992.

K.S. Jayaraman

UK embryo research

Voluntary authority set up

THE British Medical Research Council (MRC), in association with the Royal College of Obstetricians and Gynaecologists (RCOG), last week replied to the government's inquiry into human fertilization and embryology (the Warnock report). MRC endorses the inquiry's recommendation for a licensing authority for research in these fields, and, recognizing that legislation will take some time, has set up a voluntary licensing authority under the chairmanship of Dame Mary Donaldson and consisting of MRC and RCOG scientists and doctors as well as lay members. The authority would both license experiments and draw up a code of practice. Although agreeing with the Warnock committee's 14-day limit on experimentation on embryos, MRC prefers that the limit be set in terms of stage of embryo development rather than days after fertilization, because of variations in the rates of growth between embryos.

MRC also seeks to address wider issues than those covered by the Warnock report: to define the term "embryo" (a viable conceptus developed from a fertilized egg and not tissue or cell cultures) and that "research" should include "new and untried treatment", a concept excluded in the Warnock report.

Human embryo research was not financially supported at all by MRC before the first British "test-tube" baby was born. Since then, MRC has recognized that research can improve understanding of infertility, may prevent some inherited diseases and congenital abnormalities and may produce safer contraceptive methods. Possible lines of research include:

- Finding the best culture conditions for egg maturation, of help to people suffering recurrent miscarriages after normal conception.
- Tests on defective sperm function, involving egg penetration and subsequent limited development of the fertilized egg. (Up to 50 per cent of human infertility is due partly to male-related disorders.)
- Some 60 per cent of eggs fertilized *in vivo* do not develop beyond implantation because of fetal abnormalities and unknown factors.
- Some congenital abnormalities (for example, Down's syndrome, spina bifida) probably occur during sperm and egg development.
- Better understanding of the development of chromosomal abnormalities.
- Investigation of infertility caused by production of antibodies to sperm in some women. Such research could lead to a contraceptive vaccine.

The MRC/RCOG report is one of many being submitted to the government. Eventually, legislation will result. But if the Powell bill (see *Nature* 21 February 1985, pp. 612 and 618) becomes law, considered reports such as the MRC statement will be so much wasted paper, for all research and development involving human embryos will be illegal. Techniques such as GIFT (gamete intrafallopian transfer), developed in Texas, where an unfertilized egg is removed from the ovary and immediately transferred to the fallopian tube where it can then be fertilized, would never be developed with such a bill operating. Later this month the first such baby will be born in Britain.

Hazardous chemicals

Congress acts on clean air

Washington

IN the wake of the Bhopal disaster, pressure is mounting in the United States to enforce new limits on emissions of toxic substances from chemical plants.

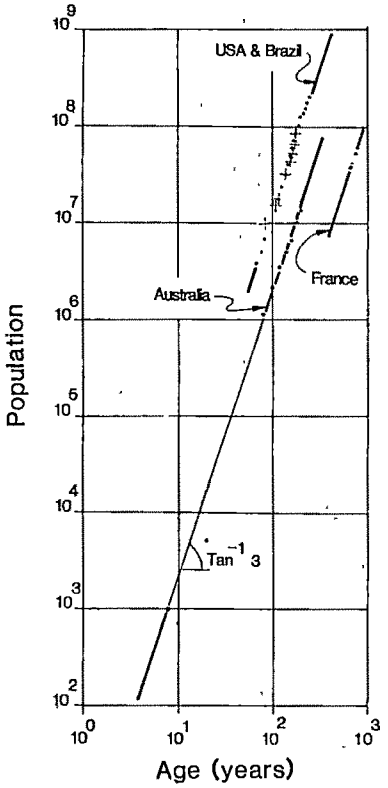
The effort has been given a recent impetus by a series of revelations from Union Carbide (which operates a methyl isocyanate plant in West Virginia) and other chemical manufacturers concerning accidental and routine venting of hazardous substances. In responding to a survey conducted by the subcommittee on health and the environment under the chairmanship of Representative Henry Waxman (Democrat, California), 67 chemical companies acknowledged venting a total of some 204 chemical substances that the companies themselves identified as "hazardous". Many of the companies had been reluctant in the past to provide this data; Waxman approached the companies directly after discovering that the Environmental Protection Agency (EPA) had failed to collect this information in connection with its existing programme of regulating hazardous air pollutants.

The subcommittee is still analysing the data and will not release a complete report for several weeks. But a preliminary survey shows that at least a few plants emit surprisingly large quantities of hazardous substances. Borg Warner, for example, reported that one of its plants in West Virginia releases some 8,000 pounds of acrylonitrile, a known human carcinogen, into the air each day.

The subcommittee also found striking variations in emissions between similar plants run by different companies, and even between plants in different states run by the same company.

Under current EPA regulations, only five chemicals are controlled as hazardous air pollutants: vinyl chloride, benzene, asbestos, beryllium and mercury. Congress's environment committees have complained for years about EPA foot-dragging; EPA has listed 27 substances as "suspected hazards" but has not yet decided whether to issue control regulations. Although the legislative history of the 1970 clean air act shows that Congress expected EPA to consider regulating at least 12 specific substances (including chlorine gas, hydrochloric acid, several heavy metals, pesticides and radioactive compounds), the law itself gives the agency broad discretion to decide what constitutes a hazardous air pollutant and what action to take to limit release of pollutants into the atmosphere.

EPA has further provoked Congress by recently proposing a relaxation of controls on emissions of vinyl chloride, a known human carcinogen. Under existing rules, plants that produce vinyl chloride may only vent the chemical through relief valves under emergency conditions. Each time a venting occurs, EPA investigates the incident to determine if it could have been prevented; if it was preventable, the company is subject to civil or criminal penalties. Yet EPA records show that "emergency" venting of vinyl chloride is almost routine; one million pounds was released into the air during the period 1977-80. EPA is now proposing to recognize the fact by allowing each plant four to seven "free" ventings per year; EPA would no longer investigate each incident.



Waxman's subcommittee is working on a bill that would require EPA to produce regulations on a specific list of chemicals and with deadlines incorporated into the legislation. Similar efforts (albeit milder) have been passed by various subsets of Congress as part of proposed revisions of the clean air act, but always to die as the act itself founders on unresolved differences over other issues, notably acid rain controls. Waxman will try to have his bill considered as a separate piece of legislation, not tied to the clean air act.

Stephen Budiansky

Population growth

SIR — The literature, both popular and specialist, often refers to population growth rates as exponential. More often than not this implies merely a rapid rate of increase and not necessarily its proper meaning of a fixed proportional increase in a set timespan. For example, reference to almost any long-term demographic time series shows that the expansion is not truly exponential as it does not result in a straight line on a graph of the logarithm of population against time.

Now let us explore an alternative expansion rate — according to the cube of time since the modern nation was born. Australia is a nation for which the demographic record is known fairly precisely for the non-aboriginal population since its birth in the 1780s, about 200 years ago. There is thus very little flexibility to be tolerated on the birth date of the nation and retrospective analysis

leads to the initial date of 1780 from the application of this hypothesis to Australian population data[1]. In fact, that population generated from the "dumping" there a few years later of several hundred largely undesirable British citizens. The relation shown in the figure for Australia exhibits a general slope of gradient 3, that is, it represents an expansion according to the cube of time on this double logarithmic plot. The only anomalies are in the very early years when the embryonic settlement was subject to reduction by disease in the exotic environment and in the mid-nineteenth century when a gold rush generated an unnatural influx.

Encouraged by the well-documented Australian example, we might explore others. The figure shows similar relations for data from France[2], United States[3] and Brazil[4] from which it can be concluded that these nations began in the sense of a modern society in 1233, 1724 and 1783 respectively. Historians may care to comment on events that could justify that conclusion.

In the meantime, it seems appropriate to draw attention to the far more accurate demographic projections available from this model than from the variably time-dependent exponential expansion models commonly found in the literature. The reader can test this conclusion by exploring, say, the 50-year forecasts that would have been made at decadal intervals over the past century or so using both this cubic expansion and any exponential model. The results are most encouraging and promise much for demographic planning.

Viscosity, noses and IQ

SIR — P.M. Gaylarde's assertion (*Nature* **313**, 425; 1985) that I speculated "that the shape of a person's nose determines his IQ" is both offensive and inaccurate. In fact, what Gaylarde interpreted as an "attempt to establish spurious grounds for white supremacy" in a manner "as unsavoury as those...used to justify the extermination of Jews and Gypsies in Hitler's Germany", was, both in intent and content, exactly the opposite. I urge readers who saw only Gaylarde's response to read what I wrote before passing judgement (*Nature* **311**, 515; 1984).

It is true, as Gaylarde states, that "the viscosity of moist air is less than that of dry air", but the relevant comparison is between the cool dry air of temperate zones and the hot humid air of the tropics. Unlike liquids, gases gain viscosity with increases in temperature, and that gain more than offsets the reduction from increased humidity. For example, air going from 0 to 40°C and simultaneously from dry to saturated (maximizing the effect of humidity), gains about 20 micropoises of viscosity as a result of increased temperature[1] while it loses about two micropoises of viscosity from increased humidity[2] — a net gain of 18. Gaylarde is also wrong to think that nose shape, length and hairiness have little effect on airway resistance[3]. If the length of a tube is doubled, pressure must be increased twofold to maintain constant flow, and if the radius of a tube is halved, pressure must be increased an additional sixteenfold to maintain flow — a 32-fold increase. Add the fact that saturated hot air (say 40°C) contains less oxygen (about 7 per cent less), and one can begin to appreciate the value of a short wide hairless nose in hot humid climates.

But the brunt of my nose argument, the entirety of which was not essential to my point, was that it might be disadvantageous not to have a dust-trapping nose in dusty environments. In support of this speculation I pointed out that "among American racial and ethnic groups, only blacks and non-Japanese orientals have a conspicuous prevalence of lung disease". I agree with Gaylarde that lung disease "is related to socioeconomic factors", but its relative inconspicuousness in hispanics leaves my point intact.

The objective of my contribution was to explain the fact that heritable differences in IQ need not be attributed to differences in "IQ genes", and I have argued that any heritable difference in IQ between races is especially unlikely to be caused by such genes[4]. My point was that adaptations taken out of their evolutionary context (such as pale thin skin and long, thin, hairy noses in the tropics) are liable to be disadvantageous and could have an incidental effect on IQ. I pleaded that such questions should be investigated because "there are many factors that something could be done about if we knew what they were", for example, "people with non-dust-trapping noses can have humidifiers in their homes during the winter and take care to wear a dust-mask when doing a dusty job". And I lamented the fact that "looking for genetic differences that incidentally affect IQ is politically unacceptable". Gaylarde has proven me right in this last regard.

Misrepresentation of facts, misreading, an astounding failure to comprehend and knee-jerk reply aside, as the son and nephew of men who fought against Hitler's Germany, and as one who grew up in a home where racists, anti-semites and fascists were clearly "the enemy", I resent Gaylarde's ludicrous insinuations.

The importance of impatience

Unifying gravity with the other three fundamental forces has been brought a large step nearer. But there is a long way still to go.

IN a week in which there appears in *Nature* an account of a theoretical framework that may be the best hope yet that theories of particle physics will be united with gravitation, a reminder of how frustrating this problem has become may be in order. The point is nicely illustrated by Dr C. Villi of the University of Padua in the latest issue of *Il Nuevo Cimento* (85A, 175; 1985).

Villi's interest is simple, to explore the question whether the mathematical infinities that have plagued the calculation of particle properties, and which persist, are merely consequences of leaving gravitation out of the calculations. For, as he puts it, "the most significant aspect of the divergences encountered in quantum field theory is that they do not exist in Nature". His method is straightforward: to suppose that true curved space-time is everywhere approximated by flat Minkowski space-time, essentially that of special relativity, from which it follows that the function which defines the approximation at each point of space-time (the form factor) must satisfy Einstein's equation of gravitation.

At this point, another of Villi's discontents comes to the surface. Soon after Einstein first formulated his equations of gravitation (in 1917), he confused the issue by adding to the simplest form admissible on the grounds of geometrical consistency an extra term containing a constant, the gravitational constant. Equations with this extra term are consistent with the physical arguments leading to general relativity, while the presence of the constant made it possible to construct a finite universe containing a uniform distribution of matter whose density was not identically zero.

Villi is scornful of the way the cosmological constant has been dealt with ever since. It is agreed that it must be numerically small, but is it right to follow Pauli (and Einstein's second thoughts) in dropping it altogether? Villi is in no doubt "No efforts have been made to understand the *raison d'etre* [of the cosmological constant] This is indeed astonishing because its cosmological significance is purely accidental... the parameter would appear in Einstein's equations even if cosmology had never been thought of."

Villi's objective is to show that the cosmological constant can somehow smooth out (with the help of his form factor) the infinities that arise in the calculation of particle properties. Although accepting that the constant is numerically small for large-scale phenomena, he would have it very large on the scale of particle phenomena.

There are precedents for this line of thinking. One way of making a connection, however tenuous, between gravitational and particle phenomena is to remark that the bending of distant starlight at the limb of the Sun (one of the three accepted tests of general relativity) could otherwise be accounted for if the refractive index of the vacuum were different from unity, which may in turn be explained if the vacuum is polarizable. Villi notes that all attempts to forge such connections have been defeated by objections of doubtful weight.

"In surveying this matter, one is oppressed not only by objective difficulties, but by arguments open to serious doubts and by unnatural assumptions which breed confusion and scepticism. Too many dissertations based on unfruitful and controversial theoretical subtleties have contributed to shattering the problem of the role played by gravity in the subnuclear universe into fragmentary aspects generally contradicting each other . we shall pursue a different line of thought . to overcome the apparent irreconcilability of general relativity with quantum field theory, a dilemma that may provide the seed for a radical rethinking of some physical concepts and of the theoretical schemes developed."

Fighting talk? Villi confesses that he cannot at this stage provide the general prescription that his programme requires, but goes on to give some telling if particular examples. The form-factor way of regarding space-time as locally flat does get rid of some of the infinities arising in solutions of the Kelin-Gordon equation, for practical purposes the generalization of the wave equation for photons to particles with non-zero mass and spin. He thinks it important to tackle the problem in the way in which Feynman first made quantum electrodynamics respectable, by the "path-integral" method, but only after this statement:

"I confess my inability of profiting heuristically from the jungle of theoretical approaches invented in order to transpose to general relativity Feynman's methodology It is difficult to see a way out of such a puzzle, not only because there are conceptual black corners still unexplored, but also because one does not know how to evaluate the formulae thus obtained, nor how to give them a mathematically precise meaning " And, having translated Feynman into general relativity which, Villi warns, "is not very exciting", he has this stirring comment on the way in which field theorists get rid of their infinities.

The "daring manipulation of infinite quantities based on the killing of infinities by counter-infinities raises questions which indicate the need for a thorough revision of the renormalization theory . there remain inherent mathematical ambiguities in handling divergent expressions it is a challenging task to find a way towards an alternative formulation of quantum electrodynamics, free from the slaveries of renormalization "

Where does it all lead? Villi is in no doubt. The vacuum fluctuations beloved of particle physicists must endow empty space with what Einstein called an energy-momentum tensor that differs from zero, and the consequence must be a short-range "cosmological constant" that not merely differs from zero but is very large. And "this has nothing to do" with the large-scale cosmological constant related to the mass-density of the universe at large. Villi's other important general precept is that it may be an illusion on the part of the field theorists to look for a unification on equal terms of the four fundamental forces (strong and weak nuclear interactions, electromagnetism and gravity). Perhaps, he says, gravity always enters on a qualitatively different footing, and should be handled differently from the start.

What M.B. Green (see p.409) has to say notwithstanding, Villi should not be scorned There is a natural temptation among those who construct theories to account for phenomena not previously well categorized to suppose that only one mathematical framework will accommodate the phenomena, and the trick is to find it. That is how it is at first, but time accretes other ways of solving these problems.

It is too soon for Green to have figured out whether what he has done (and what earlier users of Kaluza-Klein theories, in which redundant "internal" dimensions are collapsed onto ordinary space-time, have attempted) fulfils the objective of Einstein and his later collaborators (Infeld and Bohm, for example) to define the "hidden variables" that would make quantum mechanics determinate. For the time being, it is more important to win some physics from the mathematics. But Villi and his like will continue to be angry if they are forever fobbed off with the answer that their questions cannot be answered in the terms in which they are put. **John Maddox**

Halley's comet

Prospects for Giotto and Halley

from M.K. Wallis

AT the final pre-launch preview*, scientists involved in the Giotto mission to Halley's comet concluded that the risk to the spacecraft from dust particle impacts (see *Nature* **303**, 659; 1983 and **305**, 756; 1983; *ESA J.* **7**, 15; 1983; *Earth, Moon Planets* **30**, 31; 1984) is considerably less than had been feared.

Initial pessimism had centred on the likelihood of impacts that would cause a deviation of Giotto's spin axis in excess of 1°, when radio contact would be lost. Although milligramme and smaller-sized grains impacting the protective shield will contribute to the deviation, it is now agreed that the original pessimism was based on an over-weighting of the rather improbable grains exceeding 0.1 g, which might anyway smash through the rear shield and destroy instrumentation.

Predictions of survival are based on predictions of the density and size-distribution of dust particles. The probability of survival against 1° perturbations is now given as around 90 per cent on the nominal dust model for a 500 km flyby distance, although calculations need extending to give a secure guide for future targeting decisions.

Much scientific effort has gone into elaborating models of the comet's dust coma; rather than assuming instantaneous formation, it is now agreed that dust grains can reside in the coma for weeks or even months, forming into anisotropic structures purely because of the comet's motion around the Sun. Model calculations at the NASA-Jet Propulsion Laboratory (JPL) have been extended to encompass long-lived dust grains and are now in agreement with an alternative analysis by ESOC scientists (Fertig, J. & Schwehm, G.H. *ESA Bull.* **38**, 36; 1984).

There has been concern about much higher dust densities in jet-like regions. JPL scientists (Sekanina, Z. & Larson, S.M., *Astr. J.* **89**, 1408; 1984) have applied digital image-enhancement techniques to photographs of comet Halley's 1910 apparition, and infer enhanced densities, some 10-100 times the mean. It is now accepted, however, that these would be of submicron size (like cigarette smoke) and present a desirable target rather than a threat to the spacecraft's integrity. Study of the jet phenomenon might, alternatively, indicate where to expect the dangerous, slowly-moving, millimetre-sized grains.

Originally, the mission was scheduled to terminate one hour after closest approach, supposing that the spacecraft is unlikely to survive. But there was pressure from experimenters at the meeting to retain transmission options for two days on the outward flight through the extensive gas coma.

The meeting heard that the Pathfinder concept agreed with the Soviet Space Agency is going ahead; data from the Soviet VEGA spacecraft will be used to cut down the error in targeting. If the two VEGAs are tracked by very long baseline radio-interferometry, the error should be under 100 km. Supplementary ground-based astrometry is also to be investigated.

The reserve of one month in the original schedule has now been used up, with final instrument acceptance checks due in late March. No significant problems have arisen on subsystems or experiments during the system test programme, although the spacecraft as a whole is hotter than predicted, requiring modifications to radiating surfaces. Assembly and final testing of the television camera is running late, so installation and checking procedures have been reorganized around it. One advantageous change to the original schedule gives scientists the option of integrating fully-calibrated versions of their experiments just before delivery of the spacecraft.

The planned launch campaign is due to commence at the beginning of May 1985 with an expected launch date of 2 July 1985 on an Ariane 1 vehicle from the European launch site at Kourou, French Guiana. The optimistic hopes of securing data on the inner coma and pictures of the nucleus from a few hundred kilometres seem likely to be achieved on the basis of this review. □

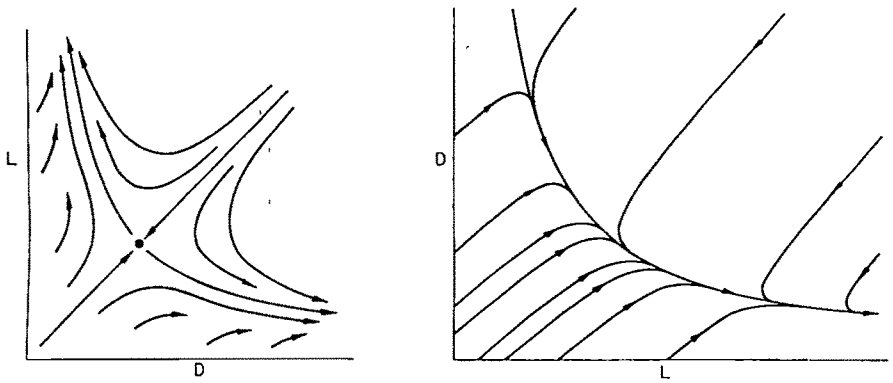
Chemical evolution

Origin of biomolecular chirality



from Stephen Mason

THEORIES accounting for the ubiquity of the L-amino acids and the D-sugars in the biochemistry of living organisms centre on mechanisms for the selection of enantiomers of one hand from the heterochiral mixture of a racemic substrate, and for the propagation of optically pure homochiral products. Surprised to learn, in 1953, that the origin of biomolecular handedness still appeared to be problematic, Frank proposed a homogeneous chemical kinetic mechanism for an open flow-reactor system[1]. The mechanism contained no internal bias, and the dominance of the L-amino acids and the D-sugars in the natural products, rather than their respective enantiomers, seemed to be wholly a matter of chance. By extending the mechanism and incorporating a recently evaluated internal bias, Kondepudi and Nelson[2] now define the particular conditions under which a small electroweak advantage factor for the L-series of amino acids and polypeptides[3] leads to a determinate choice in the evolution of homochiral biomolecules from an achiral or racemic substrate.

Frank's model avoided the direct intervention of external agencies, such as a chiral field or panspermatic celestial seeding, and the various heterogeneous mechanisms advocated in the grand debate on the subject in the correspondence columns of *Nature* during 1898 following F.R. Japp's paper on "Stereochemistry and Vitalism"[4]. Ironically, that correspondence ignored the 1884 conjecture of Pasteur that a dissymetric force pervades the physical world, extending even to the crystallization dish used for the separation of enantiomers. The discovery, in 1956, of the non-conservation of mirror-image symmetry in the weak nuclear interaction supported Pasteur's surmise, and the subsequent unification with electromagnetism has allowed the characterization of both the sign and the magnitude of the universal chiral electroweak interaction. The sign is in accord with the observed products of natural selection. The L-amino acids and the L-polypeptides are more stable than their D-enantiomers. But the advantage ratio of the electroweak enantiomeric energy difference (ΔE_{ew}) to the thermal energy (kT) at ambient temperature is only about 10^{-17} (ref.3), too small according to one school of thought[5] to affect the outcome of biochemical evolution.

Frank envisaged an open reactor system with a continuous input of an achiral substrate from which both enantiomers, L and D, are formed (see figure). Each of the optical isomers autocatalyses its own production and competitively inhibits propagation of its enantiomer. In general, the dynamic generation of a racemic product is metastable and subject to a bifurcation catastrophe. Chance fluctuations sooner or later trigger a kinetic switch to one of the homochiral reaction channels, producing either the L-isomer or the D-enantiomer. Which is produced, in the absence of an internal bias or an external perturbation, depends on the sign of the chance fluctuation[1].

The general solution to the kinetic relationships of the extended mechanism is shown to be a cubic equation in the enantiomeric excess of the handed products, $(\alpha/\beta = ([L] - [D])/([L] + [D])$, where [L]

The time evolution of L and D enantiomers from an achiral or racemic substrate in an open flow-reactor system, with an autocatalytic production of each isomer and an enantiomeric cross-inhibition: left, for identical values of the activation parameters of corresponding enantiomeric intermediates and right, for a small bias favouring the production of the L-isomer. Metastable racemic production is represented by the unique point in the left hand graph, to which either an achiral or a racemic substrate leads, and from which the two homochiral production branches diverge. Modified from reference 1.

and [D] refer to the concentrations of the enantiomers[2]. One root of the cubic equation, correlating with a small input concentration of the substrate into the flow-reactor system, corresponds to a vanishing enantiomeric excess, $(\alpha/\beta) = 0$, giving a racemic product. The other two roots ($\alpha/\beta = +1$ or -1) correlate with high substrate input concentrations, and correspond to the two homochiral reaction branches, giving only the L-isomer or the D-enantiomer. At the transition point, where the racemic production process becomes metastable and bifurcates into the oppositely handed reaction channels, the system develops a magnified hypersensitivity to minor inequalities between the activation parameters of corresponding enantiomeric intermediates in the two homochiral reaction branches. Thermal fluctuations at the temperature, T, of the system randomize and annul any initial trend towards the D or the L production branch unless the difference in activation energy, ΔE, between the enantiomeric intermediates satisfies the relationship $(\Delta E/kT) > 10^{-17}$ (ref.2).

At ambient temperature, the electroweak advantage ratio for the L-series of amino acids and polypeptides, $(\Delta E_{ew}/kT)$, meets the lower limit of the relationship, so that selection of the reaction branch for the L-series becomes determinate over a limited range of conditions. With realistic rate constants for the elementary kinetic stages of the model mechanism, the homochiral reaction branch for the L-series is selected with a 98 per cent probability if the passage through the critical hypersensitive transitional bifurcation state is slow. Over 10^4 years this would correspond to an increase in the input concentration of the substrate by 10^{-2} to 10^{-3} moles in a flow reactor with the volume of a small lake, approximately one kilometre in diameter and some four metres deep. This estimate takes into account quantifiable disordering effects, such as the known rates of spontaneous racemization of the amino-acid enantiomers, and the minor enantionmeric photodiscrimination of solar radiation at twilight, when there is a small net circular polarization, oppositely handed at dawn and dusk[2]. □

Cell biology

Baseless flagellation

from Jeremy S. Hyams

COMPARED with its enigmatic alter ego, the centriole, the basal body is a fairly straightforward organelle. Basal bodies sit, appropriately, on the base of eukaryotic cilia and flagella. Unlike the structures associated with the base of bacterial flagella, they are not actively involved in motility. Rather, they provide the template for the assembly of the 9+2 axoneme and, through their association with various rootless structures, anchor the beating cilium or flagellum against the generated torque. This rather comfortable view of basal body function may, however, have to be re-examined in view of a paper by H.J. Hoops and G.B. Witman on the green alga *Chlorogonium*[1].

In design, the flagellar apparatus of *Chlorogonium* resembles that of its better studied relative *Chlamydomonas*[2]. The two flagella arise from the anterior of the cell in a 'V' configuration. The basal bodies which from the crotch of the V are maintained by a group of striated fibres and serve as the focus for a series of microtubule rootlets that head off towards the cell's posterior. During forward swimming the two flagella sweep away from each other in a motion which, superficially at least, resembles a human swimmer's breast stroke. Unlike *Chlamydomonas*, where the flagella are resorbed before mitosis, *Chlorogonium* contrives to swim during cell division, the parental flagella remaining attached to the anterior-most daughter cell. Electron microscopy of these dividing cells reveals that the basal-body complex detaches from the flagella to become associated with the poles of the spindle.

Remarkably, not only do the flagella continue to beat in the complete absence of their basal apparatus but the cells still exhibit their normal photophobic and phototactic responses. In *Chlamydomonas*, these responses involve distinct changes in the pattern of flagella beating. During the photophobic response the flagella switch from the asymmetrical ciliary mode used during forward swimming to a symmetrical flagellar waveform that drives the cells backwards[3]. Phototaxis, on the other hand, involves the inactivation of one flagellum whilst its partner continues to beat, causing the cell to turn[4].

Experiments on detergent extracts of either isolated flagella or whole cells have shown that both responses are mediated by calcium ions[4-6]. A rise above 10^{-6} M in the intracellular concentration of calcium triggers the photophobic reaction[6,7], whilst a differential response of the two flagella to submicromolar levels of calcium probably underlies phototaxis. The two flagella of *Chlamydomonas* can be distinguished on the basis of their position relative to the asymmetrically positioned eyespot. The flagellum furthest from the eyespot is inactivated below 10^{-8} M calcium whilst the other flagellum continues to beat. Conversely, the flagellum closest to the eyespot is inactivated by 10^{-7} - 10^{-6} M calcium whilst the other flagellum remains active.

By obtaining similar results with dividing *Chlorogonium* cells, Hoops and Witman show that the complex behavioural responses of green algae are intrinsic to the flagella themselves and independent of accessory structures associated with the flagellar base. Taken together with the recent identification of a rhodopsin in *Chlamydomonas*[8,9], these new findings suggest that our understanding of tactic responses of eukaryotic microorganisms may soon approach the sophistication of equivalent studies on prokaryotes. □

Astronomy

Direct estimate of Hubble's constant from the double quasar

from C. Martin Gaskell

DETERMINATION of the time delay between observed variations in the two images of the first gravitationally lensed quasar to be discovered (0957+561 or 'the double quasar') has enabled Hubble's constant (H_0) to be estimated directly[1]. This way of measuring H_0 short-circuits the many intermediate steps in 'classical' estimations but, unfortunately, is very model dependent.

The double quasar was discovered by D. Walsh, R.F. Carswell and R.J. Weymann as a pair of quasars, 6 arcseconds apart, with virtually identical spectra[2]. Subsequent research verified their initial guess that these two images come from one and the same quasar: the gravity of a galaxy in the line of observation is bending the light and producing two images of the more distant quasar[3]. Long before this system was discovered it had been pointed out that variability of a gravitationally lensed object would allow an estimate of the distances involved and hence of H_0, the constant that relates the velocity of recession of the galaxy or quasar to its distance ($1/H_0$ is the approximate age of the Universe)[4]. In essence, the method is simple: if the shape of the various light paths is known, then the time delay due to the difference in light travel time) between seeing a given variation in one image and the other, gives the scale size. (For the double quasar there are actually three images, but the third is very faint.)

Like virtually all quasars[5], 0957+561 was quickly shown to exhibit 'flickerings' in brightness (of 30 per cent or so) that last weeks or months[6]. Once that was known, a number of observatories mounted photometric monitoring programmes, and, while waiting for the results, theoreticians refined the model of the mass distribution in the 'lensing' galaxy and the cluster in which it is located[7,8]. The expectation was that variability of the northern image would precede variability of the southern image by a couple of years.

R. Florentin-Nielsen and K. Augustesen of Copenhagen University Observatory were among the observers following 0957+561. They took repeated photographs with a 20-inch Schmidt camera, a small telescope by modern standards, and in much poorer sky conditions than United States' observers, but with the advantage of being far enough north to follow the double quasar all year round. In early 1980, the southern image brightened while the northern one stayed constant; the southern image was presumably showing some event that could have been seen a year or two earlier in the northern image. Both images then stayed constant in brightness until 1982 when the northern image started to brighten by 30 per cent while the southern image stayed constant. In 1983, the northern image started to fade. There had been a clear 'event'. It was then just a matter of waiting until the southern image followed suit for an estimate of H_0 to be made. By July 1984 it was clear to Florentin-Nielsen that the long-awaited rise in the southern image had begun. In his recent paper[1], he estimates the time delay to be 1.55 ± 0.1 years and derives H_0 as 77 km s^{-1} Mpc^{-1} corresponding to a Hubble age ($1/H_0$) of 13 x 10^9 years.

How reliable is this estimate of H_0? The formal observational error is only ± 5 km s^{-1} Mpc^{-1}. Classical astronomical methods (for example, using Cepheid variable stars) currently yield H_0 values of 43–95 km s^{-1} Mpc^{-1}, and a recent review favours 68 or 82 km s^{-1} Mpc^{-1}, depending on the methods used. The latest work on type I supernovae[10] favours a value of 58 km s^{-1} Mpc^{-1}. The Florentin-Neilsen value is clearly well within the range under debate.

Within a year or two the observational uncertainty in the time lag should have been narrowed down by a factor of two or more. But the real uncertainty is greater. To calculate H_0, Florentin-Nielsen relies on detailed modelling by Borgeest and Refsdal[8] of the mass distribution in the lensing galaxy and the cluster that contains it. The question is whether Borgeest and Refsdal have correctly modelled the influence of the cluster on the estimate of H_0. They believe it is less influenced by the cluster parameters than had been feared by, for example, Dyer and Roeder[7], and that the effect of the cluster galaxies might be leading to a slight overestimate of H_0 from the double quasar. Nevertheless, it remains the largest source of error.

Fortunately, the free parameters in the mass distributions may soon be narrowed down by radio observations of very high spatial resolution that are underway. The models of the mass distributions will have to match the twisting and distortion seen in the radio structure. If they do, then there is some confidence that the time delays, and hence H_0, have been calculated correctly. Meanwhile, optical observers will be calmly continuing to follow the two images to ensure that the current outburst in the southern image really matches the 1982 – 3 record for the northern image. If not, some major rethinking will be necessary. □

Parasitology

Towards schistosomiasis vaccines

from F.E.G. Cox

SCHISTOSOMIASIS, one of the world's major diseases, is caused by adult worms that inhabit blood vessels associated with the lower intestine or bladder. The worms survive in these immunologically exposed sites largely because while migrating there as juveniles they acquire host-like surface antigens from the skin, where they enter the body. So effective is this disguise that it is not at all clear if there is any effective immunity in man [1]. Vaccines consisting of irradiated juvenile worms[2] have been the basis of successful field trials in cattle in the Sudan [3] and China[4] but are unlikely to be acceptable for human use. Therefore, several groups have investigated the potential of extracts of juvenile and adult worms. The results are disappointing, although some purified surface antigens have been used with limited success in mice and rats. The most recent study indicates that some protection can be induced in monkeys[5]. This is a major step forward.

Maire Smith and John Clegg, of the Wellcome Research Laboratories, have identified and purified two surface antigens associated with both juvenile and adult worms [5]. The larger molecule, given twice with alhydrogel adjuvant, induces partial protection both in mice and cynomolgus monkeys. The smaller antigen, which could be extracted from the adult worms only with difficulty, also protects mice. These results are promising in that antigens common to the surfaces of both juvenile and adult worms have some protective capacity, but disappointing in that the levels of protection are low and inconsistent. Nevertheless, they indicate that the approach of identifying and purifying surface antigens is worth pursuing. The next step is to clone the genes encoding these molecules, to express them and to test the products.

Although it is now possible to predict future directions of research, it would be

foolish to assume that all is now plain sailing. André Capron and his colleagues in Lille have shown that an IgG2a antibody is involved as a bridge between a schistosome surface antigen and the eosinophils that act as killer cells in the protection of rats against schistosomiasis[6]. More recently, however, they have shown that the same antigen can also elicit the production of an IgG2c antibody, which actually blocks the protective activity of the IgG2a[7]. In developing a vaccine based on purified antigens, therefore, it will be essential to ensure that the antibodies produced do not actually block some unrecognized protective mechanism. Similarly, care will have to be taken to ensure that a vaccine does not result in the death of the migrating juveniles in an unsuitable part of the body. In rats immunized with irradiated juveniles, the worms in the vaccine die in the skin or lungs, whereas those of a challenge infection die during migration from the lungs to the liver[8]. The dangers of the release of antigen in the lungs or liver are obvious, placing yet another constraint on the development of a vaccine.

The relative lack of success in vaccinating animals, especially primates, against schistosomiasis has led some workers to investigate less conventional methods, including the induction of non-specific immunity by the use of immunostimulants. Results obtained in baboons have been equivocal but do suggest that non-specific activators of macrophages and monocytes can provide some protection against schistosomiasis[9]. Overall, specific and non-specific immunization can at best only reduce the worm burden in the host to about half, which may be of advantage to the individual but not to the community, as it would have a negligible effect on transmission.

Some may argue that a vaccine against schistosomiasis is not really necessary because excellent drugs are available. But the first warnings have already been sounded that this situation may not last for long. Praziquantal is an extremely effective and safe drug, albeit somewhat expensive, but several serious side effects have been reported recently from a small community in Zaire[10] and it must be assumed that similar reports will be forthcoming from elsewhere. Both chemotherapy and vaccination have advantages and disadvantages. Ideally, a programme of schistosomiasis control would incorporate the best of both approaches, with health education and the use of molluscicides. □

Palaeontology

Outlines of the distant past

from Peter Gambles

THE dawn of life was also the dawn of death. Since the remote Precambrian, more than 3,500 million years ago, countless plants and animals have died, but only an incredibly small fraction have been preserved in the rocks as fossils. Yet it is this meagre record that charts the path of evolution.

Most people will be familiar with the more common forms of preservation, such as sea-shells in limestones or the great mineralized skeletons of dinosaurs in museums. Although palaeontologists can glean a lot of information from the morphology of these 'hard parts' of animals and from their tracks and marks (known as trace fossils), ideas concerning their appearance and behaviour when alive are difficult to substantiate. But every once in a geological while, circumstances combine to yield fossils with exquisitely preserved outlines of 'soft parts' — limbs and internal organs. Extraordinary fossil biotas of that type were the subject of a recent meeting at the Royal Society*.

Many of the specimens recovered are objects of (sometimes morbid) interest in their own right. The structure of the leg of a trilobite from the Burgess Shale (Fig. 1), which died 530 Myr ago, or the outlines of the feathers of *Archaeopteryx*, help relate these creatures to their modern counter parts. Other finds are so outlandish they can barely be classified (indeed, one has been called *Hallucigenia*).

Trace fossils of crawling animals, such as horse-shoe crabs, are not uncommon. But in the Solenhofen limestone (150 Myr) a dead animal is found at the end of the tracks. Elsewhere there are insects trapped in amber, mammoths in ice, even a mother ichthyosaur dead in childbirth. It seems that an essential requirement for this exceptional preservation is that the environment suddenly becomes inimical to life. This can happen when there is rapid deposition of a smothering blanket of mud on otherwise normal seafloors, or if creatures fall or are swept into an anoxic trap. The Burgess shale formed in such a trap at the base of a Cambrian reef.

Perhaps of even greater significance is the preservation of wholly soft-bodied organisms. About 70 per cent of modern biota is soft-bodied and S. Conway Morris (Cambridge University) asked whether this proportion has varied with time. Effectively no shells or exoskeletons have been preserved from before the so-called Cambrian evolutionary explosion. But detailed studies of the Cambrian Burgess Shale fauna suggest that there has been little change in the proportion of soft-bodied biota over the past 600 Myr. Put another way, more than two thirds of the original biota are not represented in most 'good' fossil localities, so any fossils of soft-bodies organisms may help fill large gaps in our understanding of the ecology of ancient environments. As an example, there has seemed to be a lack of predators in 'typical' shelly Cambrian faunas, which has led some workers to believe that the world was then a tamer place. But, according to Conway Morris, several soft-bodied organisms from the Shale look decidedly ferocious; their preserved gut contents identify them as predators.

*'Extraordinary fossil biotas: their ecological and evolutionary significance', Royal Society, London, 20-21 February 1985.

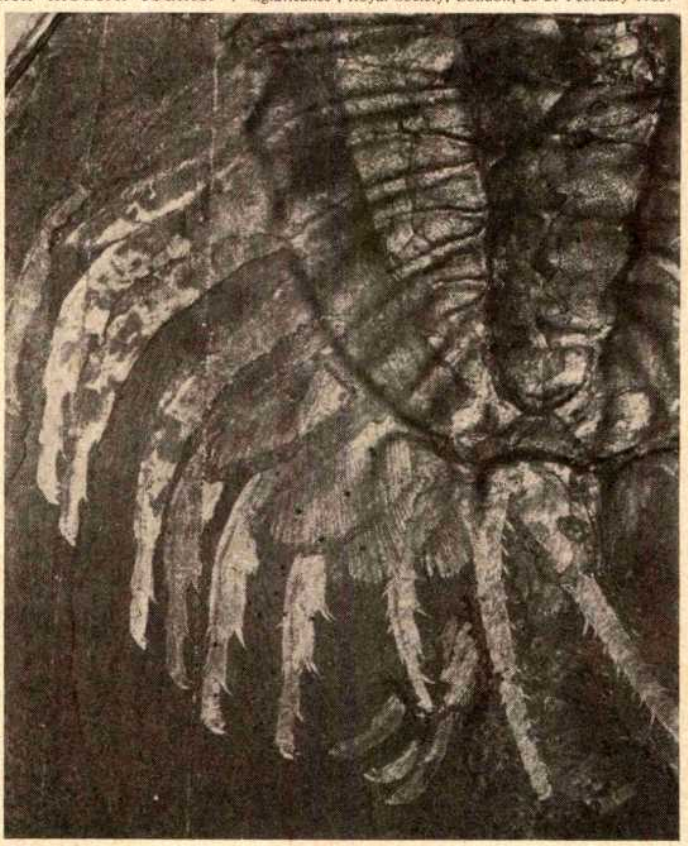

Fig. 1 The trilobite *Olenoides serratus* from the Burgess Shale, showing details of the legs and gills (H.B. Whittington, Cambridge University).

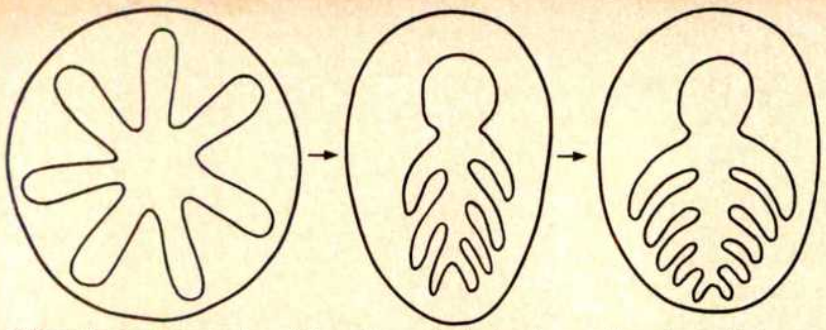

Fig. 2 Evolutionary progression of the metazoan bodyplan from odd-number radial symmetry through "glide reflection" to true bilateral symmetry (M. Fedonkin). See text for details.

A question that arises out of this reappraisal concerns the role of soft-bodied organisms in the evolutionary radiation of the early Cambrian. Many of the more enigmatic fossils seem to represent body plans that are not exhibited by any living creature. The present-day Metazoa (multicellular animals) are dominated by bilaterally symmetrical body plans, often with a degree of segmentation. The coelenterates, with concentric or radial symmetry, today constitute only a small part of the animal kingdom. But M. Fedonkin (USSR Academy of Sciences, Moscow), studying the soft-bodied biota from the Vendian (about 650 Myr) of the White Sea Russian Platform and polar Siberia, concludes that ≥ 70 per cent of animals were then radially or concentrically symmetrical; those with bilateral symmetry are often totally absent.

Some of the more bizarre forms exhibit radial symmetries that today are very rare or non-existent. Thus, an homogeneous group with primary 3-fold symmetry is recognized, and forms with 4- and 7-fold ordering are also common. A particularly important group, according to Fedonkin, is that in which the symmetry remains radial, but the order (number of arms, gastral cavities, and so forth) actually increases during growth. A possible insight into metazoan evolution comes from fossils such as the late Precambrian *Dickinsonia* which at first sight are bilaterally symmetrical but on closer examination have different numbers of segments on the left- and right-hand sides. Fedonkin terms this phenomenon "glide reflection" and believes that such forms would not be dynamically stable and so evolved to become properly bilateral. He envisages a major evolutionary pattern, recorded in the Vendian rocks, of a gradual change from the dominance of concentric and radial organization, through variable-order radial symmetry and glide reflection, to bilateral segmentation (Fig. 2). A. Seilacher (Universität Tübingen) and others dispute this view, finding no evidence that *Dickinsonia* had a mouth or a gut or any semblance of a metazoan digestive system. Consequently they believe such extraordinary fossils represent not the dawn of metazoans but perhaps a completely different kingdom. □

Nitrogen fixation

Differentiating cyanobacteria rearrange their *nif* genes

from William D.P. Stewart

CYANOBACTERIA (blue-green algae) are oxygenic photosynthetic prokaryotes, many strains of which fix N_2 and which probably dominated the Earth's biota during the middle Precambrian, 2,500–570 million years ago. On page 419 of this issue, J.W. Golden, S.J. Robinson and R. Haselkorn report that, despite their ancient origin, the N_2-fixing photosynthetic cyanobacteria possess a molecular complexity that belies their morphological simplicity[1].

Although long regarded as algae, mainly because of their pigment composition and mode of oxygenic photosynthesis, cyanobacteria are probably more akin to prokaryotic bacteria than to eukaryotic chlorophyllous plants, and are seldom still classified as blue-green algae. They are most noticeable in extreme environments, for example in parts of Antarctica where they may form 'algal peat', in hot desert regions including parts of the Sahel, on bare rock surfaces, in hot-spring regions and in living stromatolites. Cyanobacteria are also important components of the marine phytoplankton and they, or more probably their colourless analogues, are components of the microflora of the hydrothermal vent regions of the Galapagos Rift. In many parts of the world, but particularly in south-east Asia where fertilizer nitrogen is not readily available, cyanobacteria are important providers of biologically fixed nitrogen for the growth of the rice plant[2,3].

It is partly because of their unique ability to fix N_2 while photosynthesizing in the manner of higher plants that the cyanobacteria have recently aroused the attention of molecular biologists. Their study may, in the long term, have relevance to the possibility of introducing the genes responsible for N_2-fixation (the *nif* genes) into the plastids, whether chlorophyllous or not, of higher plants. They have also gained attention as possibly useful models for developmental molecular biologists because many forms occur as simple unbranched filaments with a maximum of three cell types: heterocysts, the sites of N_2 fixation; akinetes, which are perennial; and vegetative cells, from which akinetes and heterocysts develop[4]. Haselkorn and co-workers now add to the scientific attractions of cyanobacteria by showing that they possess a so-far unique capacity to rearrange some of their N_2-fixing genes, notably two that encode the major components of nitrogenase.

The mechanism that allows the O_2-sensitive nitrogenase to function in oxygenic cyanobacteria such as *Anabaena* was for long unknown. It was then discovered[3,5,6] that the peculiar, empty-looking heterocysts[7], which occur in most N_2-fixing cyanobacteria, are the loci of nitrogenase activity in air and in the light, and that by various biochemical modifications, they provide an anaerobic microenvironment in which nitrogenase is synthesized and is functional.

A drawback, until recently[8], to the detailed genetic analysis of N_2-fixation and heterocyst production in cyanobacteria has been the fact that although mutants of cyanobacteria are readily obtainable, there has existed no good system for the transfer, in the laboratory, of genes into heterocystous cyanobacteria. Thus, genetic analysis by complementation of cyanobacterial mutants has not been possible. An alternative approach, used by Haselkorn and colleagues, is to use the *nif* genes of the enteric bacterium *Klebsiella* as probes for those of *Anabaena*. In *Klebsiella* there are 17 *nif* genes, organized into seven or eight transcriptional units and arranged in a cluster occupying about 23 kilobases of DNA and located near the genes for histidine biosynthesis (see ref. 9). The genes that encode the major nitrogenase components — the iron protein and the iron–molybdenum protein — are *nif K*, *nif D* and *nif H*. The iron protein is composed of two identical subunits, both encoded by *nif H*. The iron–molybdenum protein contains one pair of identical subunits encoded by *nif K* and another by *nif D*. Although the two proteins do not fix N_2 alone, in combination they may do so in the presence of a source of reductant, Mg^{2+} and ATP, and in the absence of O_2 (see ref. 10).

Haselkorn and his colleagues have already shown that, while the *nif K*, *D* and *H* genes are clustered in *Klebsiella* and some other N_2-fixing organisms, in DNA extracted from filaments of *Anabaena* 7120 the *nif D* and *nif H* genes are contigous but separated from *nif K* by about 11 kilobases. The Chicago group has

now compared the arrangement of the *nif K, D* and *H* genes in whole filaments of *Anabaena* with that in heterocysts during their differentiation from vegetative cells. While confirming that *nif K* is separated from *nif D/H* in vegetative cells, they show that a gene rearrangement occurs within the heterocyst at a late stage in differentiation. What happens is that the 11-kilobase intervening DNA sequence between *nif D/H* and *nif K* is excised, so that the three genes become clustered and function as a single transcriptional unit, with nitrogenase structural proteins being synthesized, and nitrogenase activity commencing, within the heterocysts. The excised portion remains in the heterocyst as a circular molecule of unknown function.

These findings are of interest not only because they are unique but because they emphasize the usefulness of cyanobacteria for the study of differentiation. The heterocysts of cyanobacteria such as *Anabaena*, show a distinct spatial pattern; between 8 and 10 per cent of the total cells along a filament are heterocysts and new heterocysts develop equidistantly from two existing heterocysts. That is, in some as yet unknown way, existing heterocysts may regulate the spacing pattern of new heterocysts (there is no evidence that nitrogenase is involved in the process). Furthermore, in organisms such as *Nostoc* 7524 there is evidence that with certain external (and no doubt internal) conditions, a cell that normally develops into a heterocyst develops instead into an akinete[12]. The molecular events leading to the cessation of cell division and determining whether a differentiating cell regresses, or further differentiates, and if so into which cell type, is an intriguing area of molecular biology that has relevance not only to nitrogen fixation but to our basic understanding of cellular developmental biology. At a time when the UK Agricultural and Food Research Council is examining N_2-fixation research, the new results with cyanobacteria will, perhaps, emphasize the merits of scientific diversity in this field. □

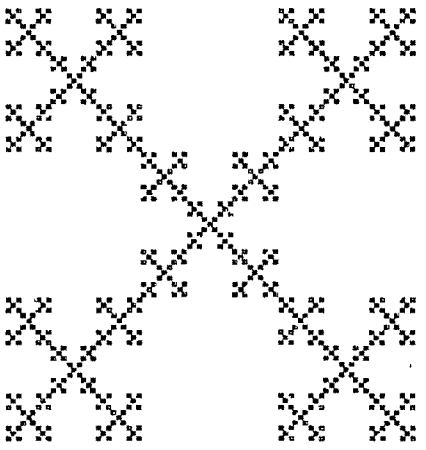
Scale-invariant phenomena

Viscous fingers and fractal growth

from L.M. Sander

A RECENT article in Nature by Nittmann, Daccord, and Stanley[1] is a particularly instructive example of the power of basic science to find connections between apparently unrelated natural phenomena. It is an experimental account of the shape of the interface between two fluids with relevance to oil-field technology. The shape is shown to belong to a class that includes the shapes of electrolyte deposits[2,3], metals and dielectric breakdown structures such as lightning[4]. The common feature of the objects is that they are all scale-invariant fractals of the same fractal dimension[5].

The experiment of Nittmann *et al.* deals with the long-known fact that when a relatively non-viscous fluid is forced against a viscous fluid an instability results: 'fingers' of the less viscous fluid intrude into the other. For example, when carbon dioxide is pumped into an oil field, the efficiency of oil recovery is not very large because instead of the oil being pushed uniformly across the field, it is broken up by the branching pattern of the fingers. The usual laboratory realization of the system is a Hele-Shaw cell: water is pumped into a long channel in which oil is trapped between closely-spaced parallel plates. In the essentially two-dimensional region between the plates, fingering is easily seen.



In past experiments, the shape of the fingers has been dominated by the interfacial tension between the two fluids, which tends to favour coarse fingers. Typically, one finger is formed with a width near to that of the cell. But, in an oil field, the region of interest is much bigger than a single finger. To simulate the oil field in their experiments, the essential step of Nittmann *et al.* was to use two fluids whose interfacial tension is essentially zero — water and an aqueous polymer solution that has a slow rate of mixing with water. In addition, the polymer solution has very high effective viscosity. Both these factors favour the formation of small fingers.

It is with respect to the sprawling, many-branched structures formed as the small fingers of water advance into the polymer solution that connections can be made to disparate phenomena. For, as Paterson has pointed out[7], the fundamental instability in this situation is the same as in other systems where diffusion limits growth. Here, fingers grow because it is easier for viscous fluid to flow away from a sharp tip than a flat interface. In dielectric breakdown, the electric field is largest at the end of the breakdown channel, leading to further extension at the point. In electrolyte deposition, new ions more easily find sharp tips than flat areas; the tips thus extend.

For instability dominated growth, the unifying framework is the diffusion-limited aggregation (DLA) model[8]. In this idealization of growth by diffusion, which is used in computer simulations, a particle walks randomly until it finds a nucleation centre, where it sticks. Then another particle is released and walks until it finds either the centre or the other particle and sticks. And so on. The remarkable result of the simulations is that the structures they form are scale-invariant and fractal.

Scale-invariant objects look the 'same' at any magnification. The disorderly structures already mentioned share this property with other natural objects, such as coastlines. The figure gives a simplified example, generated by an obvious rule, which looks the same at a discrete set of magnifications. In order to see what is meant by a fractal, we define D, the fractal dimensionality[5]. Cover the object in the figure with a set of disks of radius r. This takes a certain number of disks, $N(r)$. Now change r and see how N changes. Almost always we find $N(r) = Cr^{-D}$ where C is a constant. For a straight line, $D=1$ and for a square, $D=2$; in these cases D corresponds to our usual ideas of dimensionality. But for the illustrated figure, dividing the radius by 3 multiplies N by 5. Thus $D=\log(5)/\log(3)$. An object whose D is not given by its topology is a fractal.

Electrolyte deposits, dielectric breakdown stuctures and DLA clusters all have a measured D of about 1.7 in two dimensions of space. Their fractal properties can be studied using the simple DLA model. The fingers of Nittmann *et al.* have a smaller D, but the authors show that this is probably the effect of the finite width of their channel. All of these structures belong to the same universality class which seems to be that associated with growth far from equilibrium. Another class, corresponding to DLA in three dimensions (with $D=2.4$), has been seen in electolyte deposition[2]. Still another class appears in

the description of flow through porous materials — 'the percolation problem'.

The experiment of Nittmann *et al.* is also significant in that it gives insight into the minimum requirements of a DLA-like structure. Although DLA seems quite simple, it has defied complete analysis. A major point of contention is whether noise due to the discrete nature of the particles making up the cluster dominates the dynamics. Dielectric breakdown structures have links of more-or-less fixed length and electrolytic deposits are polycrystalline. Experiments on these systems shed no light on the question. But the fluid system of Nittman *et al.* is continuous. Apparently, discreteness is not essential to make a DLA-like fractal. There has been speculation that this would indicate that DLA is an example of chaos. In practical terms it may mean that solidification far from equilibrium, which can also be mapped onto DLA, could give rise to fractals — for example, if a snowflake were allowed to grow very large, it would probably be fractal, too. □

100 Years Ago

THE following account, we learn from *Science*, of unusual phenomena was received, March 10, at the Hydrographic Office, Washington, from the branch office in San Francisco. The barque *Innerwich*, Capt. Waters, has just arrived at Victoria from Yokohama. At midnight of February 24, in latitude 37° north, longitude 170° 15′ east, the captain was aroused by the mate, and went on deck to find the sky changing to a fiery red. All at once a large mass of fire appeared over the vessel, completely blinding the spectators; and, as it fell into the sea some fifty yards to leeward, it caused a hissing sound, which was heard above the blast, and made the vessel quiver from stem to stern Hardly had this disappeared when a lowering mass of white foam was seen rapidly approaching the vessel. The barque was struck flat aback; but, before there was time to touch a brace, the sails had filled again, and the roaring white sea had passed ahead The master declares that the awfulness of the sight was beyond description and considers that the ship had a narrow escape from destruction.

From *Nature* **31** 514, 2 April 1885.

Oceanography

Sonar classification of sea beds

from M.L Somers

ALTHOUGH side-scan solar is used widely in both scientific and engineering investigations of the sea bed, the task of extracting a numerical classification of sea beds from the backscattered sound has proved intractable. But an experienced human observer who has had access to the results of comparisons between sonographs and physical samples can rapidly make accurate qualitative classifications, so there must be some quality of the backscattering that gives the necessary clues. On page 426 of this issue, Z. Reut, N.G. Pace and M.J.P. Heaton offer a solution to the problem and a method of classification into six sea-bed types — mud, sand, clay, gravel, stones and boulders.

The backscattering of sound from the sea bed is a complicated function of the grazing angle of the sonar signal and the roughness of the sea bed, with further complications thrown in by the acoustic impedance of the sea-bed material: if the ratio of sea bed to water impedance is close to unity (as in the case of mud), then there is appreciable penetration of sound into the sea bed and the possible production of a boundary wave, which can interact with the incident wave, profoundly modifying the backscattering process (see Somers, M.L. and Stubbs, A.R. *IEE Proc.* **131**, Pt F; 1984). To circumvent these problems, Reut *et al.* have concentrated on the rate of fluctuation of the backscattered sound over short periods of time. Their method is based on the observation that the fluctuations generally become more rapid as the ground gets rougher. There are, of course, large differences in total energy, and the peak-to-valley ratios can actually be greater over a soft or smooth sea bed than over a rough one, but the rate of fluctuation is still generally less than if the sea bed is rough.

The method requires fairly careful normalization, for which Reut *et al.* have chosen to use cepstrum analysis, an outline of which is given in their paper. By taking the mean of the power spectrum, all considerations of phase can be ignored, so ensuring that when the inverse transform is taken the result peaks at, or near to, zero time delay. The effect of taking logs before doing the inverse transform is to de-emphasize any d.c. level in the signal, which shows up as a large peak at zero frequency in the power spectrum. The two-power cepstrum integral parameters give a measure of how closely the cepstrum is confined to low time-lag values.

Justification of the method comes both from the foregoing qualitative arguments that can be mustered in its favour and from the fact that it seems to work — 120 sea-bed areas are correctly classified into the six types with the only overlap being between gravel and stone types. A similar result could probably be obtained by applying automatic gain control, removing the mean and taking the auto-correlation function, though this would possibly be computationally less attractive.

It would be interesting to see the method applied to a wider selection of sea-bed echoes, using a number of frequencies instead of the single 48-kHz frequency used by the authors. An application which comes to mind concerns the problem of mapping and assessing fields of manganese nodules in oceans that are several thousand metres deep. This will require low-frequency sound, such as used in the long-range side-scan sonar, GLORIA II. Manganese nodule fields occur very widely in the Abyssal Plain regions of the deep ocean and should be visible on a GLORIA record. If so, it might at least be possible to delineate the boundaries of the fields, and perhaps even to give a measure of nodule abundance.

Side-scan sonar requires oblique incidence for its best visual effect, so that depth/range ratios need to be less than about 0.2. But most systems working from the surface in deep water, or at high frequencies in shallow water, operate at near-vertical incidence and the backscattering process is somewhat different. It will be interesting to see how the classification system of Reut *et al.* performs in such circumstances.

Turning from their concern with problems of propagation and surface reverberation, the underwater-acoustics community is devoting increasing attention to sonar scattering. Many theoretical papers and some reporting measurements or equipment will be given at the International Conference on Scattering Phenomena on 2-3 April at the Admiralty Research Establishment, Portland, UK. Various applications of the analysis of sea-bed backscattering, both civil and military, are being explored. Of the civil applications, many involve the estimation of resources. Manganese nodules have already been mentioned. Gravel provides a second example. Over ten per cent of the gravel used in the United Kingdom is dredged from the sea bed, and a rapid and reliable means of detecting suitable gravel fields would be of considerable value. The accuracy of acoustic logs for ships that measure their speed by observing the Doppler shift of sound backscattered from the sea bed should also be improved by application of the new system of classification. □

Ramsey's silicate core revisited

SIR — The case for believing that the Earth has an iron core was called the "classical view" by Birch [1] when, in 1952 he reviewed and rejected Ramsey's earlier argument [2-4] that "the mantle and core are not chemically distinct". Briefly, Ramsey's proposal was that, because the terrestrial planets were not originally of the same composition (as reflected by lack of correspondence in relative mass and mean density), then the amount of iron in the cores of the planets must be out of correspondence, so that the iron core hypothesis must be rejected. Instead, Ramsey suggested that the core should be regarded as a metallic phase of a silicate such as olivine.

The arguments which led Birch to reject Ramsey's theory are still valid. One was that elements with a low atomic number would not reach the required density even at core pressures. On the basis of theory, he concluded "...that a compound such as Mg_2SiO_4, of mean atomic number equal to 10, would reach a density of 10 only at a pressure ten times as great as the pressure of the core boundary, even in the fully ionized conditions".

In 1952, there were no laboratory data on iron at the conditions of the Earth's core, but, by 1960, because of advances in shock-wave physics, experimental data [5,6] were sufficient for the subject to be examined again. In 1963, Birch [7] reviewed the experimental evidence on shocked iron, and concluded that the sound velocity of silicates at core pressure could not possibly be as low as the sound velocities of the core reported by seismologists. Thus, experimental evidence backed up his earlier conclusions.

The shock-wave evidence accumulated since 1963 has repeatedly verified Birch's position, but this laboratory evidence is ignored when the proposal of a silicate core is revived, as it has been from time to time, most recently in *Nature* [8,9].

A *News and Views* article stated that R. Lyttleton is "entirely right to carry a torch for Ramsey's theory, which is in a category too neat not to be true". The view was expressed that the chief objection to Ramsey's hypothesis was that the experiments of high pressure geophysics had failed to verify Ramsey's hypothesis, but might be "irrelevant", although why these important experiments are irrelevant was not explained. It, therefore, is timely to review the most important experimental evidence in favour of the iron core and against the silicate core.

The chief objection to Ramsey's hypothesis is not that the shock-wave experiments have failed to find the postulated phase transition in olivine and similar minerals, although that is significant, but that shock-wave experiments have shown that pure iron at inner-core pressure and temperature has the mechanical properties that seismologists find for the inner core.

It is important to distinguish the properties of the inner core from those of the outer core; not only is one solid and the other liquid, but the former is virtually pure iron and the latter, iron diluted by lighter elements.

The argument assembled by Birch in 1963 has been largely overworked in the past decade. He found a correspondence between the velocity of sound found by seismologists and by shock-wave determinations.

The seismically determined shear and longitudinal sound velocity, V_P and V_S respectively, determined in the Earth at every depth, is related to the bulk modulus and density, K and ϱ, by $\phi = (K/\varrho)^{1/2} = (V_P^2 - 4/3\ V_S^2)^{1/2}$. Now ϕ is the bulk sound velocity, also given by $(\delta P/\delta\varrho)^{1/2}$, where P is pressure measured by shock waves. By measuring $(\delta P/\delta\varrho)^{1/2}$ on iron at core pressures and temperatures, using shock waves, comparisons are made between the value of ϱ for iron and the seismic ϕ in the core. Birch pointed out that the velocity of sound has an important relationship to density, forming a pattern that has come to be known as velocity-density systematics, and which has been widely used to estimate unknown compositions in the Earth's interior from seismological data. For metals under shock waves, the pattern relating the bulk sound velocity and density is dependent on the atomic number. The larger the atomic number, the smaller the velocity for a given density. Birch's (1963) graph, modified by additions, is reproduced as Fig.1.

In the period, 1965-75, velocity-density studies showed that a phase transition in an oxide such as olivine increases both K and ϱ, but that K increases as a power of ϱ ($K \sim \varrho^x$, $x = 4.5$) [10-13]. Thus, the ϕ and ϱ curve for the high pressure phase in a silicate is merely a projection of the ϕ-ϱ trajectory for the low pressure phase, as shown (Fig.1) by the dunite and olivine curves [14]. Because all phases of dunite lie on a line in the field of low atomic numbers, it was generally concluded that if Ramsey's theory were correct, the value of $\phi = \sqrt{K/\varrho}$ of a silicate would have to be quite large at the densities found in the core, exceeding perhaps 20 km s^{-1}. In brief, the bulk sound velocity for the core is far too low to be compatible with a silicate. Whatever the core is composed of, it must have an average atomic number near 25 or 26.

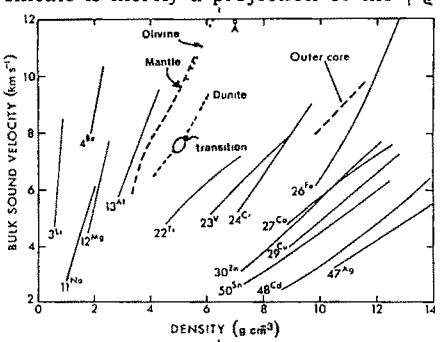

Fig.1 Bulk sound velocity $\phi = (\delta P/\delta\varrho)^{1/2}$ plotted against density ϱ along the Hugoniot compression curves for metals of low atomic number [5]. The heavy dashed lines show the bulk sound velocity, $\phi = (V_P^2 - 4/3\ V_S^2)^{1/2}$, of the mantle and core as determined from seismology. Compression curves are given for dunite [14] through a transition at $\varrho = 4.5$ g cm^{-2}; and for dunite (A) at a very high shock pressure [6]. The ϕ versus ϱ curve for shocked olivine is also shown. Silicates cluster near the mantle curve, near an effective atomic number of 14. The outer core curve is in the vicinity of metals with an effective number near 25 (modified from ref 7).

Moreover, the density changes in dunite are small compared with the differences between mantle to core, as is the case for all silicates so far measured by shock-wave experimentation.

Refinements of shock-wave data on iron show that the density of the outer core is not quite as large as expected for pure iron [15], so the outer core is presumed to be iron with a small concentration of solutes (as inferred by Birch [7] from his equation of state).

Birch's 1952 and 1963 papers convinced most Earth scientists that the Earth's core is iron diluted with a small concentration of solutes. The live issue in the field became that of what those solutes could be.

Experiment after experiment has verified Birch's concept (Fig.1). Refinements of shock-wave measurements have shown that the candidate solutes in the liquid core are S, O, or Si (refs 16-19). For example, Ahrens [16] used his shock-wave experiments to demonstrate the relation of the density of Fe-S compounds to the density of the outer core as determined from seismic data. By the early 1980s, shock-wave experiments of improved resolution had shown that the data for pure iron at core conditions corresponds to the seismically determined density of the inner core [16,19]. The Earth's inner temperatures had become better constrained by this time, so that the mechanical properties of iron (ϕ, K and ϱ) could be computed; Jeanloz [19] found that they agreed with the known properties of the inner core.

By 1982, the hypothesis that the inner core has the same physical properties as pure iron had been widely accepted; the question that remained was that of from which phase of pure iron it is constituted. There were two possibilities, ε-iron (hexagonal close-packed) or γ-iron (face-centred cubic). Several theoreticians favoured γ-iron and computed physical properties based upon this choice [20-22]. But in 1980, Brown and McQueen [23,24], using an elegant modification of shock-wave techniques, were able to measure the longitudinal velocity, V_P, of iron at core pressures. The significance of this measurement is that, when the shock wave encounters the liquid state, V_P abruptly decreases to ϕ, since the shear velocity, V_S, vanishes, with the result that the pressure and temperature of a point on the fusion curve of iron are determined. They found [25] melting

at 243 ± 2 GPa and the ε-γ transition at the lower pressure of 200 ± 2 GPa. The corresponding temperatures are 5,000-6,000 K and 4,400 ± 300 K.

A simple extrapolation (from 243 to 350 GPa) of the measured V_p to inner core pressures, after correcting for the temperature expected, indicates that the V_p of pure iron at core conditions matches the seismic V_p of the inner core (Fig.2). Since Poisson's ratio is determined by ϕ and V_p, a good match is obtained between pure iron at inner core density and that reported by seismologists for the inner core. Thus, we have agreement for the values of ϕ, σ, V_p, and ϱ when comparing shock-wave measurements for pure iron with those inferred by seismologists for the Earth's inner core.

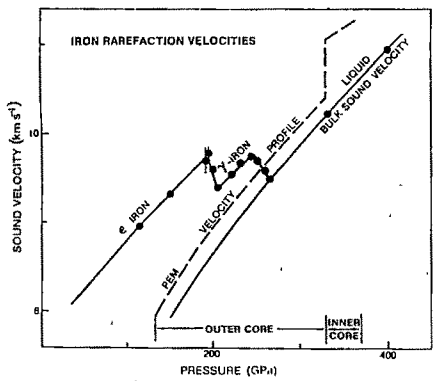

Fig.2 The plot of compressional velocity V_P against pressure is shown by solid circles for shocked iron along the Hugoniot. At lower pressure, shocked iron is in the ε-phase; at 243 GPa, it transforms by a solid-solid transition to the γ-phase; and at 250 GPa, it further transforms to the liquid phase. The liquid phase is indicated by the fact that V_P has the same value as the bulk sound velocity. The dashed line shows the plot of V_P against pressure for the outer core and the inner core (called PEM), as determined from seismology[35]. Note that V_P for shocked ε-iron extrapolates to higher pressure values of V_P for the inner core (modified from Fig.1 of ref.24).

The convergence of current research on the view that the inner core is ε-phase iron is supported by the extrapolation of the physical properties of the ε and γ phases to inner-core pressure; the ε-phase gives better agreement than the γ-phase[25]. The choice of ε-iron is not universally accepted however; for example, Spiliopoulos and Stacey[22] still hold out for γ-iron as the sole constituent of the inner core, using theoretical arguments on the behaviour of phase boundaries at high pressure.

Cosmochemists require alloys of iron for the cores of planets[26-29] and many theories suggest a steady cooling of their interiors. Thus, there is fractional crystallization by a moving solid-liquid interface as the inner solid core slowly grows, tending to concentrate the solute in the outer liquid part of the core[30]. This releases potential energy and is widely believed to be the energy source of the core dynamo that generates the Earth's magnetic field.

The shock-wave data of iron are thus consistent with a clear model of the core: The inner core is growing, the impurities are concentrated in the outer core, the Earth is cooling and the dynamo is gravitationally driven.

The solutes in the outer core are atoms lighter than iron, according to cosmochemistry[26,28], so the density of the outer core is less than that of pure iron. Thermodynamically, it does not matter much what these light atoms are, for so long as the concentration is small, different solutes will equally well depress the density of pure iron to give the measured seismic velocity and density of the outer core. The detailed composition of the outer core is, of course, of intense interest to cosmochemists and cosmologists, but whether the solute is sulfur[18], oxygen[28], silicon or hydrogen[31], or combinations thereof, does not affect the conclusion that the Earth's outer core is predominantly iron, and that the inner core is essentially pure iron.

The details of the phase diagram of iron, up to inner-core pressures and temperatures, have been evolving for twelve years[32-34]. I accept the conclusion of Brown and McQueen that ε-iron constitutes the inner core[24,25], which means that the ε-γ-liquid triple point is at a pressure below that of the boundary between the inner and outer core. The phase diagram of iron (Fig.3) is slightly adapted from ref.34. A complete description of the phase diagram of iron at inner core conditions is presented elsewhere[35]. There the thermodynamically derived density of iron at conditions at the top of the inner core is found to be 13.0 g cm^{-3}, compared with the seismically determined density of 12.86 g cm^{-3} by one report[36], and 13.4 by another report[37].

Thus, in the past twenty years, evidence for the iron core hypothesis has mounted to the point that it is overwhelming. Most now involved in research on the properties of the Earth's core find Ramsey's 1948 hypothesis[2], and Lyttleton's revival of it, somewhat quaint. To restore the acceptance of Ramsey's idea of a silicate core would require not only the verified proof of the existence of a high-pressure phase change of a silicate wherein the density is doubled, but also proof that all the physical properties (K, ϱ, σ, V_p) of such a high pressure phase duplicate the properties of the inner core.

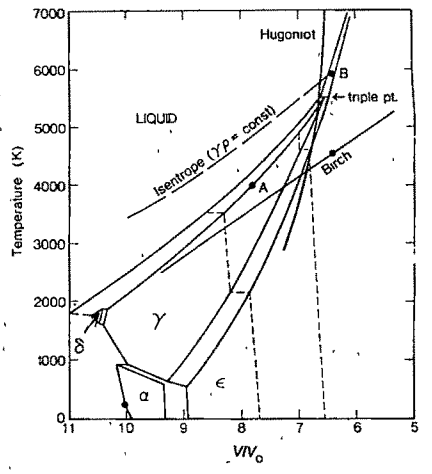

Fig.3 The volume-temperature phase diagram of iron (adapted from Fig.5 of ref.34). The phase boundaries are concave upward, and connect three triple points. B marks the inner-outer core boundary pressure, and A marks the core-mantle boundary pressure. The two broken lines are isobars at 100 and 250 GPa. The upper triple point (γ-ε-liquid) is placed at slightly above 250 GPa. Birch's 1972 extrapolation[32], based on an assumed linear T_m versus V/V relationship, is shown. The temperatures along the solidus are determined by the data represented by Fig.2.

I thank Professor S.K. Runcorn for his encouragement and the Department of Energy (DE-FG03-84 ER13203) for financial support. I thank Dr J. Michael Brown for advance copies of his paper.

Unification of forces and particles in superstring theories

Michael B. Green

Physics Department, Queen Mary College, University of London, Mile End Road, London E1 4NS, UK

Superstring field theories have emerged as potentially consistent quantum field theories that unify gravity with the other fundamental forces in an almost unique manner. They are based on the dynamics of string-like fundamental quanta rather than the point-like quanta of more familiar relativistic 'point field theories' such as Yang–Mills gauge theory or general relativity. In these theories the observed fundamental particles, such as the leptons and quarks, may arise as the ground states of a string. This amounts to a profound generalization of the conventional field theory framework.

IN this article I will review the structure of superstring theories developed over the past five years[1-4]. I will describe in particular how these theories are restricted by requiring that they be consistent with quantum mechanics. Recently we have understood how these restrictions (which cannot be satisfied by point field theories) constrain the possible internal symmetry groups of superstring theories to just two possibilities, namely the special orthogonal group SO(32) or the product of two exceptional groups $E_8 \times E_8$ (ref. 5). The fact that the internal symmetry is determined almost uniquely by requiring the quantum consistency of a theory containing gravity is a novel development. The hope is that this will provide a realistic unified theory that will explain experimental observations with few or no free parameters. I will outline some interesting developments in this direction.

Grand unification and supersymmetry

In the past decade a variety of Grand Unified Theories (GUTs) have been developed to unify the strong and the electro-weak interactions at an energy scale of $\sim 10^{16}$ Gev. GUTs are gauge invariant (Yang-Mills) point field theories which do not attempt to incorporate the gravitational force, and so there are few theoretical constraints on the possible symmetry groups. These groups as well as a large number of undetermined adjustable parameters are therefore chosen to account for observations as well as possible. The most favoured GUTs are based on the special unitary group SU(5), the special orthogonal group SO(10), or the exceptional group E_6. In such schemes the quarks and leptons are unified into families. The quarks and leptons so far discovered make up three of these families but the question of how many families there are in total is a matter of speculation in the absence of a fundamental theory.

The observed elementary particles have masses that are tiny compared with the natural mass scale in a GUT of $\sim 10^{16}$ GeV. To a first approximation these masses are taken to be zero and the observed non-zero mass values arise from small perturbative corrections. Supersymmetry is an important ingredient in GUTs that ensures the possibility of predicting reasonable masses for these particles. It is a symmetry that relates bosons to fermions rather as internal symmetries relate groups of particles. However, as supersymmetry relates particles of different spins it is not an internal symmetry but an enlargement of the Poincaré group (the group of Lorentz transformations and translations) to the 'super-Poincaré group'. This amounts to an extension of space-time to 'superspace' that includes extra spinorial anticommuting coordinates as well as ordinary coordinates. Although theoretically appealing, the existence of sypersymmetry in nature has yet to be established experimentally. It probably requires there to be a host of particles (known as squarks, sleptons, Winos, Zinos, ...) which have not yet been discovered

Supergravity theories are point field theories that incorporate local (that is, gauged) supersymmetry, thereby enlarging Einstein's theory of general relativity. In recent years such theories have been the focus of much research in constructing quantum theories containing gravity as well as unifying gravity with the other forces. There are fundamental problems in uniting quantum mechanics and general relativity that are associated with effects at the Planck scale (10^{-35} m). Despite early optimism that incorporating supersymmetry would resolve these problems and also unify the interactions in a geometrically appealing manner, it now seems probable that none of the supergravity theories will lead to a consistent quantum theory.

However, there is now the possibility of predicting an almost unique unified theory as a low-energy approximation to a consistent superstring theory (where the term 'low energy' means an energy low compared with the Planck scale, 10^{19} GeV).

What are superstrings?

The behaviour of a relativistic string moving in space-time differs significantly from that of a structureless point particle. Unlike a point particle, a classical relativistic string has an infinite number of vibrational modes with arbitrarily high frequencies and angular momenta. This means that in the quantum theory a single string has an infinite number of states with masses and spins which increase without limit. The scale for the mass splitting between these states is set by the string tension T (with dimension (mass)^2 in natural units). String theories were developed originally in the early 1970s as models for strong interaction physics (see refs 6, 7 for reviews). For example, a meson was thought of as a string with a quark attached to one end and an antiquark to the other. T was then supposed to be ~ 1 GeV^2 and the excited states were interpreted as hadron resonances. The main theories of this type were the 'bosonic' string theory, which only described bosons, and the 'spinning' string theory, which incorporated fermions as well as bosons. These early string theories, however, had severe theoretical inconsistencies because the string ground state always turned out to have negative mass-squared (that is, it was a tachyon).

Superstring theories, which evolved from the spinning string theory, incorporate supersymmetry and do not suffer from the inconsistency of having tachyonic ground states. In fact, the ground states have zero mass and are simply the fundamental states of interesting supergravity point field theories. Superstring theories are therefore interpreted as theories that include gravity and the natural mass scale set by T is the Planck scale (that is, $T^{1/2} = 10^{19}$ GeV). The excited states are so massive that for many

purposes they can be taken to be infinitely heavy and the theory can be approximated by an effective point field theory of the massless states only. In other words, at energy scales well below the Planck scale (or distances $\gg 10^{-35}$ m) the string looks like a point. The quantum mechanical consistency of certain superstring field theories, however, depends crucially on the fact that at energies approaching the Planck scale the higher mass states are excited. The short distance structure therefore differs radically from that of any point field theory, such as Einstein's theory of gravity.

The classical dynamics of a relativistic string is described by an obvious generalization of the dynamics of a point particle. Just as a relativistic point particle moves along a world-line in space-time a string sweeps out a world-sheet as it moves. The obvious invariant action for a single point-particle is the length of its world-line and, similarly, the action for the simplest type of string is the area of its world-sheet[8-10]. For a superstring, the action is a generalization of the surface area to something like the area in superspace (which again requires additional spinorial dimensions to be adjoined to the space-time dimensions)[11].

The passage from classical mechanics to quantum mechanics turns out to impose severe constraints on any string theory. For example, all string theories contain massless spin-1 and spin-2 states which are associated with a Yang–Mills gauge boson and a graviton, respectively. Furthermore, the consistency of the quantum theory selects a special dimension for space-time (the 'critical' dimension). For the original (bosonic) string theory this was 26 dimensions, whereas superstring theories require 10-dimensional space-time. Just as in any theory containing gravity, the structure of space-time should be determined dynamically and so, to be of relevance to physics, the extra six dimensions must curl up and be very small (they must 'compactify'). This is analogous to the idea originally proposed by Kaluza and Klein[12,13] in the early days of general relativity as a way of unifying gravity with electromagnetism which has received renewed interest recently in the study of supergravity point field theories. However, in the context of any point field theory, the extra dimensions make the problems of the quantum infinities of the theory even worse than they already are in four dimensions. One of the remarkable aspects of the quantum superstring field theories is that certain of them seem to have no infinities at all, even though they are defined in 10 dimensions.

Restrictions on chiral theories

A very important physical constraint on any theory is that it must give rise to the observed 'chirality' of our (approximately) four-dimensional world, that is, the lack of invariance of the laws of physics under parity inversion. In the past few years it has become clear that obtaining a chiral four-dimensional world from a higher dimensional theory imposes severe restrictions on such theories[14,15]. It seems to be essential that the theory have chiral fermions in the higher dimensions (that is, in 10 dimensions for superstring theories) as well as a Yang–Mills gauge symmetry. In that case, the chirality of the higher-dimensional fermions can be maintained when the extra dimensions compactify, if the gauge fields twist up in a topologically non-trivial manner in the internal compact space. An example of such a non-trivial field configuration would be that of a magnetic monopole. A theory formulated in an odd number of dimensions cannot be chiral and so would seem to have little prospect of predicting sensible four-dimensional physical laws.

A theory with chiral particles will have terrible problems, however. The conservation of the Yang–Mills charges as well as the energy–momentum that is built into the classical theory may be violated in the quantum theory. Theories in which there is a quantum mechanical breakdown of such sacrosanct conservation laws are said to have 'anomalies'. These anomalies allow unphysical degrees of freedom (such as the longitudinal mode of the photon) to couple to the physical ones rendering the theory inconsistent. In 10 dimensions (and more generally in $4n+2$ dimensions), parity violation is an intrinsic property of a theory with chiral fermions (or self-dual bosons) independent of the Yang–Mills group G or to which representation of G the fermion belongs. (In contrast, in four dimensions a theory only violates parity if it contains chiral fermions in a complex representation of the gauge group.) For this reason, gravitational and Yang–Mills anomalies can generally be expected in any chiral 10-dimensional gauge theory. Requiring the absence of all anomalies leads to such stringent conditions that until recently it was thought that no interesting chiral theory could satisfy them. The results I shall describe show that for just two choices for the gauge group G it is possible to construct an anomaly-free theory. This requires a very intimate relationship between Yang–Mills and gravitational interactions, which looks somewhat contrived when viewed in terms of the effective point field theory that approximates the string at large distances However, this unification of the Yang–Mills and gravitational forces is one of the most striking aspects of string theories.

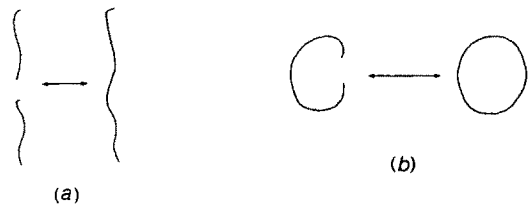

Fig. 1 The Yang–Mills interactions of strength g. *a*, Coupling between two open strings and a third open string (This interaction contains the usual interaction between three massless gauge bosons) *b*, The transition between an open and a closed string.

Classification of superstring theories

Type I theories describe the dynamics of open strings that have free endpoints. These strings carry quantum numbers in the n-dimensional defining representation of a classical group G = SO(n) or the symplectic group USp(n) at their endpoints (SU(n) leads to inconsistencies in the string field theory). This is similar to the way in which the quark quantum numbers were incorporated in the original string picture of mesons. It has not been understood how to incorporate the exceptional groups in this type of string theory. Although the string is locally invariant under two supersymmetries (that is, $N=2$), the free-end boundary conditions break this down to just one (that is, $N=1$) supersymmetry. The massless open-string states are the usual states of supersymmetric Yang–Mills theory in 10 dimensions with the gauge group G. Two open strings can interact when two ends touch and join to form one open string or, conversely, one string splits into two (Fig. 1*a*). An important corollary to this is that the two endpoints of a single string can join to form a single closed string so that type I theories necessarily contain a closed string sector (Fig. 1*b*). The massless states of a closed string form a supergravity multiplet (and do not carry the Yang–Mills quantum numbers).

This means that the effective field theory that emerges as the low energy approximation to type I theories is $N=1$ Yang–Mills coupled to $N=1$ supergravity. The fact that the existence of the Yang–Mills sector requires the existence of the gravitational sector is quite unfamiliar in ordinary point field theories. This unification of the Yang–Mills and gravitational forces leads to the relationship $\kappa = \text{const.} g^2 T$ between the gauge coupling constant, g, and the gravitational coupling (Newton's constant), κ.

Because these are chiral theories with a Yang–Mills gauge group, they may be of interest in describing observed physics for the reasons mentioned earlier. I will describe later how requiring the absence of all anomalies in type I theories restricts the choice of gauge groups to only one possibility—SO(32). I will also argue that, from the point of view of the low-energy point field theory, the group $E_8 \times E_8$ is also anomaly-free. This suggests that there might also be a way of incorporating it in a type I theory.

Type II theories only involve closed strings. These can have an 'orientation' associated with the fact that waves can run around the string in two possible directions. The two orientations allow for two chiral supersymmetries, so these theories are invariant under 10-dimensional ($D=10$) $N=2$ supersymmetry. In the type IIa theory the two supercharges have opposite chirality and so the theory has no net chirality and is not of much physical interest. Its low-energy effective point field theory limit is $D=10$, $N=2$ non-chiral supergravity, which is the theory that can be thought of as the trivial reduction of $D=11$ supergravity. The type IIb theory is more interesting because it has supercharges of the same chirality. Its low-energy point field theory limit is the chiral $D=10$, $N=2$ supergravity theory (which was actually constructed this way). This theory is remarkable in being chiral and yet not having any gravitational anomalies[16].

Unfortunately, the type IIb theory does not have any Yang-Mills gauge invariance and so it seems unlikely that interesting chiral compactified theories of this type exist.

Recently a third kind of superstring theory has been discovered, called the Heterotic string[17]. It is based on closed strings only, although it carries a Yang-Mills gauge group and has $N=1$ supersymmetry. The way the gauge quantum numbers are incorporated is very different from the method used in the type I theories. Instead of the Yang-Mills charges residing at the ends of the string there is a charge density along the string. This construction is closely related to the representation theory of Kac-Moody algebras, which has been developed over the last few years by mathematicians and physicists interested in string theories. It turns out that the only Yang-Mills groups that can be incorporated in this kind of theory are SO(32) and $E_8 \times E_8$. The occurrence of just these groups is related to the fact that they are associated with the only even self-dual 16-dimensional lattices. The construction of the heterotic string theory involves some aspects of the original 26-dimensional bosonic string theory with 16 of the dimensions being the maximal torus of one or other of the two groups (see also refs 27-29). This leaves 10 space-time dimensions. In the heterotic string theory, the gauge coupling constant and the gravitational coupling constant are related by $\kappa = \text{constant} \times g/(T)^{1/2}$.

Superstring field theory

In this section I will describe the formulation of a superstring field theory which provides a framework for describing the interactions between strings in the language of quantum field theory.

At present, the field theory of strings does not have formulation based on a geometrical principle. We are restricted to describing the theories in a special parametrization of the world-sheet swept out as the string moves, known as the light-cone parametrization. This is not very satisfying for a theory which includes gravity. Nevertheless, this field theory is convenient for perturbative calculations around flat space-time and illustrates many novel features of string theories. The open-string fields, $\Phi[x(\sigma), \theta(\sigma), \tilde{\theta}(\sigma)]$, and the closed-string fields, $\Psi[x(\sigma), \theta(\sigma), \tilde{\theta}(\sigma)]$, are functionals of the string configurations. In other words, they are functions of the superspace coordinates of the whole string and are thus generalizations of conventional point fields. The superspace coordinates in the light-cone parametrization are functions of the parameter σ which labels the points on a string and consist of the transverse positions $x^i(\sigma)$ (in ten dimensions there are eight dimensions transverse to the two light-cone directions $x^{\pm} = (x^0 \pm x^9)/\sqrt{2}$, so $i \pm 1, 2, \ldots, 8$), two grassmann spinors $\theta(\sigma)$ and $\tilde{\theta}(\sigma)$ (which are the anticommuting superspace partners of x^i) and the momentum component p^+ (which is independent of σ in this parametrization). The fields Φ and Ψ can be thought of as describing an infinite set of point fields, one for each mode of excitation of the string. The zero modes are just the usual massless fields of super-Yang-Mills and supergravity, respectively. The open-string field Φ carries the internal quantum numbers of the gauge group G (either SO(n) or USp(n)) and is therefore a matrix in the fundamental representation of the group whereas the closed-string field Ψ is a group singlet, carrying no charge.

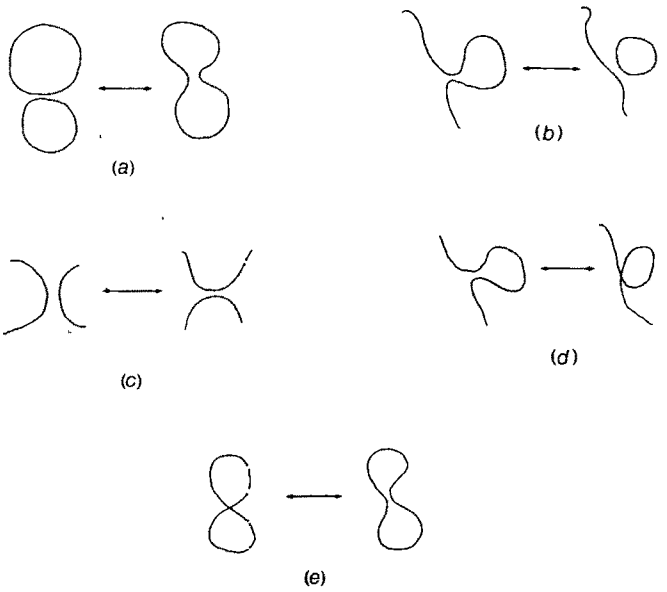

Fig. 2 The 'gravitational' interactions of strength κ. *a*, The coupling between three closed strings that contains the usual interaction between three massless gravitons. *b*–*e*, Other interactions that are locally the same as *a* at the point where the strings touch

One advantage of the light-cone parametrization is that the theory is formulated entirely in terms of a Hilbert space of physical transverse states without any redundant auxiliary or gauge degrees of freedom. However, the special parametrization destroys the manifest Poincaré invariance of the theory by picking out two directions along the light-cone in a special way. As a result, the full super-Poincaré invariance of the interacting theory is represented non-linearly on the fields. Some of the generators develop interaction terms that are cubic or of higher order in the fields. In fact, imposing the requirement that the hamiltonian of the interacting theory be invariant under super-Poincaré transformations determines it. In this manner, we have determined the superstring interaction hamiltonian which turns out to only involve local interactions only. These fall into two classes[18,19].

Class 1. 'Yang-Mills Interactions.' These are interactions with a coupling constant g in which two ends of a string join or, conversely, a string breaks to form two new endpoints. This gives rise to the term in the interaction hamiltonian, referred to earlier (pictured in Fig. 1*a* and cubic in the string fields); that is, it describes the breaking of one string into two or the joining of two strings into one. Exactly the same interaction is also responsible for the transition between open and closed strings pictured in Fig. 1*b* and mentioned above. The full expressions for these terms in the hamiltonian are given in ref. 18 as functional integrals over the string light-cone superspace. The fact that these two terms involve the same local interaction is very important for causality, because the two processes are indistinguishable near the joining point, differing only in the string boundary conditions far away from that point. These interactions generalize the usual cubic Yang-Mills coupling of point field theory. The zero-mode piece in the interaction of Fig. 1*a* is precisely the cubic super-Yang-Mills coupling.

Class 2. 'Gravitational Interactions.' These are interactions of strnegth κ in which two internal points touch and string pieces are swapped between incoming strings. An example of an interaction term of this type is shown in Fig. 2*a*, where two closed strings join to form one closed string or, conversely, one closed string splits into two. The zero-mode piece of the closed-string field is just the point superfield of supergravity and Fig. 2*a* includes the familiar coupling between three gravitons given by

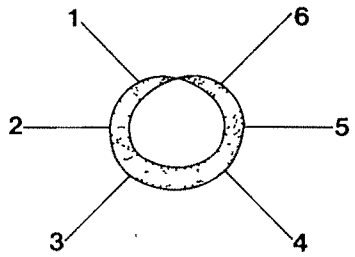

Fig. 3 The anomalous planar open-string hexagon diagram. A contribution to the anomaly in the Yang-Mills invariance

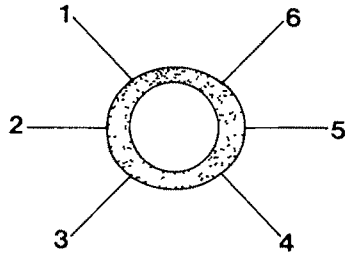

Fig. 4 One of the 32 non-orientable anomalous open-string hexagon diagrams

the Einstein-Hilbert action (as well as the infinite number of other interactions involving the excited modes). For the type II theories, the interaction of Fig. 2*a* is the only term in the interaction hamiltonian. The type I theories, which describe unoriented strings, involve five terms with this kind of interaction, shown in Fig. 2.

The heterotic string theory describes the dynamics of an oriented closed string field. Just as with the type II theories, there is only one term in the interaction hamiltonian (Fig. 2*a*). This single interaction term contains both the cubic super-Yang-Mills coupling as well as the cubic supergravity coupling

There are no higher-order contact interactions. This is quite different from point field theories like Yang-Mills or general relativity in which, for example, there are vertices which couple arbitrarily many graviton fields. These contact interactions emerge in a string theory as low-energy effective vertices resulting from the exchange of the massive string states. This is analogous to the way in which the four-fermi model of the weak interactions is now understood as a low-energy approximation to the Glashow-Weinberg-Salam theory, which involves massive W or Z boson exchange. The short-distance behaviour of superstring theories is therefore radically different from that of point field theories of gravity, as the massive modes are excited at length scales around $(T)^{-1/2}$.

These interactions, together with the free hamiltonian, lead to a set of perturbation theory rules for strings. Perturbation theory diagrams are constructed by tying together interaction vertices and free propagators to form trees and loop diagrams analogous to Feynman diagrams in point field theories.

Superstring anomaly cancellations

In earlier work we had studied one-loop perturbation theory diagrams with four external ground-state open-string particles (Yang-Mills gauge particles or their supersymmetric fermion partners). We found that, to this order, the type II theories are finite[1], unlike 10-dimensional point field theories such as type II supergravity, which diverges badly at one loop. This illustrated the possibility that superstring theory may be quantum mechanically consistent. The finiteness results from a conspiracy of divergence cancellations between the infinite numbers of supersymmetric fermion and boson states circulating around the loop. We also found that type I theories with a gauge group $G = SO(n)$ or $USp(n)$ (with general n) have a divergence (which might be eliminated by a redefinition of T). A result of the recent work to be described below is that the SO(32) type I theory is finite at one loop. These properties contrast with those of supersymmetric point field theories which, though less divergent than non-supersymmetric ones, are nevertheless badly divergent in 10 dimensions.

Recently we investigated the possible anomalies that can arise in chiral string theories in a manner analogous to the occurrence of anomalies in chiral point field theories. In 10 dimensions, an anomaly in the conservation of the Yang-Mills charge is associated with a non-vanishing coupling of the longitudinal mode of a gauge particle to five physical, transverse gauge particles in a Feynman loop diagram. This hexagon diagram is the analogue of the familiar triangle diagram associated with anomalies in four-dimensional gauge theories.

Although it should be possible to calculate the anomaly in the light-cone formalism described earlier, it is easier to use a covariant formalism based on the old 'spinning string' theory. This is not initially 10-dimensionally supersymmetric, but can be made so by projection onto a suitable subspace of the full Hilbert space. The anomalous hexagon diagrams fall into three classes: (1) The first class contains only the planar diagram shown in Fig. 3. The internal propagators in the diagram are drawn as stippled strips to emphasize that they are complete string propagators, whereas the external particles are the string ground states. The diagram is therefore an annulus formed by the world-sheet of the string circulating around the loop, with all the external particles attached to one boundary. The group theory factor associated with this diagram contains a factor of n (where the group is either $SO(n)$ or $USp(n)$) which arises because the annulus in Fig. 3 has one boundary with no external particles attached. The form of the anomaly calculated from this diagram reduces at low energy (compared with $\sqrt{T}$) to the usual point-field theory hexagon diagram result, as expected.

(2) The second class of diagrams that contribute to the one-loop Yang-Mills gauge anomaly consists of those which are non-orientable, such as the example shown in Fig. 4 which has a twist in one of the string propagators. In total there are 32 diagrams of this type which have an odd number of twists and hence world-sheets which are Möbius strips. These diagrams do not have the factor on n as they only have one boundary. In other respects they each contribute to the anomaly with the same weight as the annulus in Fig. 3 but with a relative sign that is + for the group $USp(n)$ and − for $SO(n)$.

(3) The last class of diagrams to consider consists of the diagrams with an even (but non-zero) number of twists such as Fig. 5. Remarkably, this turns out to be free of anomalies, which is apparently at odds with the corresponding low-energy limit point-field theory hexagon diagram. The resolution of this apparent contradiction is based on the fact that the open-string hexagon diagram of Fig. 5 contains closed-string bound states in the 5-6 channel. This can be seen by distorting the stippled world-sheet of Fig. 5 to look like a cylinder, as in Fig, 6, in which case the intermediate closed-string states are apparent. As the closed-string sector includes the massless supergravity multiplet, the low energy effective point field theory must include the effects resulting from the exchange of the gravity states as well as the usual hexagon loop effects. This interplay between gravity and Yang-Mills contributions is the key to understanding how the anomalies cancel.

The total Yang-Mills gauge anomaly is therefore obtained by combining the contributions from (1) and (2). The result is proportional to $(n \pm 32)$ and hence vanishes for the group SO(32). Similar arguments lead to the vanishing of gravitational anomalies (which arise from hexagon diagrams with external gravitons) for the same gauge group.

We have also reconsidered the question of infinities in scattering amplitudes. It turns out that just for the gauge group SO(32) the infinities in the four-particle scattering amplitude also cancel[19]. In fact it is probable on very general grounds that there is a connection between the absence of anomalies in chiral string theories and the cancellation of infinities in those theories to any order in perturbation theory. This is not true in conventional point field theories.

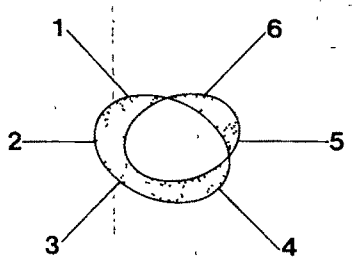

Fig. 5 A non-planar open-string hexagon diagram which turns out to be free of anomalies for any Yang-Mills gauge group

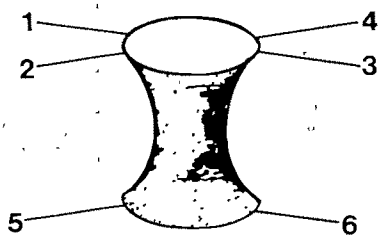

Fig. 6 Another representation for the world-sheet of the process of Fig. 5 which illustrates the closed string (gravitational) intermediate states in the channel formed by particles 5 and 6. The occurrence of gravitational states is responsible for the cancellation of the anomalies in Fig. 5.

Similar results have subsequently been found for the heterotic string theory with either gauge group SO(32) or $E_8 \times E_8$.

'Low-energy' effective point theory

The fact that all anomalies cancel for specific Yang-Mills gauge groups can be explained in the language of point field theory by considering the effective theory that emerges from the string theory at low energy. In principle the superstring field theory can be formulated exactly in terms of its massless states by integrating out the massive string-field modes in the generating functional of the theory. The resulting effective point field action, which would be expressed entirely in terms of massless fields, would be horribly complicated but could be expanded in a power series in energy/$(T)^{1/2}$ for energies $< 10^{19}$ GeV. The lowest-order terms in such an expansion give the usual point-field theory action for the $D = 10$ coupled $N = 1$ super-Yang-Mills supergravity system that had been studied previously in this 'minimal' form[20,21]. It turns out that to understand the absence of anomalies it is crucial to keep further terms in the effective action. Among the massless fields that occur in $D = 10$, $N = 1$ supergravity, there is an antisymmetric second-rank tensor, B, which plays the key role in understanding how the anomalies cancel.

The details of the anomaly cancellation in the effective point field theory are given in ref. 5 and I will simply outline the major points here. The important terms in the low-energy effective action include terms that involve the coupling of B to the other fields that are not present in the minimal action of ref. 21. These extra terms include some which spoil the Yang-Mills and the general coordinate invariances of the classical action. However, they arise in just the correct way so that they exactly compensate for the violation of these invariances by the one-loop quantum effects. The fact that this is possible depends on several remarkable identities which restrict the possible theories. For example, the cancellation of the Yang-Mills anomalies, arising from a hexagon loop with external gauge particles, restricts the possible gauge groups to ones for which

$$\mathrm{tr}\, F^6 = 1/48\, \mathrm{tr}\, F^2 (\mathrm{tr}\, F^4 - 1/300\, (\mathrm{tr}\, F^2)^2)$$

where F^{ab} is an arbitrary matrix in the adjoint representation of the group and tr denotes the trace. The gravitational anomalies arise from hexagon diagrams with external gravitons and chiral fermions circulating round the loop. These fermions are the gravitino and its spin-1/2 partner as well as the spin-1/2 matter fermions from the Yang-Mills sector (of which there are m, where m is the dimension of the Yang-Mills gauge group). For the gravitational anomalies to cancel, it is necessary for the dimension of the group to be $m = 496$. There are other conditions that arise by requiring the absence of anomalies which arise from hexagon diagrams with both external gravitons and Yang-Mills particles. The only groups that satisfy all these conditions are SO(32) and $E_8 \times E_8$. This analysis, based entirely on an effective point field theory, suggested that as well as the SO(32) superstring theory described earlier, there may be an $E_8 \times E_8$ string theory. The 'heterotic' string constructed recently[17] encompasses both SO(32) and $E_8 \times E_8$ and no others.

Towards four space-time dimensions

To make contact with physics it is important to understand the predictions of superstring theories at energies well below the Planck scale. The full superstring equations should determine the structure of space-time and hopefully lead to the collapse of the extra six spatial dimensions together with a breakdown of the very large gauge group to a subgroup which might be one of the usual GUT groups or directly to the 'standard model' with symmetry $SU(3) \times SU(2) \times U(1)$. The structure of these equations is far from understood but, nevertheless, certain general features can be abstracted by studying the terms in the expansion of the low-energy effective point field theory described earlier. The equations of motion based on this low energy approximation should not be used too literally because terms that have been dropped from the expansion may be as important as the terms that have been kept. However, certain pertinent features of the effective theory are probably properties of the complete theory. For example, as emphasized in ref. 22 there is an interesting topological constraint in the theory

$$\int (\mathrm{tr}\, R_{\mu\omega}\, R_{\rho\tau} - 1/30 \mathrm{tr}\, F_{\mu\omega}\, F_{\rho\sigma}) \varepsilon^{\mu\omega\rho\sigma} = 0$$

where $R^{mn}_{\mu\omega}$ is the Riemann curvature tensor (which is a matrix in the 0(9, 1) tangent-space group) and F^{ab} is the Yang-Mills strength (which is a matrix in the gauge group SO(32) or $E_8 \times E_8$). The integral is over an arbitrary four-dimensional compact submanifold of the full 10-dimensional space. This is a relation between topological properties of space-time and of the Yang-Mills field configurations which connects the breaking of the Yang-Mills and the space-time symmetries. It is another aspect of the unification of Yang-Mills and gravity implied by the theory. It is also, remarkably enough, the relation that is needed to ensure that the anomaly cancellation discovered in flat 10-dimensional space-time continues to work in an arbitrary curved space-time. In general, this relation requires that F has a non-zero expectation value in some subgroup H of SO(32) or $E_8 \times E_8$ in the curved dimensions, and this causes the symmetry to be broken to some commuting subgroup G which is then the symmetry group for the approximately four-dimensional theory. This may be a completely specified GUT in which the observed elementary particles are approximately massless relative to the natural mass scale of 10^{19} GeV. The spectrum of massless particles in the theory when some of the dimensions are curled up can be deduced from various index theorems on the internal space and so the number of families (and their quantum numbers) is determined by the topological structure of the theory.

One very general feature of this picture which distinguishes it from the usual Kaluza-Klein schemes is that the Yang-Mills group in the 10-dimensional theory can provide all the experimentally desirable internal symmetries. It may then be true that the dimensional compactification produces no extra gauge invariances which would happen, for example, if the internal space had no isometries. In most other schemes, these gauge symmetries are supposed to emerge from isometries of the compact internal space (for example, the $D = 11$ supergravity theory has no Yang-Mills gauge group and all the observed

four-dimensional Yang-Mills symmetries are supposed to emerge from isometries of the compact seven-dimensional space in that theory). Ricci-flat spaces have no isometries and are therefore natural candidates to consider for the extra dimensions.

There has been an interesting specific suggestion as to how the observed (approximately) four-dimensional physics might emerge from the 10-dimensional theory[23]. This makes use of a Ricci-flat space for the compact six dimensions. (Such Ricci-flat higher-dimensional spaces, known as 'Calabi-Yau' spaces, were conjectured to exist by Calabi and proved to exist by Yau[24].) Despite the fact that the full content of the string field equations is not yet understood, the authors of ref. 23 point to strong indications from the low-energy effective field theory that Ricci-flat internal manifolds are singled out. For example, if it is assumed that the four-dimensional theory has one surviving supersymmetry (desirable for phenomenological reasons), then the internal space has to be a Calabi-Yau space with holonomy group SU(3) (the curvature two-form lies in an SU(3) group), which is a severe restriction on the possible four-dimensional theories.

Furthermore, there are strong indications that the breaking of the big gauge symmetry of the 10-dimensional theory (SO(32) or $E_8 \times E_8$) is tied to the curvature in the compact dimensions. Starting with the $E_8 \times E_8$ theory in 10 dimensions, the Yang-Mills field strength associated with a SU(3) subgroup of one of the E_8 factors acquires an expectation value proportional to the curvature of the internal manifold. This causes a breaking of an SU(3) subgroup of that E_8 factor (E_8 contains $E_6 \times SU(3)$), resulting in a four-dimensional effective theory which is the supersymmetric GUT with symmetry group $E_6 \times E_8$. This is encouraging because E_6 has long been considered as a possible group for a GUT. The particle content of this unified theory is uniquely determined by specifying which Calabi-Yau space is used as the internal manifold, as the number of families is given by $1/2 \times$the Euler characteristic of the space. For simply-connected Calabi-Yau spaces, this turns out to be a rather large number, but there are multiply-connected spaces for which the number of families is smaller. These spaces also provide an attractive topological reason for why the GUT should break down to give low-energy symmetries which might well be realistic. The extra E_8 factor describes matter which only interacts gravitationally with the charged matter in the E_6 GUT because it is neutral under the E_6 Yang-Mills group. In fact, the existence of two types of matter which only interact via the gravitational force is a general prediction of the $E_8 \times E_8$ theory when it is compactified on any internal manifold with no isometries (so that no new gauge symmetries emerge from the compactification). This may have important implications for the 'dark matter' in the Universe[25] as well as for the so-called 'hidden sector' suggested by phenomenological super-unified theories for breaking the last supersymmetry.

At the present level of understanding, there is no theoretical reason for demanding one supersymmetry to survive the compactification to four dimensions. Another example mentioned as a possibility in ref. 23 is a theory in which the internal Calabi-Yau space has 0(6) holonomy and no supersymmetry survives the compactification. This results in the internal symmetry group $SO(10) \times E_8$ which is also an attractive grand unified group. These Ricci-flat internal manifolds have the virtue of not producing a cosmological constant from the compactification. But it is not yet clear why the usual purely four-dimensional sources for a cosmological constant should be absent; its absence in nature still remains a mystery.

Discussion

Recent developments have confirmed that superstring theories are interesting generalizations of point field theories containing gravity. Although these are still early days for understanding their full predictive content, the scheme proposed in ref. 23 (outlined in the previous section) suggests that there is a real chance of making contact with presently known phenomena as well as making predictions that should be testable. Other possible ways in which four-dimensional physics might emerge from these theories have been suggested in refs 23 and 26.

Our present formulation of these theories is probably not the most suitable for fully understanding their structure. For example, the relationship between the two possible Yang-Mills gauge groups and 10-dimensional space-time presumably has some geometric origin which has not been elucidated.

A more general question is why do string theories contain a massless spin-2 particle associated with gravity and a massless spin-1 particle associated with Yang-Mills theory at all? The only gauge principles used in their construction involve invariances of the two-dimensional world-sheet swept out as the string moves. String theories are not formulated in terms of any 10-dimensional gauge principle, and yet, at energy scales $< (T)^{1/2}$, they embody the principle of equivalence as well as Yang-Mills gauge invariance. Perhaps there is some generalization of the equivalence principle that gives a geometric understanding of the superstring field theory and that reduces to the usual principle at low energies. Such a generalization might be an important element in understanding the structure and hence the predictions of the theory.

The shadow world of superstring theories

Edward W. Kolb*†, David Seckel* & Michael S. Turner*†

* NASA/Fermilab Astrophysics Center, Fermi National Accelerator Laboratory, Batavia, Illinois 60510, USA

Recent attempts to construct a superstring theory that unifies all the interactions of nature, including gravity, in a finite anomaly-free quantum theory have led to the speculation that there may exist another form of matter ('shadow matter') in the Universe, which only interacts with 'ordinary matter' (for example, quarks, leptons) through gravity or gravitational-strength interactions. The existence of shadow matter would have many astrophysical and cosmological implications, some of which are discussed here.

SUPERSTRING unified theories seem to offer the possibility of constructing a consistent quantum theory that unifies all interactions, including gravity[1-3]. In fact, it has been speculated that superstrings are the only possibility for such a unification. The low-energy limit of a string theory ($E^2 \ll$ string tension $= m_{pl}^2$, where $m_{pl} = 1.22 \times 10^{19}$ GeV is the Planck mass) is an ordinary quantum field theory (QFT). Because string theories are formulated in 10 dimensions, the effective QFT we see (and feel) is the low-energy limit of a compactified string theory. Green and Schwarz[4] have shown that the only theories that are anomaly-free and finite are those based on the gauge groups SO(32) or $E_8 \times E_8$ and have constructed a type I superstring theory based on SO(32). Recently, Gross *et al.*[5] constructed a heterotic string theory based on either $E_8 \times E_8$ or SO(32). It has been speculated that if the gauge group is $E_8 \times E_8$, the $E_8 \leftrightarrow E_8$ symmetry may persist even in the dimensionally-reduced theory[4,5]. If this is the case, then there would be two forms of matter: ordinary matter, whose interactions would be described by E_8, and shadow matter, whose interactions would be described by E_8; these two kinds of matter would only interact through gravitational-strength interactions. We consider here some of the possible astrophysical and cosmological implications of 'generic' shadow matter; that is, matter which only interacts gravitationally with ordinary matter, and which may or may not be identical in its properties to ordinary matter. It should be stressed that although our interest in shadow matter was stimulated by recent developments in superstring theories, our discussions apply to any theory that predicts the existence of 'shadow matter' (that is, matter which only interacts gravitationally with ordinary matter). In fact, there are a variety of theories (for example, those with so-called 'hidden' sectors[6]) that predict shadow matter.

Shadow matter

We will consider several possible realizations for the shadow world. The first realization we will explore is that the shadow world exactly 'mirrors' the ordinary world. By this, we mean that both the microphysics of the shadow world (for example, symmetry breaking pattern, particle spectrum and masses) and macrophysics (for example, photon temperatures) are identical. After the Planck epoch (age of the Universe $t \leq 10^{-43}$ s, temperature of the Universe $T \geq 10^{19}$ GeV) we can be sure that the interaction between shadow and ordinary matter is unimportant on the microscopic level, because the rate for gravitational-strength interactions is much less than the expansion rate of the Universe. So although interactions among ordinary and shadow particles themselves will keep each separately in thermal equilibrium, the two worlds will not feel each other's presence on the microscopic level. If the two components are initially well mixed, they will remain well mixed until non-gravitational forces become important on macroscopic scales. In the standard cosmology, this does not occur until the later stages of galaxy formation. During the early stages of structure formation ($t \geq 10^{10}$ s, $T \leq 10$ eV), small density inhomogeneities grow via the gravitational (or Jeans) instability. When the density contrast $\delta\rho/\rho$ begins to go non-linear (redshifts ≤ 30), non-gravitational forces begin to play an increasingly important role and these forces will act separately on ordinary and shadow matter.

Structure formation which proceeds through the fragmentation of larger objects into smaller ones through hydrodynamic or thermodynamic instabilities will lead to the segregation of ordinary and shadow matter because of the random nature of the instabilities which act independently on the two components. In the hot dark matter or 'pancake' picture[7] large structures such as superclusters form and then fragment into galaxies through such instabilities, and so we would expect a segregation of ordinary and shadow matter on the scale of galaxies. In this case we expect to find some galaxies that are predominantly ordinary matter and others that are predominantly shadow matter, together in clusters of galaxies. If galaxies do not form from the fragmentation of a larger object, as in the cold dark matter or hierarchical picture[8], galaxies should contain equal amounts of ordinary and shadow material. However, objects that form via instabilities within galaxies, for example, stars, will have ordinary/shadow segregation. Therefore, it is reasonable to expect that even if the disk of a galaxy contains equal amounts of ordinary and shadow matter, there may be local segregation of the two components (perhaps on scales larger than our Solar System). We note that a roughly equal component of shadow matter in the disk of our Galaxy would explain one of the several dark matter problems: that the gravitational mass of the disk (as inferred from dynamics) seems to be about twice that of the material we can see or detect (for example, stars, white dwarfs, gas, dust)[9]. One might also expect some binary systems comprised of an ordinary star and a shadow star. Such a system would manifest itself as an isolated star with a periodic proper motion. In fact there are nearby stars (at distances <5 pc) which are suspected of having invisible companions[10]. Of course, there are less exotic explanations for these invisible companions; they could be neutron stars, black holes, black dwarfs or planetary-size objects.

It is possible that our Solar System formed from nebulae containing ordinary and shadow matter (although if the initial collapse of the protostellar nebulae were triggered by a shock wave in the ordinary matter, only the ordinary matter would have responded and collapsed). The shadow matter present would have formed into separate objects. However, with the possible unlikely exception of Nemesis (the death star[11,12]), we can be confident that there are no unseen planet-sized (or larger) objects in our Solar System.

Shadow matter in the Solar System

Based on the previous discussion, it seems unlikely that the Solar System would contain a significant amount of shadow matter. Those considerations aside, what can one directly infer about the amount of shadow material in the Earth or in the Sun? Material in the Earth is supported against gravity by atomic degeneracy pressure. The same would be true of shadow material in the Earth. It would settle at the centre of the Earth (any initial

motion relative to the centre would be damped by tidal dissipation) and be distributed with an approximately constant density of the order of 10 g cm^{-3}. The mass of the Earth derived from the motion of its many satellites, $M_{grav} = 4\pi \int (\rho_S + \rho) r^2 \, dr = M_S + M$, and the mass derived based on seismic determinations of ρ, $M_{seismic} = 4\pi \int \rho r^2 \, dr = M$, are consistent at about the 10% level[13]. (Here ρ and ρ_S refer to the density of matter and shadow matter, respectively.) This means that the amount of shadow material in the Earth must be significantly less than that of ordinary material.

Next, we consider the Sun. If the amount of shadow and ordinary material were equal, then the Sun would be simultaneously a star and a shadow star, each burning its own kind of hydrogen to helium. However, as we shall see, the Sun would seem very different. If the shadow matter in the Sun were distributed identically to the ordinary matter, then the equations of stellar structure for each component are identical, and equivalent to the usual equations with G replaced by $2G_N$ (G_N = the gravitational constant, whose value is 6.67×10^{-8} cm^3 g^{-1} s^{-2}) and the usual mass variable $M(r)$ (= mass interior to radial coordinate r) accounting for either the ordinary or shadow mass only (so that $M_{total}(r) = 2M(r)$). Using the standard $n = 3$ polytrope approximation to the Sun[14], it follows that the luminosity $\mathcal{L}$, rate of release of nuclear energy Q, central temperature T_c and radius R are given by

$$\mathcal{L} \propto \mu^7 (GM)^5 G^2 T_c^{1/2}$$

$$Q \propto \mu^{-3} (GM)^{-1} G^{-2} T_c^{p+3}$$

$$T_c \propto \mu^{10/(p+25)} (GM)^{6/(p+25)} G^{4/(p+25)}$$

$$R \propto \mu (GM) T_c^{-1}$$

where μ is the average molecular mass per particle and $p \simeq 4$ accounts for the approximate temperature dependence of the nuclear reactions responsible for energy generation in the Sun. (Note that the central temperature is determined by the equilibrium condition: $\mathcal{L} = Q$.)

A solar mass star composed of equal quantities of ordinary and shadow matter corresponds to $G = 2G_N$ and $M = M_S = M_\odot/2$. The $n = 3$ polytrope model of such an object predicts: $\mathcal{L} \simeq 5 \, \mathcal{L}_0$, $T_c \simeq 1.5 \, T_{c0}$ and $R \simeq 0.65 R_0$, where 'subscript zero' indicates the value of that quantity for a standard solar mass star ($M = M_\odot$, $G = G_N$) with the same chemical composition. Such a star would be easily distinguishable from 'our Sun' by its luminosity, size and solar neutrino flux (the flux of ^{8}B neutrinos detected by the Davis experiment is very temperature dependent, neutrino flux $\propto T_c^q$, $q \simeq 13$; ref. 15). Although $\mathcal{L}$, T_c and R are all dependent on the chemical composition, it is not possible to adjust μ to obtain a model which resembles 'our Sun'. Ulrich[16] and Mikkelsen and Newman[17] have constructed numerical models of the Sun where they fixed GM but allowed G to differ from G_N; from such models they concluded that G/G_N must be in the range 0.6–1.5. In passing, we note that the Chandrasekhar mass ($\equiv M + M_S$) for a star containing equal amounts of ordinary and shadow matter is smaller than the usual value by a factor of $\sqrt{2}$.

If there is only a small amount of shadow matter in the Sun ($M_S \ll M_\odot$), the shadow material will sit at the centre of the Sun and will be supported by shadow electron degeneracy pressure. The size and central density of the shadow ball at the core of the Sun will be

$$R_S \simeq 0.2 \, R_\odot (M_S/M_\odot)^{1/6}$$

$$\rho_S \simeq 2{,}000 \text{ g cm}^{-3} \, (M_S/M_\odot)^{1/2}$$

As the shadow matter would be concentrated in the core of the Sun ($r \lesssim 0.1 \, R_\odot$), it seems more reasonable to take GM fixed and $G \to G_N(1 + \rho_s/\rho_c)$, rather than $G \to G_N(1 + M_S/M_\odot)$, to estimate the effect of the shadow matter on the central temperature, etc. Using the $n = 3$ polytrope model once again, it follows that the central temperature rises by an amount $\delta T_c/T_c \simeq 6(M_S/M_\odot)^{1/2}$. As mentioned earlier, the most sensitive indicator of the central temperature of the Sun is the solar flux of ^{8}B neutrinos. Taking the flux to vary as T_c^{13} and insisting that the predicted rate does not triple, say, implies that $\delta T_c/T_c \lesssim 0.09$ or $M_S/M_\odot \lesssim 0.001$.

To conclude the discussion of shadow matter in the solar neighbourhood we can say that, apart from the possibility that Nemesis is a shadow object, there can be little shadow matter in the Solar System. We again emphasize that as the shadow matter and ordinary matter could easily be segregated in the Galaxy on scales the size of the Solar System, this observation does not preclude the existence of an exactly mirror shadow world.

Primordial nucleosynthesis

Let us turn to the early Universe. The yields of big bang nucleosynthesis depend sensitively on the expansion rate of the Universe one second after the bang, when the temperature of ordinary matter was ~1 MeV[18] The expansion rate of the Universe at nucleosynthesis is related to the total energy density, $\rho_T = \rho + \rho_S$, by

$$\dot{R}/R = [(8\pi G_N/3)(\rho + \rho_S)]^{1/2}$$

where R is the cosmic scale factor. During this early epoch the Universe is radiation-dominated, with $\rho = g_*(\pi^2/30)T^4$, where g_* counts the effective number of degrees of freedom of particles with mass less than T

$$g_* = \sum_{\text{bosons}} g_B + 7/8 \sum_{\text{fermions}} g_F$$

The addition of shadow matter results in an effective g_* at the time of nucleosynthesis

$$\rho_T = g_{\text{eff}}(\pi^2/30)T^4$$

$$g_{\text{eff}} = g_* + g_{*S}(T_S/T)^4$$

where g_{*S} counts the effective number of degrees of freedom in the shadow world and T_S is the temperature of the shadow matter, which in general need not necessarily be the same as that of the ordinary matter. Increasing the expansion rate results in the production of more ^{4}He; $\Delta Y_p \simeq 0.19 \log_{10}(1 + \Delta g/g_{\text{eff}})$[18]. Here, Y_p is the mass fraction of ^{4}He synthesized and Δg is the change in g_{eff}.

Taking into account observational data (which strongly suggest $Y_p \lesssim 0.25$), uncertainty in the neutron half life and uncertainty in the calculated abundances, Yang *et al.*[19] conclude that unless the number of light ($\lesssim$ a few MeV) neutrino species $N_\nu \lesssim 4$, ^{4}He will be overproduced. In fact if Y_p were known to be $\lesssim 0.250$ (that is, to three significant figures), $N_\nu = 4$ is not quite allowed. Note that $N_\nu = 4$ corresponds to $g_* = 12.5$.

The limit on the number of neutrinos is really a limit on the total effective number of degrees of freedom, g_{eff}. For the purposes of our discussion, we will be conservative and take the primordial nucleosynthesis limit to g_{eff} to two significant figures, $g_{\text{eff}} \lesssim 13.0$. For the exact mirror shadow world ($g_{*S} = g_*$ and $T_S = T$), $g_{\text{eff}} = 25 (N_\nu = 4)$, $21.5 (N_\nu = 3)$ or $18 (N_\nu = 2)$. Thus, big-bang nucleosynthesis eliminates exact mirror symmetry, as we know that at least two of the neutrino species are light.

Macroscopic asymmetry

Having eliminated the possibility of an exact mirror shadow world, we next discuss the possibility of a macroscopic asymmetry between the two worlds with identical microphysics. First, we note that the Solar System limits discussed in the previous section still apply. However, as before, they cannot be used to set universal limits, as shadow and ordinary matter can easily be segregated on scales as large as the Solar System. We therefore return to big bang nucleosynthesis to place limits on the macroscopic asymmetry.

A quantity which specifies the macroscopic asymmetry in a very useful way is the ratio of the entropies per co-moving volume γ

$$\gamma \equiv \frac{s_S R^3}{s R^3} = \frac{g_{*S}(T_S)}{g_*(T)} \frac{T_S^3}{T^3}$$

where s (s_S) is the ordinary (shadow) entropy density, R is the cosmic scale factor and, as before, T and T_S are the temperatures of the ordinary and shadow matter, respectively. In the absence of entropy production in either world, γ remains constant. For the scenario at hand (identical microphysics), $g_* = g_{*S}$ so that γ, the ratio of the entropy of the shadow world to our world, is just $\gamma = r^3 \equiv (T_S/T)^3$. Lacking a detailed understanding of how the compactification from $d = 10$ to $d = 4$ took place, we do not know what value of γ to expect, although starting with equal amounts of entropy in the two worlds ($\gamma = 1$) would seem to be a plausible assumption. For $g_{*S} = g_*$, $\gamma = 1$ also implies that $T_S = T$.

The primordial nucleosynthesis constraint (that is, $g_{\rm eff} \leq 13.0$) implies that

$$\gamma = r^3 \leq \begin{cases} 0.55 & N_\nu = 2 \\ 0.31 & N_\nu = 3 \\ 0.09 & N_\nu = 4 \end{cases}$$

If we assume that the ordinary and shadow baryon-to-entropy ratios are identical (however, see below), this implies that ordinary baryons must outnumber shadow baryons by a modest amount

$$n_B/n_{BS} \geq \begin{cases} 1.8 & N_\nu = 2 \\ 2.0 & N_\nu = 3 \\ 11.0 & N_\nu = 4 \end{cases}$$

Baryogenesis

If the temperatures of the shadow and ordinary matter are not the same, as primordial nucleosynthesis suggests, the shadow baryon asymmetry may differ from the normal baryon asymmetry even though the microphysics is the same for both worlds. In baryogenesis scenarios, the baryon-to-entropy ratio, B, is a function of $K = (\Gamma_I/H)_{T=M_X}$, where Γ_I is the microphysical interaction rate of some baryon number violating boson X, M_X is its mass and H is the expansion rate of the Universe ($\simeq \rho_T^{1/2} m_{\rm pl}^{-1}$; ref. 20). If the shadow and ordinary microphysics are the same and the Universe is radiation-dominated at baryogenesis ($\rho_T \propto T^4 + T_S^4$), the relevant values of K for ordinary and shadow baryogenesis (K and K_S) will be

$$K \propto \frac{m_{\rm pl}}{M_X[1+r^4]^{1/2}}$$

$$K_S \propto \frac{m_{\rm pl}}{M_X[1+r^{-4}]^{1/2}}$$

where, as before, $r = T_S/T$. If no entropy is created between baryogenesis and nucleosynthesis, r must be <1 and so $K_S < K$. The baryon asymmetry decreases with increasing K (ref. 20), so the ordinary baryon asymmetry must be less than or equal to the shadow baryon asymmetry. For $K \leq 1$, the baryon asymmetry is independent of K and thus would be the same for ordinary and shadow matter. For $K \geq 1$, the baryon-to-entropy ratio is roughly proportional to K^{-1}, and the ratio of shadow to ordinary baryon numbers is given by

$$B_S/B \simeq [1+r^{-4}]^{1/2}/[1+r^4]^{1/2} = r^{-2}$$

The number density of shadow baryons, n_{BS}, is related to the number density of ordinary baryons n_B by

$$\frac{n_{BS}}{n_B} = \frac{B_S}{B}\frac{T_S^3}{T}$$

$$= r^3 \quad (K, K_S < 1)$$

$$= r \quad (K, K_S > 1)$$

As we know that $r < 1$ from nucleosynthesis, it is difficult to imagine a scenario where shadow baryons dominate ordinary baryons (by number).

Double-bubble inflation

We have shown that γ must be <1. Even if γ were ≥ 1 initially, it is possible that it was reduced exponentially by inflation[21], as we will now explain. If the two worlds are microscopically identical we would expect inflation to occur in both sectors, but not necessarily simultaneously. Remember that inflation involves a random event—the nucleation of a bubble or the formation of a fluctuation region. At the beginning of inflation the Universe is in a false vacuum state for both worlds. A bubble will nucleate (or a fluctuation region will form) for one of the worlds first, say the shadow world. As that bubble grows exponentially in physical size (that is, inflates), both T and T_S decrease exponentially and γ remains constant. When the shadow vacuum energy is converted into radiation the shadow temperature will rise to T_{RH}, and γ increases dramatically. The Universe, however, is still inflating, driven by the vacuum energy of the ordinary sector. Eventually, a bubble (or fluctuation region) forms for the ordinary world within the shadow bubble. During this second phase of inflation, the new bubble grows exponentially in size, while both T and T_S decrease exponentially. When the vacuum energy of the ordinary world is converted into radiation, the temperature of the ordinary world rises to T_{RH}, a temperature which is exponentially larger than the temperature of the shadow world. Thus, γ has been reduced to an exponentially small value by 'double-bubble inflation'. If double-bubble inflation did occur, then the shadow world is exponentially uninteresting. We note that if inflation occurs in the 10-dimensional phase, or during the compactification transition, inflation and $\gamma = 1$ are not necessarily incompatible.

Asymmetric microphysics

Now let us consider the possibility that the symmetry between the ordinary world and the shadow world is broken microscopically. A scenario has been discussed recently where the ten-dimensional string theory is compactified on a six-dimensional, Ricci-flat Calabi–Yau Manifold to the four-dimensional theory $E_8 \times E_6$ (ref. 22). In this scheme, E_6, which eventually breaks down to $SU(3) \times SU(2) \times U(1)$, is the gauge group of the ordinary world and E_8 is the gauge group of the shadow world. (Here SU(3) is the gauge group of the strong interactions (QCD), and $SU(2) \times U(1)$ is the gauge group of the electroweak interactions.)

Once again we will use the entropy ratio of the two worlds, γ, to quantify the macroscopic asymmetry. However, when the microphysics of the worlds is not identical, g_{*S} is not necessarily equal to g_*, and so $\gamma = 1$ does not correspond necessarily to $r = T_S/T = 1$. Nevertheless, the entropy ratio is somewhat more useful than the temperature ratio in that it remains constant in the absence of entropy production, whereas the temperature ratio varies whenever g_{*S}/g_* does

$$r = (T_S/T) = \gamma^{1/3}(g_*/g_{*S})^{1/3}$$

We note that when the microphysics of the shadow world is not identical to that of the ordinary world, there are additional means (other than inflation) for changing the entropy ratio γ. They include the very out-of-equilibrium decay of a massive particle species[23–25] or a phase transition that is only mildly inflationary (for example, an entropy increase of $<10^6$ during the $SU(2) \times U(1) \rightarrow U(1)$ transition).

In the case of asymmetric microphysics, the very stringent nucleosynthesis bound can be evaded even if the two worlds have identical initial entropies. Recall that nucleosynthesis bounds $g_{\rm eff}$ to be ≤ 13. If we assume that the expansion of the Universe has been isentropic since the beginning, then $g_{\rm eff}$ is given by

$$g_{\rm eff} = g_*(1 + \gamma^{4/3}(g_*/g_{*S})^{1/3}_{\rm BBN})$$

where BBN denotes the value at big-bang nucleosynthesis, that is, when the temperature of the ordinary matter is O(1 MeV). The primordial nucleosynthesis constraint $g_{\rm eff} \leq 13.0$ results in a lower bound on $(g_{*S})_{\rm BBN}$

$$(g_{*S})_{\rm BBN} \geq \gamma^4 \begin{cases} 103 & N_\nu = 2 \\ 1{,}172 & N_\nu = 3 \\ 1.95 \times 10^5 & N_\nu = 4 \end{cases}$$

If the E_8 of the shadow world remains unbroken and the representational content of the shadow world is, as has been suggested, a single $N=1$ gauge supermultiplet, then $g_{*S}=930$ Of course, if γ is <1 (macroscopic asymmetry), the constraint could also be satisfied.

If one writes this constraint in terms of the initial temperature ratio $r_i=(T_S/T)_i$ instead of the entropy ratio γ, the constraint becomes an upper bound on g_{*S}

$$(g_{*S})_i(g_{*S})_{BBN}^{-1/4}\leq(g_*)_i r_i^{-3}(13-g_{*BBN})^{3/4}g_{*BBN}^{-1}$$

where i denotes the value of a quantity at the initial epoch and BBN the value at the epoch of primordial nucleosynthesis. If $(g_{*S})_i=(g_{*S})_{BBN}$, then the constraint becomes

$$(g_{*S})_{BBN}\leq(g_*)_i^{4/3}r_i^{-4}\begin{cases}0.213 & N_\nu=2\\ 0.095 & N_\nu=3\\ 0.017 & N_\nu=4\end{cases}$$

Massive shadow states

In gauge theories, the coupling strengths of particles are not constant, but instead evolve (or 'run') with energy. The evolution of the coupling constant g with energy scale μ is determined by the β-function

$$\mu(\partial g/\partial\mu)=\beta(g)$$

where $\beta(g)$ depends on the particle content of the theory. For the group E_8 with a single adjoint supermultiplet, $\beta(g)=-45g^3/4\pi^2$. If the coupling constant is g_0 at the Planck scale, at an energy scale μ it will be given by

$$g^2(\mu)=g_0^2(1+g_0^2 45\ln(\mu/m_{pl})/2\pi^2)^{-1}$$

If, for instance, $g_0=0.3$, then at $\mu\simeq 10^{-2}\,m_{pl}$ the coupling constant will be of the order of unity. When the gauge coupling reaches order unity in a non-abelian theory, the theory can become confining, that is, the only finite energy states in the theory are bound objects which are neutral under the gauge group, and non-abelian charge is 'confined' to these states. This phenomenon occurs in QCD at an energy scale $\Lambda\simeq O(1\text{ GeV})$: quarks become confined in colour neutral objects, hadrons. The mass scale for the bound states is the energy scale at which the gauge coupling becomes order unity. However, there can be bound states which are significantly lighter (in fact, massless) for example, Nambu-Goldstone bosons, or states which are protected from getting mass by another symmetry. The lightness of the pion (140 MeV) is understood in terms of its being a pseudo Nambu-Goldstone boson.

If the shadow group (or some non-abelian subgroup of it) remains unbroken, some coupling may become strong, say at an energy scale Λ_S, and the shadow sector may become confining. If this does occur, then the typical mass of the physical states would be Λ_S, with the possible exception of massless Nambu-Goldstone particles. In this section we will discuss the various cosmological implications of massive shadow states. We first consider the case where none of the massive states are stable, then the case where at least one massive state is stable. Although our motivation for consideration of these states is the possibility that the shadow sector is confining, our arguments do not depend on the origin of mass for the shadow states.

Consider the case where all the massive confined states can decay into shadow states of zero mass. This is possible only if all conserved quantum numbers carried by the massive states are carried by a massless state into which they can decay. If there are such massless shadow states, the typical decay width for a massive state should be $\Gamma_S\simeq\Lambda_S$. If there are no such massless shadow states, the massive ones can only decay through gravitational-strength interactions to gravitons or ordinary matter. Here, we will only treat the graviton case for which the decay width is $\Gamma_S=\Lambda_S(\Lambda_S/m_{pl})^n$, where $n=4$ for a two body bound state which annihilates to gravitons.

If $\Gamma_S\simeq\Lambda_S$, the massive states decay before they become dynamically important and the story is over. If, however, at least one massive state must decay by gravitational-strength interactions to gravitons the lifetime may be sufficiently lor that the massive state(s) dominates the energy density of th Universe before they decay. When they decay into graviton the gravitons will have an energy density $\rho_g\simeq\Lambda_S T_{SD}^3$, whe T_{SD}^3 is the number density of the massive shadow particles decay. The gravitons will act as shadow matter during nucleosy thesis as they will not thermalize with ordinary matter. At th decay epoch, ordinary matter has an energy density $\rho=T_{SD}^4 r_i^-$ After decay and through nucleosynthesis ρ_g/ρ will remain co stant. Primordial nucleosynthesis requires that ρ_g/ρ be <0 (for $N_\nu=3$); using this we can obtain a bound on Λ_S. Th massive particles decay when the expansion rate of the Univer (inverse of the age of the Universe) equals their decay widt (inverse of the lifetime). Setting $H=\rho^{1/2}\,m_{pl}^{-1}\simeq T_{SD}^2 r^{-2}m_{pl}^{-1}$ equal to $\Gamma_S\simeq\Lambda_S(\Lambda_S/m_{pl})^n$, gives $\rho_g/\rho=r^4\Lambda_S/T_{SD}$ $r_i^3(\Lambda_S/m_{pl})^{(1-n)/2}$. The limit that follows from $\rho_g/\rho<0.2$ is

$$\Lambda_S\geq(5\,r_i^3)^{2/(n-1)}\,m_{pl}$$

$$\Lambda_S\geq 3r_i^2 m_{pl}\quad(n=4)$$

If $r_i=O(1)$, the theory would have to confine at a scale $\Lambda_S\approx m$ for the massive states to be able to decay early enough to avo interfering with nucleosynthesis.

Before leaving the question of decay we would like to cor ment on the possibility that the massive states decay in ordinary matter. In that case, the decays can 'heat up' th ordinary matter and increase the ordinary entropy[25]; constrain follow from nucleosynthesis[25] and baryogenesis[23,24]. Such ve stringent constraints have been derived for the gravitino, particle predicted to exist in supersymmetric theories and whic decays only via gravitational strength interactions[26,27].

Now consider the possibility that at least one massive sta is stable (or very long lived). In this case the only way suc particles can diminish in number is by annihilations. If the are massless shadow states into which the massive state ca annihilate, the annihilation cross section will be $\sigma_A\simeq\Lambda_S^{-2}$. there are no such massless shadow states, annihilation must t via gravitational-strength interactions into gravitons (or possib ordinary matter) with $\sigma_A\simeq\Lambda_S^{-2}(\Lambda_S/m_{pl})^n$, where for two-boc annihilation via graviton exchange $n=4$. If $\sigma_A\simeq\Lambda_S^{-2}$, the rel abundance of massive particles that survive annihilation h been calculated by Wolfram[28] and Steigman[29]. The remainir massive shadow states which escaped annihilation would tod contribute a fraction of the critical density

$$\Omega_S\simeq 10^{29}r_i(\Lambda_S/m_{pl})^2\quad(\sigma_A=\Lambda_S^{-2})$$

where, because of the inherent uncertainties, we have ignore factors of g_*, g_{*S}, a logarithmic correction and the dependen on the Hubble parameter. The fact that Ω_S must be less than few implies

$$(\Lambda_S/m_{pl})\leq 3\times10^{-15}r_i^{-1/2}\quad(\sigma_A=\Lambda_S^{-2})$$

If the massive states can only annihilate into gravitons, then th annihilation rate is always much less than the expansion ra and the abundance of the massive states is not significant reduced by annihilation. In this case the present density of th massive states will be

$$\Omega_S=10^{27}\gamma(\Lambda_S/m_{pl});\qquad(\sigma_A=\Lambda_S^{-2}(\Lambda_S/m_{pl})^4)$$

Requiring $\Omega_S\leq O(1)$ implies that

$$\Lambda_S/m_{pl}\leq 10^{-27}\gamma^{-1}$$

To summarize the results of this section, if the decay of th massive confined states cannot occur through strong shado forces, then for these states to avoid interfering with primordi nucleosynthesis, Λ_S/m_{pl} must be $\geq 3r_i^2$. If this inequality is n satisfied, or if some quantum number forbids decay, then th massive states must diminish in number by annihilation, avoid contributing too much mass density at the present epoc Λ_S/m_{pl} must be $<3\times10^{-15}r_i^{-1/2}$ if there are massless confine states, or Λ_S/m_{pl} must be $<10^{-27}\gamma^{-1}$ if there are no massle confined states. If one of the annihilation bounds is saturate 'shadow relics' would be the dark matter and provide $\Omega_{total}\simeq 1$.

Conclusion

The effect of shadow matter is hard to detect in everyday life; the reader could be living in the middle of a shadow mountain or at the bottom of a shadow ocean. But it would have many effects in the early and contemporary Universe. We have shown that an exact mirror Universe is precluded by primordial nucleosynthesis. Our constraints, however, do not eliminate the possibility that shadow matter plays an interesting role in the evolution of the Universe.

Rearrangement of nitrogen fixation genes during heterocyst differentiation in the cyanobacterium *Anabaena*

James W. Golden, Steven J. Robinson* & Robert Haselkorn

Department of Molecular Genetics and Cell Biology, The University of Chicago, Chicago, Illinois 60637, USA

Nitrogen fixation by the cyanobacterium Anabaena *is carried out in heterocysts, specialized, non-dividing cells which differentiate under conditions of ammonia or nitrate deprivation. In* Anabaena, *heterocyst differentiation is accompanied by rearrangement of some nitrogen fixation genes. A site-specific recombination between an 11 base-pair direct repeat sequence flanking the* nifK *and* nifD *genes removes 11 kilobases of intervening DNA, resulting in juxtaposition of the two genes and an alteration of the* nifD *protein-coding sequence.*

OVER 30 years ago, McClintock suggested that a mobile genetic element inserted next to a specific gene could alter the time at which the gene was activated during development[1]. Several examples of genome rearrangements occurring either spontaneously at low frequencies or under the control of external or developmental cues have been identified subsequently, the best example of a developmentally regulated rearrangement being that of vertebrate immunoglobulin genes[2]. Other rearrangements have been described in some detail in the lower eukaryotes trypanosomes and yeast[3,4].

Genome rearrangements, termed recombinational switching, have been described in three related prokaryotic systems: *Salmonella* flagellar antigen phase variation and the host range variation of bacteriophages Mu and P1 (refs 5, 6). In each of these systems, a section of DNA is inverted by site-specific recombination in short inverted repeat sequences flanking the section. The recombination is catalysed by a recombinase encoded by DNA adjacent to one of the inverted repeats. Inversion, and consequently expression of alternate genes, is controlled by factors such as the level of recombinase. Inversion does not seem to be regulated in response to environmental cues. Transposable elements of the TnA class encode an enzyme, the product of the *tnpR* gene, that resolves cointegrate structures by deleting a section of DNA between direct repeats[7]; *tnpR* regulates its own expression but does not respond to environmental cues. The integrated form of bacteriophage λ, however, has developmentally regulated site-specific recombination[8]. When repression is lifted in response to environmental cues, the *int* and *xis* genes are transcribed. These, together with host factors, promote site-specific recombination between direct repeats in *attL* and *attR*, resulting in excision of circular λ DNA and initiation of lytic development.

We show here two developmentally regulated rearrangements of DNA adjacent to the nitrogen fixation (*nif*) genes of *Anabaena* 7120, a filamentous cyanobacterium. One rearrangement corresponds to the excision of DNA from the chromosome, resulting in the formation of an 11-kilobase (kb) circular molecule. The other, bringing DNA to a new location adjacent to a *nif* gene, could result from a deletion, inversion or transposition. These rearrangements are specific to the differentiation of heterocysts and are triggered by the environmental cue of nitrogen deprivation.

Heterocysts

Heterocysts differentiate at regular intervals (approximately every tenth cell) along filaments of *Anabaena* deprived of ammonia or nitrate[9] and provide an anaerobic microenvironment for nitrogen fixation. The ultimate product of nitrogen

* Present address: Botany Department, University of Massachusetts, Amherst, Massachusetts 01003, USA.

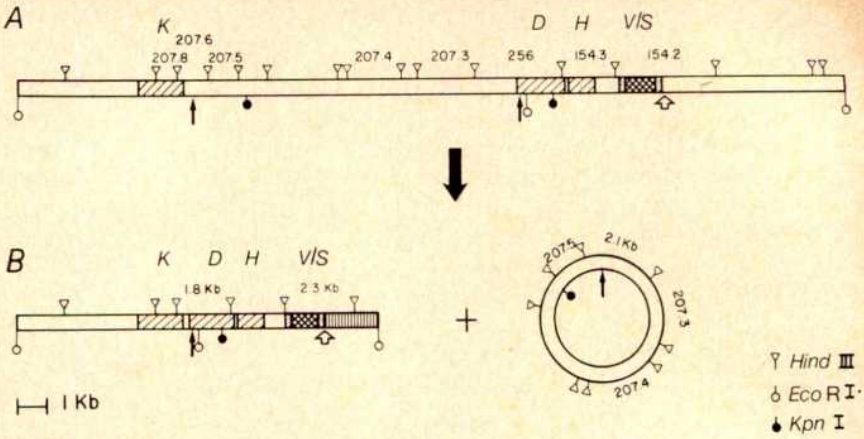

Fig. 1 Organization of nitrogen-fixation genes in *Anabaena* vegetative cell[11] and heterocyst DNA. *A*, Two contiguous *Eco*RI fragments in vegetative cell DNA containing the genes *nifK*, *nifD*, *nifH* and *nifV* or *S*. *B*, In heterocysts, the DNA is rearranged such that *nifK* and *nifD* are adjacent on the chromosome; the intervening DNA is excised from the chromosome and is found as a circle. A second rearrangement places new sequences near the *V/S* gene. The sequence originally to the right of the *V/S* gene has moved to an unknown location in heterocyst DNA. The *nifK*, *nifD* and *nifH* genes have been sequenced and their coding regions are shown[15–17]. The *nifV/S* gene has not been completely characterized, but is known to be homologous to the *nifV/S* region of *Klebsiella*. The approximate location of this homology is shown by cross-hatching[11]. *Hin*dIII restriction fragments described in the text are labelled. The position of 11-bp direct repeats involved in the excision of 11 kb between *nifK* and *nifD* are indicated by solid arrows. An open arrow indicates the approximate position of the breakpoint involved in the rearrangement near the *nifV/S* gene.

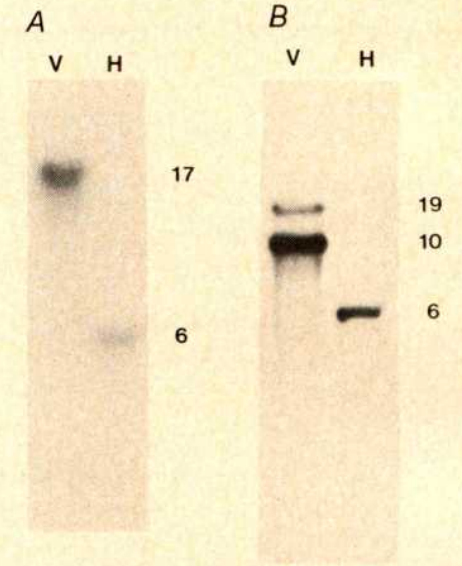

Fig. 2 Rearrangement of heterocyst DNA near the *nifK* and *nifH* genes. Vegetative cell (V) or heterocyst (H) DNA was digested with *Eco*RI and probed with *A*, 207.8 (*nifK*) or *B*, 154.3 (*nifH*). Sizes of the DNA bands are in kb.

Methods. Heterocyst purification. *Anabaena* 7120 was grown at 23–25 °C in 10 l of modified Kratz/Myers medium containing 2.5 mM $(NH_4)_2SO_4$ as described previously[13]. Filaments from a mid-log culture were collected and the cell pellet resuspended in 10 l of medium without $(NH_4)_2SO_4$ and incubated for 48–60 h. Filaments were collected by centrifugation, the cell pellets were resuspended in 100 ml of 50 mM Tris-HCl, 100 mM EDTA, *p*H 8 and lysozyme was added to 5 mg ml^{-1}. The filaments were incubated at room temperature for 60 min. The following procedures were then performed at 4 °C. The digestion mixture was diluted to 400 ml with 10 mM Tris-HCl, 10 mM EDTA, *p*H 8 (10 mM TE) and SDS was added to 0.5%. The mixture was lightly sonicated to reduce the viscosity and heterocysts were collected by centrifugation at 3,000*g* for 5 min. Debris was removed by resuspending the heterocysts in 10 mM TE and centrifuging at 500*g* for 5 min. Preparation of heterocyst DNA. Purified heterocysts were resuspended in a 25-ml Corex centrifuge tube with 5 vol. 50 mM Tris-HCl, 50 mM EDTA, *p*H 8.0, 0.5% Sarkosyl, and 0.5% Triton X-100 to which was added an equal volume of phenol/chloroform (1:1) and an equal volume of 0.45-mm glass beads. The tube was vortexed vigorously for 5–10 min, followed by centrifugation at 12,000*g* for 10 min. The aqueous supernatant was extracted twice more with phenol/chloroform (1:1), once with chloroform and then precipitated with ethanol. The nucleic acids were resuspended in 6 ml TE to which was added 3 g CsCl. This sample was layered over 2.5 ml of 5.7 M CsCl, 100 mM EDTA and centrifuged in a SW-41 rotor for 12 h at 35,000 r.p.m. RNA pellets through the lower cushion while DNA remains at the interface. The DNA was collected and banded in a CsCl-ethidium bromide gradient, dialysed, and precipitated with ethanol. Vegetative cell DNA was isolated as described previously[11]. Restriction enzymes were used according to manufacturers' recommendations. 1 μg DNA was electrophoresed through a 0.7% agarose gel and blotted onto nitrocellulose paper. Southern blotting and hybridizations were done using standard procedures[25].

fixation, glutamine, is exported to neighbouring vegetative cells and, at the same time, carbohydrate is imported from vegetative cells to provide reductant for nitrogen fixation. Complete differentiation of a vegetative cell into a mature, nitrogen-fixing heterocyst requires ~30 h. Early in differentiation, unique glycolipid and polysaccharide components of the heterocyst envelope are synthesized. Proteases are induced which break down the phycobiliprotein light-collecting apparatus as well as enzymes that fix CO_2. The photosynthetic membranes are reorganized to contain photosystem I units only, thus producing ATP by cyclic photophosphorylation without the generation of O_2 associated with photosystem II. Nitrogenase, hydrogenase and enzymes of the oxidative pentose pathway are induced, together with glutamine synthetase and elements of the transport systems for glutamine and carbohydrate.

Complete differentiation of mature heterocysts is not essential for induction of nitrogenase in *Anabaena* if anaerobiosis is established in another way. This can be accomplished by removal of combined nitrogen, addition of a herbicide to inhibit O_2 evolution by photosystem II, and bubbling the culture with argon. In these conditions, differentiation of *Anabaena* is arrested at the proheterocyst stage[10–13]. Admission of O_2 to such an induced culture results in rapid inactivation of nitrogenase and disappearance of *nif* gene transcripts[12].

Organization of nitrogen fixation genes

The genes encoding the polypeptide components of the nitrogenase complex (*nifH*, *D* and *K*) of *Anabaena* have been cloned from vegetative cell DNA, physically mapped and sequenced[11,14–17]. The physical map differs from that of the corresponding genes in the well-studied bacterium *Klebsiella pneumoniae* in an unexpected way. In *Klebsiella*, these three genes are contiguous and, based on polar insertions, are co-transcribed from a promoter next to *nifH*[18]. In *Anabaena*, the *nifH* and *nifD* genes are contiguous, but *nifK* is separated from *nifD* by ~11 kb (Fig. 1*A*; ref. 11). Another region of *Anabaena* DNA identified by homology to *Klebsiella nif* gene

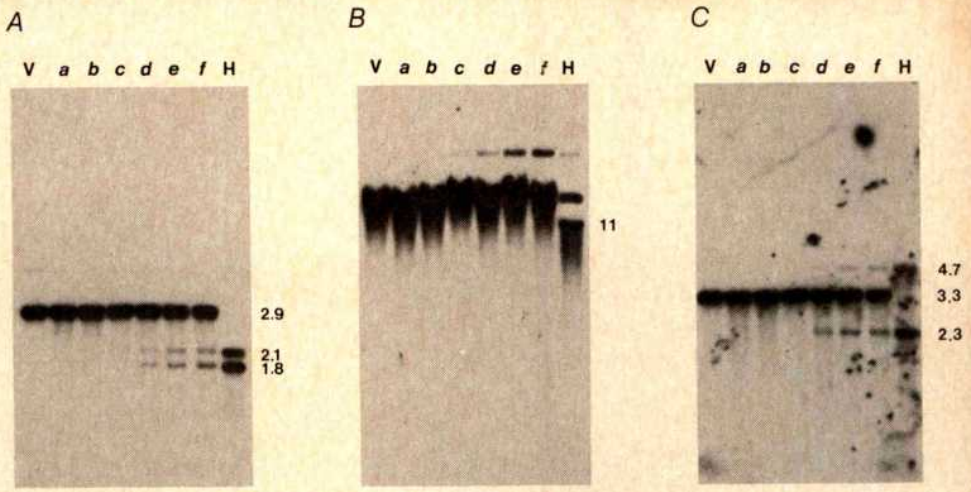

Fig. 3 Time course of DNA rearrangement and location of DNA breakpoints. *Hin*dIII-digested or undigested DNA was fractionated on 0.7% agarose gels and blotted onto nitrocellulose. *A*, *Hin*dIII-digested DNA probed with 256; *B*, undigested DNA probed with 207.3; *C*, *Hin*dIII-digested DNA probed with 154.2. (See Fig. 1 for a map of the probes.) DNA was isolated from vegetative cells (V), heterocysts (H), and at 6-h intervals during synchronous heterocyst differentiation (lanes *a*–*f*). Lanes *a*–*f* contain total DNA prepared 6, 12, 18, 24, 30 and 42 h after initiation of nitrogen starvation, respectively.

Methods. Mid-log vegetative cells from a 10-l culture containing 2.5 mM $(NH_4)_2SO_4$ were collected, washed and resuspended in 10 l of ammonia-free medium. Samples (1 l) were removed at 6-h intervals (up to 30 h) and at 42 h. The cells were collected by centrifugation, washed once with ice-cold 50 mM Tris-HCl, 50 mM EDTA, *p*H 8, and frozen in a dry ice ethanol bath. DNA was isolated from these cell pellets, which contained both vegetative and differentiating cells, as described in Fig. 2 legend. At 48 h, the cells in the last 4 l of culture were collected, heterocysts were isolated as described in Fig. 2 legend and DNA prepared; this DNA is shown in lanes H. Microscopic analysis showed proheterocysts at 18 h; 10% of the differentiated cells had polar bodies at 30 h.

probes is located ~1 kb to the right of *nifH* (Fig. 1*A*); this region contained 700 base pairs (bp) that are homologous to the *Klebsiella nifV* or *nifS* gene and has been termed *nifV/S*[11].

Transcription of the region of *Anabaena* DNA shown in Fig. 1*A* was studied by preparing RNA from cells induced for nitrogenase anaerobically. RNA from such cells hybridized with cloned DNA fragments containing *nifK*, *nifHD* and *nifV/S*, but not detectably with any of the DNA between *nifK* and *nifD*, with the possible exception of fragment 207.3 (Fig. 1*A*; hybridization to this fragment was about twice background[11]). The absence of transcripts from the intervening DNA suggests that *nifK* and *nifHD* are transcribed independently under anaerobic conditions. However, we show below that late in heterocyst differentiation the heterocyst DNA is rearranged so that the *nifD* and *nifK* genes are brought together on the chromosome by excision of the intervening DNA, allowing their coordinate transcription.

Heterocyst DNA

Heterocysts can be separated from vegetative cells because of their resistance to lysozyme and physical disruption. These physical characteristics have been an obstacle to the isolation of heterocyst DNA. A procedure originally developed for the preparation of heterocyst RNA, however, was observed to yield relatively high relative molecular mass (M_r) DNA (>20 kb) from purified heterocysts. Figure 2 shows the results of hybridizing *Eco*RI-digested vegetative cell and heterocyst DNA with two probes: 207.8, entirely within *nifK*, and 154.3, containing all of *nifH* and some 5′ flanking sequence (Fig. 1). The 17-kb band containing *nifK* in vegetative cell DNA is reduced to 6 kb in heterocyst DNA (Fig. 2*A*). Although there are other explanations, we show below that this decrease results from excision of 11 kb (see Fig. 1) from the 17-kb fragment. The probe 154.3 identifies two *Eco*RI bands in vegetative cell DNA (Fig. 2*B*). The 10.5-kb band contains part of *nifD* and a region homologous to the *nifV* or *nifS* genes of *Klebsiella*, as well as *nifH*[11]. The 19-kb band contains a second region homologous to *nifH*[11]. In heterocyst DNA, the 10.5-kb band is reduced to 6 kb (Fig. 1). The 19-kb band also appears to have disappeared, but the heterocyst DNA is sufficiently sheared before restriction endonuclease digestion such that it cannot yield 19-kb fragments with two *Eco*RI ends. Probing with the entire 19-kb *Eco*RI fragment cloned from vegetative cell DNA of other enzyme digests (for example, *Hin*dIII, *Cla*I) of heterocyst DNA has failed to detect evidence for rearrangement on either side of the second *nifH* gene (data not shown).

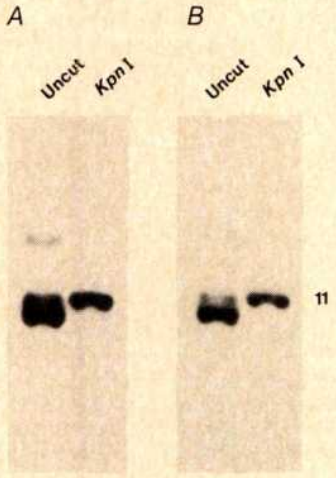

Fig. 4 Rearrangement results in the formation of an 11-kb circle. Undigested and *Kpn*I-digested heterocyst DNA was size-fractionated on a 0.7% gel, blotted onto nitrocellulose and probed with *A*, 207.4 and *B*, 207.5. Probes 207.4 and 207.5 are to the right and left, respectively, of the single *Kpn*I site found in the excised circle (Fig. 1).

Methods. Unlike the gels shown in Figs 2 and 3, the 0.7% agarose gel was run at low voltage (1.5 V cm^{-1}) in the absence of ethidium bromide for 21 h. After hybridization with probe 207.4 and exposure to film, the probe was removed by washing for 5 min in H_2O at 100 °C. Probe removal was confirmed by autoradiography and the blot was then hybridized with probe 207.5.

Heterocysts stain poorly with Feulgen's reagent; it has been suggested that they contain no DNA[9]. Thus it seemed possible that, during differentiation, the vegetative cell DNA was shattered in a manner analogous to that of the DNA in macronuclei of certain protozoa[19]. Probing with other cloned genes, however, showed no evidence of breakage in heterocyst DNA. These probes included the *Eco*RI fragment to the left of *nifK*, the *psbA* gene coding for the M_r 32,000 (32K) thylakoid membrane protein[20] and the *glnA* gene coding for glutamine synthetase[13]. For each probe, the pattern of hybridization with heterocyst DNA was identical to that of vegetative cell DNA (data not

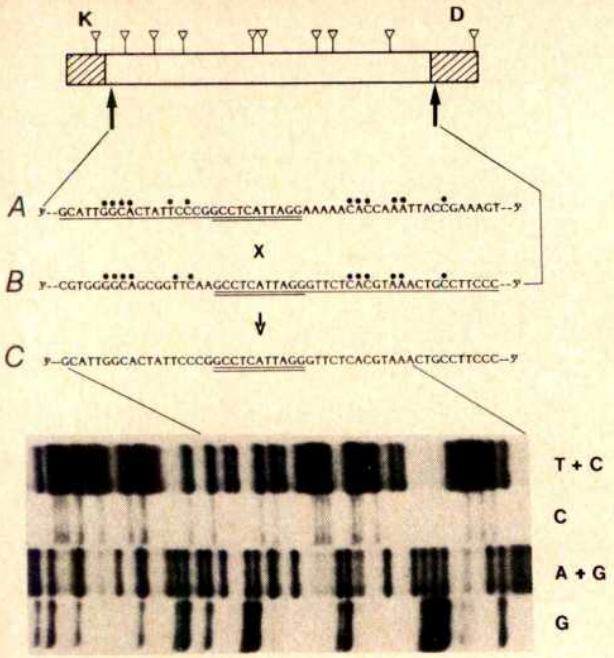

Fig. 5 DNA sequence of the fused chromosome between *nifK* and *nifD* after excision of the 11-kb fragment. The lower sequence (*C*) is that of the rearranged chromosome which contains one copy of the 11-bp direct repeat (double underline) flanked by sequences found 5′ to the *nifK* gene and within the 3′ coding region of *nifD*. The vegetative cell sequences (*A*, *B*) are shown above the rearranged sequence with the portions that are joined in the heterocyst chromosome underlined. The positions of the 11-bp direct repeats in the vegetative cell chromosome are indicated by arrows. Dots indicate partial homology in the sequences flanking the 11-bp direct repeat.

Methods. Heterocyst DNA was cloned into the vectors λgt7ara6 and λL47.1. DNA was partially digested with *Sau*3A and size-fractionated on a 0.8% low-gelling temperature agarose gel. Fragments between 8 and 20 kb were isolated and ligated into *Bam*HI-digested λL47.1 arms, packaged *in vitro*, and amplified[25]. A second library was constructed from a complete *Eco*RI digest of heterocyst DNA ligated into *Eco*RI-digested λgt7ara6 arms. This library was screened without amplification. Several clones containing the excison were obtained from the λL47.1 library using probes 207.6, 207.3 and 256. This library failed to yield clones of the rearranged chromosome. The λgt7ara6 library was screened with probes 207.8 and 154.3, yielding clones of the *Eco*RI fragments containing the *nifK* and *nifH* genes, respectively. The *Eco*RI fragments were subcloned into the plasmid vector pBR328. Breakpoints were localized in the cloned DNA by probing Southern blots of restriction digests with the known breakpoint probes 256 and 207.6. Sequence analysis was by the method of Maxam and Gilbert[26] as modified by Smith and Calvo[27].

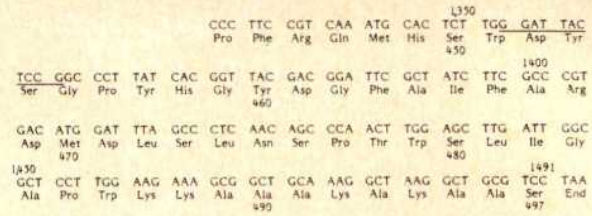

Fig. 6 Sequence of the α-subunit of *Anabaena* dinitrogenase in the rearranged *nif* region of heterocysts. The underlined nucleotide sequence is the 11-bp direct repeat (5′→3′) at the site of recombination. This corresponds to nucleotides 1,353–1,363 of the published *nifD* sequence[17] and to nucleotides 200–210 in the 5′ region of *nifK*[16]. Numbers in the figure refer to the start of the *nifD* ORF[17]. The amino acids starting with Gly 455 replace 26 amino acids predicted from the sequence of *nifD* determined on vegetative cell DNA[17]. Following the TAA stop codon there are 199 bp before the ATG that starts the *nifK* ORF.

shown). The faint banding pattern seen in ethidium bromide-stained gels of restriction digests showed no apparent differences between vegetative cell and heterocyst DNA.

As the changes shown in Fig. 2 are specific for the *nif* genes, we next asked when they occur during heterocyst differentiation. For this purpose a culture was synchronously induced aerobically and samples were removed every 6 h. DNA was isolated from total cells (10% of which were differentiating), from non-induced vegetative cells and from heterocysts separated from vegetative cells (48 h after induction), as described in Fig. 2 legend. Each DNA preparation was then digested with *Hin*dIII (or not digested), electrophoresed and hybridized with nick-translated probes. Figure 3*A* shows the *Hin*dIII-digested DNA probed with 256, which contains the right-hand breakpoint of the excised 11-kb segment (Fig. 1). Vegetative cells show a single 2.9-kb *Hin*dIII band. The major band at 2.9 kb remains at all time points because of non-differentiating vegetative cells. The two new bands in heterocysts arise from the newly fused chromosome (1.8 kb) and the joined ends of the excised circle (2.1 kb). The identity of these bands was confirmed by sequence analysis. In heterocyst DNA, the same two bands are identified by 207.6, the *Hin*dIII fragment containing the left-hand breakpoint 5′ to the *nifK* gene (data not shown).

Figure 3*B* shows undigested DNA probed with 207.3, a *Hin*dIII fragment located entirely in the excised segment (Fig. 1). The presence of multiple discrete bands in undigested DNA from heterocysts indicates that this DNA is circular. Figure 4 shows the heterocyst DNA undigested or digested with *Kpn*I, a restriction enzyme for which there is a single site in the excised segment[11]. The two probes used in Fig. 4 are located on either side of the *Kpn*I site (see Fig. 1); as they identify the same single band in the *Kpn*I-digested DNA, the multiple bands in undigested DNA must correspond to isomeric or polymeric forms of the same circular molecule. Different preparations of heterocyst DNA show different ratios of these various forms. For convenience, we shall refer to the 11-kb sequence as an 'excison'. The excison sequence is unique in *Anabaena* 7120 DNA (Figs 3*A*, 4).

The DNA samples in Fig. 3*C* were digested with *Hin*dIII and probed with 154.2, which contains the breakpoint to the right of *nifV/S* (Fig. 1). Vegetative cell DNA showed the expected single 3.3-kb band, whereas in heterocyst DNA this band was replaced by two bands of 4.7 and 2.3 kb. The new genomic location of the 4.7-kb *Hin*dIII fragment is unknown. The 6-kb *Eco*RI fragment identified in heterocyst DNA by the probe 154.3 (see Fig. 2) has been cloned (see Fig. 5). This clone contains the left portion of 154.2 on a 2.3-kb *Hin*dIII fragment, showing that this fragment in heterocyst DNA contains the *nifV/S* gene. The 6-kb *Eco*RI fragment contains, at its right end, ~2 kb of DNA originally located at least 15 kb away in vegetative cell DNA (Fig. 1*B*). This was determined by using the small *Hin*dIII/*Eco*RI fragment from the right end of the 6-kb *Eco*RI fragment (Fig. 1*B*) as a probe on restriction digests of vegetative cell DNA. This fragment identified a 3.5-kb *Eco*RI fragment and a ~16-kb *Hin*dIII fragment (data not shown). Comparison of these results with the known restriction map of the *nif* region of *Anabaena*[11] indicates that the new DNA originates at least 15 kb away from the *nifV/S* gene in vegetative cell DNA.

Comparison of the three parts of Fig. 3 shows that the excision and circularization of the 11-kb segment, the fusion of *nifD* and *nifK* and the rearrangement to the right of *nifV/S* occur simultaneously within the time resolution of the experiment. The rearrangements are late events in heterocyst differentiation, as is the appearance of nitrogenase activity[9]. Early proheterocysts, identified by their morphology, are first seen at 18 h, when the rearranged DNA fragments are detected faintly. At 24 h, the rearrangements are clearly visible, corresponding to the time at which *nifH* message can first be detected (data not shown).

Sequence of *nifK/nifD* rearrangement

To elucidate the mechanism of the excision between *nifK* and *nifD*, the two fragments of heterocyst DNA containing the breakpoints (Figs 1, 3) were cloned and sequenced. Two different clones of the excison were obtained from a partial *Sau*3A digest of heterocyst DNA cloned in the vector λL47.1 (ref. 21). Both of these clones contained 11-kb inserts, which included the 2.1-kb *Hin*dIII junction fragment formed from the right portion of 207.6 and the left portion of 256 (Fig. 1). Restriction analysis showed that the two clones were circularly permuted, differing only in the *Sau*3A site originally digested. Further restriction analysis comparing the 2.1-kb junction fragment with 207.6 and 256 was used to localize the junction for sequencing.

The junction created in the chromosome by the excison was isolated from a library of *Eco*RI fragments of heterocyst DNA cloned in the vector λgt7ara6 (ref. 22). The previously determined sequence of the junction in the excised DNA was used to predict the site of the junction on the chromosome. A portion of one sequencing gel, corresponding to the fused chromosome, is shown in Fig. 5. The new fragment (Fig. 5*C*) contains *nifK* 5′ flanking sequence[16] up to the 11-bp sequence 3′-GCCTCAT-TAGG-5′ (underlined in *A*) and then it contains nucleotides within what was believed to be *nifD* coding sequence (underlined in *B*)[17]. The junction fragment from the excison contains the reciprocal sequence with one copy of the 11-bp sequence. Thus, the excision event is a conservative site-specific recombination between 11-bp direct repeats separated by 11 kb in the vegetative cell chromosome.

The nucleotide sequence of the *Anabaena nifD* coding region was determined previously using cloned vegetative cell DNA[17]. The open reading frame (ORF) predicts a polypeptide of 480 amino acids. After excision, a new ORF is created by the fusion of the *nifD* open reading frame to *nifK* 5′ flanking sequence. This new ORF codes for 497 amino acids, of which the C-terminal 43 residues replace 26 C-terminal residues of the vegetative cell ORF (Fig. 6). The new ORF predicts an amino-acid sequence for the *Anabaena* nitrogenase α-subunit that is much more homologous to the *nifD* proteins of parasponia *Rhizobium* ANU289 (ref. 23) and cowpea *Rhizobium* IRc78 (ref. 24). Before the rearrangement, 1 of 26 C-terminal residues matches between *Anabaena* and *Rhizobium*; after the rearrangement, 28 of 43 residues are identical. Thus, it seems that the 11-kb element interrupts the real *nifD* coding region in *Anabaena*. The rearranged heterocyst chromosome allows the transcription of the *nifH, D* and *K* sequences as a polycistronic message, as in *Klebsiella*. Probes for *nifH*, *nifD* and *nifK* all identify a 4.7-kb band (with smaller transcripts) in RNA isolated from cells induced for nitrogenase, both aerobically and anaerobically (data not shown).

Why rearrange?

The two rearrangements of the *Anabaena* chromosome described here are associated with the cellular differentiation of heterocysts induced by starvation for combined nitrogen. The rearrangements are quantitative, in the sense that they occur in every genome of the differentiating cells. They are late events in the differentiation; Fig. 3 shows the first evidence for rearrangement at 18 h, while the morphological changes that characterize proheterocysts are mostly complete by 12 h. Establishment of anaerobiosis may be a necessary prerequisite for the rearrangements.

We do not yet know the functional consequence of the *nifV/S* gene rearrangement. The excision resulting in fusion of the *nifK* and *nifD* genes, however, creates an operon whose 4.7-kb transcript contains sequences of the *nifH* gene as well. It may be advantageous, and perhaps even necessary, to excise the 11-kb sequence in order to express the *nif* structural genes in *Anabaena*. The function of the 11-kb sequence in vegetative cells is unknown; it does not seem to be required for the prevention of the synthesis of nitrogenase as control of transcription initiation at the *nifH* promoter is sufficient for that purpose. We considered the possibility that a functional gene was created on the 11-kb circle by fusion of the ends of the excison, but no ORF exists in 500 bp on either side of the 11-bp repeat on the circle.

Excision of the 11-kb segment involves conservative recombination between directly repeated sequences, analogous to the excision of bacteriophage λ DNA from a lysogen[8]. Extending this analogy, it is possible that the excision is controlled by regulating synthesis of the excision enzyme. The mechanism by which the gene encoding this enzyme is regulated remains unknown, as does the regulation of transcription from the *nifH* promoter.

We are not aware of any cellular phenomena among prokaryotes or eukaryotes that display the features described here for the *Anabaena nif* gene rearrangement; that is, an environmentally triggered excision resulting in operon fusion. The closest analogy is the excision of bacteriophage λ from a lysogen. In this example, however, the elaborate controls of lysogeny have been selected to benefit the virus, rather than the host. The results presented here suggest that the 11-kb sequence confers a selective advantage on its host; how it does so remains to be discovered.

Quasar 4C39.25 is not contracting

J. M. Marcaide*, N. Bartel†, M. V. Gorenstein†, I. I. Shapiro†, B. E. Corey‡, A. E. E. Rogers‡, J. C. Webber‡, T. A. Clark§, J. D. Romney‖ & R. A. Preston¶

The milli-arc second radio structure of the quasar 4C39.25 has previously been described as consisting of two components whose angular separation remained constant at ~2 marc s, whereas their relative flux densities varied with time[1–3]. This behaviour is in marked contrast to other similar sources whose radio structures expand superluminally[4]. Recently, Shaffer[5] suggested that 4C39.25 may have been contracting superluminally in the period 1979–82. Here, based on our map of this source made from VLBI observations in 1983 at λ3.6 cm, we conclude that this conjecture is not correct. We find three distinct components in the structure, two of which are separated by 2.0 marc s, whereas the third, presumably new and not previously reported, is situated between the other two. It is possible either that the third component is stationary and that its flux density has rapidly increased to render it visible, or that it has recently been ejected from the westernmost component.

Our VLBI observations of 4C39.25 at a radio wavelength of λ3.6 cm took place on 10 May 1983. We recorded data for 2 min at 30 min intervals for over 7 h. We used Mark III instrumentation[6], a synthesized bandwidth of 28 MHz, right-hand circular polarization and the following array of eight radio telescopes: 100 m, at Effelsberg, FRG; 64 m, at Robledo, Spain; 20 m, at Onsala, Sweden; 37 m, at Westford, Massachusetts, USA; 43 m, at Green Bank, West Virginia, USA; 25 m, at Fort Davis, Texas, USA; 64 m, at Goldstone, California, USA; and 40 m, at Big Pine, California, USA. Hydrogen maser frequency standards were used at each site. The data were processed at the Mark III processor of the Max-Planck-Institut für Radioastronomie in Bonn, FRG. After calibration of the visibility amplitudes[7] we produced a map of the source using standard hybrid mapping techniques. To improve the relative calibration between the antennas we used the Cornwell and Wilkinson[8] algorithm of self-calibration, which, given the large number of antennas available, worked very well. The resulting map is presented in Fig. 1.

We have labelled the components in Fig. 1 as *a*, *b* and *c*. The separation of the centre of component *c* from that of *a* is 2.0 ± 0.1 marc s; the separation of *b* from *a* is 1.4 ± 0.1 marc s. During the 1970s the structure was well characterized at λ2, λ2.8, λ3.6 and λ6 cm by two components separated by 2 marc s[1–3]. More recently, Shaffer[5] mapped the source from observations at λ2.8 and λ3.6 cm and found it to consist of two components, their angular separation significantly <2.0 marc s, the western component being elongated. As a result, he conjectured that the source may be contracting, but he also recognized that motion in a source could be mimicked by the appearance of a new component. From our result we infer that the elongation of Shaffer's western component resulted from a blending of our two components *b* and *c*, and conclude that our *a* and *c* components correspond to those observed in the 1970s, that *b* is a new component and that the source has, therefore, not contracted.

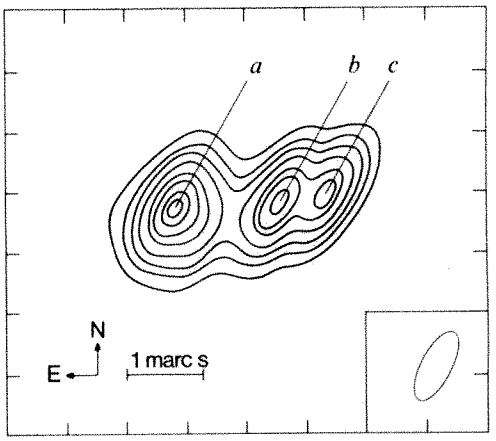

Fig. 1 Hybrid map of 4C39.25 made from λ3.6-cm data from epoch 10 May 1983. The restoring beam used is shown boxed in the lower right-hand-side corner. The contours specified are 4, 10, 18, 30, 50, 65, 85 and 95% of the peak brightness temperature.

The origin of component *b* is not clear: it could be a stationary component whose flux density has rapidly increased or it may have been ejected, say, by component *c*. Curiously, according to H. D. Aller and M. F. Aller (personal communication) the flux density of 4C39.25 has been decreasing steadily at wavelengths from λ2 to λ6 cm since 1980 with no obvious new outbursts, whereas the linear polarization at λ2 cm has increased from 1 to 2.5% since 1983. We cannot distinguish between the two proposed alternatives without the detailed analysis of other VLBI observations of comparable resolution made at different epochs. A detailed comparison of the results from our May 1983 observations, with observations at λ2.8 cm from June 1982 with similar resolution (which confirm the existence of the new *b* component) and with observations at λ6 cm from July 1982, will be presented elsewhere.

If the component *b* is stationary, 4C39.25 would surprise us again by exhibiting a milli-arc second morphology quite different from that of other radio sources whose radio spectra and variability characteristics are shared by 4C39.25. On the other hand, if component *b* has been ejected from component *c*, then its apparent motion may well be found to be superluminal. Moreover, it may overtake component *a*, as Shaffer[5] noted. Such a possibility would be rather exciting, offering a unique opportunity to test different hypotheses on the nature of the components of compact radio sources.

We thank Mr. H. Blaschke for his assistance on the Mark III processor. J.M.M.'s research at the Max-Planck-Institut für Radioastronomie was supported in part by NASA-JPL Contract 956542. The Center for Astrophysics research was supported in part by the NSF.

The radio jet of the quasar 3C273

C. Flatters & R. G. Conway

University of Manchester, Nuffield Radio Astronomy Laboratories, Jodrell Bank, Cheshire SK11 9DL, UK

Although 3C273 was was one of the first quasars to be identified[1], the extended feature 3C273A, which can be detected at radio[2,3], optical[4,5] and X-ray wavelengths[6], remains an enigma. The source is an extreme example of a one-sided radio source (3C273A has no detectable counter component[2]) and this fact, coupled with the presence of the optical emission, makes it unlikely that 3C273A is a normal (slow-moving) radio lobe. Superluminal transverse motion[7,8] at milliarc second scales shows that relativistic velocities occur within the quasar itself, 3C273B; it is an open question (see ref. 2) whether these velocities persist out to 3C273A. It has been widely suggested[9,10] that Doppler beaming causes the one-sidedness of this and similar sources by suppressing the receding half of the source, but there are no spectral lines by which the Doppler shift of 3C273A could be directly measured. Thus, any (indirect) indication of the velocity is of interest. We present here new MERLIN observations of the brightness and polarization of the radio jet of 3C273 at a resolution of 0.35 arc s. One of the most marked features of our new map, the high polarization found within the head of the source, is hard to explain. If the motion is indeed fast, then relativistic aberration should be taken into account; we suggest that this leads to a natural explanation of the high observed polarization.

The MERLIN interferometer[11] has hitherto only been able to map brightness distributions, but we have now added the facility of mapping in linear polarization (to be described more fully elsewhere). In brief, a map of brightness is produced first, using the hybrid-mapping procedure of Cornwell and Wilkinson[12], and the relative amplitudes and phases of the polarization data[13] are then used to construct the map of complex polarization $P = (Q + jU)$. The first polarization map, made from observations taken in April 1984, shows 3C273A at 1,666 MHz (λ 18 cm) with a resolution of 0.35 arc s (Fig. 1). The intensity data agree well with observations (A. R. Foley and R. J. Davis, personal communication) taken with MERLIN some three years earlier. Because MERLIN has few short-spacing baselines, it is difficult to map low-brightness regions at 18 cm, and neither Fig. 1 nor the earlier 18-cm map includes the fainter portions of 3C273A, which can be seen on the MERLIN map[2] at 73 cm, or on the Very Large Array (VLA) map[3] at 6 cm. Although the core, 3C273B, does not appear on the map, it has a flux density at this epoch of 31.0 Jy and a polarization of $1.7 \pm 0.1\%$ in position angle (p.a.) $151 \pm 8°$ (E-vector). These values have changed little since 1973 (R. J. Davis, personal communication).

The brightest component of 3C273A, labelled 2 in Fig. 1 (numbering from the outer end of the jet), has a linear polarization of $25 \pm 2\%$. The mean B-vector is at p.a. $128 \pm 3°$, that is, 86° to the main axis of the jet, here taken as 42°. In contrast, the precursor, component 1, has a low polarization, $\simeq 2 \pm 2\%$ (the uncertainty is caused by the possibility of side lobes from component 2). The magnetic field goes goes through a transition at or near component 3, and at all points further back than component 3 the field is parallel to the jet, to within a few degrees. Component 3 itself, which lies at an angle to the main axis, marks the start of the sinusoidal oscillation of the ridgeline (the 'wiggle') noted in refs 2 and 3.

In all these respects Fig. 1 shows good agreement both with the 6-cm VLA map[3] and with an unpublished VLA map at 2 cm (R. A. Perley, personal communication). It is also consistent with earlier observations[14] made with single baselines at several wavelengths. The rotation measure of component 2 is $+1.80 \pm 0.20$ rad m^{-2}, and any variations over the map seem to be $\ll 0.5$ rad m^{-2}. (The value of rotation measure corresponds to 3° of rotation at λ 18 cm, which has been allowed for in determining the magnetic position angles.) We are undertaking a full comparison of all the available radio data and will submit a more detailed discussion elsewhere; our purpose here is to discuss the unexpectedly high polarization of component 2.

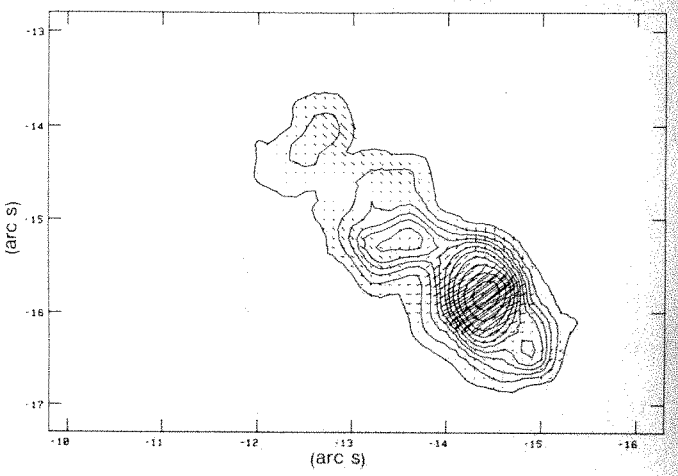

Fig. 1 MERLIN map of the radio jet in 3C273 at 1,666 MHz. The core (3C273B) is at the origin of coordinates, off the top-left of the map. The resolution is 0.35 arc s and the contours represent 0.2, 0.4, 0.6, 0.8, 1.0, 1.3, 1.6, 2.0, 2.5, 3.2, 4 and 5% of the brightness of the core, which is 31.5 Jy per beam. B-vectors of polarization (after allowing for a Faraday rotation of 3°) are superimposed on the total intensity contours. A vector 1 arc s long represents a polarized intensity of 530 mJy per beam.

Laing[15] has studied the polarization occurring in plasma that is sheared or compressed anisotropically. The apparent degree of polarization for a Laing sheet (that is, a thin sheet of plasma with the direction of magnetic field confined to the plane of the sheet) varies with aspect angle. If the spectral index is 0.7 as here, a polarization of 25% implies that θ_s, the angle between the line of sight and the normal to the sheet, is 47°. When the compression is partial and the magnetic field less well-ordered, as in a thick sheet, the aspect angle θ_s must be greater than 47°.

This argument seems to be completely at variance with the evidence of superluminal motion, which can only occur if the ejection axis is at a small angle to the line of sight. If Hubble's constant is 100 km s^{-1} Mpc^{-1}, the observed proper motion[7] of 0.76 marc s yr^{-1} at a distance of the source ($z = 0.158$) implies a transverse velocity $\beta_{obs} = 4.6$. The most probable angle to the line of sight is $\theta_0 = \tan^{-1}(1/\beta_{obs}) = 12°$, and for this angle the speed is $0.98c$, with a Lorentz factor $\gamma \simeq 5$. A velocity β_{obs} of 4.6 cannot be observed if θ_0 is 47°.

There are several possible explanations of this apparent paradox:

(1) The superluminal motion may be entirely unconnected with the jet, but we reject this hypothesis on grounds of probability.

(2) The jet axis may be bent from $\theta = 12°$ near the nucleus to 47° in the outer regions. Bends are common in jets, and a bend in position angle of 23° occurs in 3C273B[7,16], about 8 marc s from the core. This explanation therefore cannot be wholly excluded, but because position-angle bends are magnified by foreshortening, the real angle of bend is probably $\leq 5°$, whereas a bend of at least 35° would be needed to obtain $\theta_s = 47°$.

(3) Component 2 may be inclined at an angle to the axis. Hotspots set back from the head are found in other sources[17] and can be interpreted as sites where the active beam intersects the side of a pre-existing cavity[10]. In the process, an oblique shock could be set up, which would account for component 2 if the normal to the shock were more than 35° from the jet axis. For the projection of the magnetic field to appear transverse to the axis, however, the normal to the shock must lie rather exactly in the plane of the jet axis and the line of sight. It is observed in other sources that the projected magnetic fields are invariably aligned parallel with the boundaries of emission; when seen at low resolution, the resultant is either longitudinal or transverse, rarely anything in between[15,17]. The explanation of component 2 as an oblique shock is therefore a specially contrived geometrical solution, which could occur once, but not regularly.

Table 1 Intensities of the three components in the bright head of 3C273 corrected for Doppler beaming

Component	Distance from core (arc s)	Blue-shift	Observed flux density (mJy)	Intrinsic flux density (mJy)
1	22.1	1.2	450	216
2	21.4	3.4	1,500	13
3	20.4	4.0	450	3

We believe that other explanations that could be put forward are less probable than the following suggestion.

(4) The aspect angle may be modified by relativistic aberration. The angle θ_s, calculated above from the polarization, is that measured in the co-moving frame of the source. If component 2 is moving relativistically, aberration changes an inclination angle from θ_{jet} to θ_{obs}, given by $\sin\theta_{jet} = \eta \sin\theta_{obs}$, where η, the Doppler blue-shift, is given by $\eta = \gamma^{-1}(1-\beta\cos\theta_{obs})^{-1}$. If we equate θ_{obs} with $\theta_0 = 12°$ deduced from the superluminal motion and θ_{jet} with $\theta_s = 47°$ deduced from the polarization, we obtain as the Doppler shift of component 2, $\eta \simeq 3.4$. The Doppler shift measured in the frame co-moving with the quasar is larger by a factor $(1+z)_{QSO}$, that is, $\eta = 3.96$. Relative to the quasar the speed of component 2 is $\beta \simeq 0.91$ and $\gamma \simeq 2.4$. If component 2 is partially compressed (a thick sheet) then $\theta_s > 47°$ and the values of β, γ and η given above should be regarded as lower limits.

We may apply these arguments to the precursor, component 1, which we suggest corresponds to the 'working surface' of the beam[10] and moves with the speed of the bow shock. From ram pressure arguments[2] this speed must be sub-relativistic, in the range $0.02 < \beta < 0.3$. It follows that most of the deceleration occurs between component 2 and component 1. If the velocity of component 1 is $\beta = 0.2$, the Doppler shift $\eta = 1.22$, and the inclination angle in the emitting frame $\theta_{jet} \simeq 14°$. The polarization predicted for a Laing sheet would then be 2%, equal to that observed in component 1. Simulation models[18] suggest that the working surface may be curved, in which case one may expect some polarization near the edge, but little in the centre of component 1. This description is entirely consistent with Fig. 1.

In this model, the relative intensities of the different components are altered by the Doppler beaming factor[8] of $\eta^{3+\alpha}$. The Doppler shift of component 3 is not known, but the maximum value consistent with $\theta_0 = 12°$ is 4.7, and if we assume a monotonic deceleration down the jet, η_3 must lie between 4.7 and $\eta_2 = 3.4$. We take $\eta_3 = 4$.

Applying a correction to the co-moving frame using Doppler shifts as above yields the intrinsic intensities given in Table 1, where it can be seen that the precursor is no longer a minor feature in front, but is intrinsically much the brightest component, as may be expected at the site of the greatest deceleration. Components 2 and 3 correspond to secondary features, which, if they were not amplified by beaming, would probably be classed as 'knots' similar to those found in many jets.

We thank A. R. Foley, R. J. Davis and R. A. Perley for data in advance of publication. C.F. thanks the SERC for a studentship.

Computer classification of sea beds by sonar

Z. Reut, N. G. Pace & M. J. P. Heaton

School of Physics, University of Bath, Bath BA2 7AY, UK

Direct sampling of the sea bed is not always feasible and can be unreliable because the samples obtained may not be representative. An alternative approach is to classify the superficial sea bed using the backscattered signal from side-scan sonars. The usual paper display contains less information than the signal creating it, because of its low dynamic range, and interpretation of sediment types is often difficult. There are also problems with statistical analysis of the signals[1]. The usual methods of pattern recognition cannot resolve small-scale features in otherwise homogeneous regions[2] and, although the backscattering strength is a useful quantity, meaningful numerical values can be obtained only with a calibrated system[3]. To overcome these shortcomings we have now developed a spectral analysis method that is insensitive to system gain calibration. The method retrieves information from the signals that is well below the usual power spectrum point, thus effectively widening the system bandwidth, and can discriminate between the signals returned from six sea-bed types.

It can be shown theoretically that the scattered sound field depends on both roughness and hardness of the sediment/water interface[4], but analytical expressions are unsuitable for most practical applications, not so much because of their complexity but because of the difficulty in quantifying roughness (statistically random corrugations) and hardness (mixed boundary conditions) of real sea beds. Although properties of scattered sound fields corresponding to an ensemble of sea-bed patches manifest only indirectly the combined effect of roughness and hardness on the incident sound field, they are nevertheless more suitable for our present semi-empirical approach. The shape of the probability distribution (of the scattered field intensity) does relate to the sea-bed roughness[5], but is not so sensitive to its hardness.

We now consider a side-scan sonar transmitting a rectangular pulse of length T ($\gg T_0$) at carrier frequency $\omega_0 (= 2\pi/T_0)$. Received signal amplitude is proportional to the pressure of the sound field at the transducer. The received signal is a quasi-harmonic stochastic function of time ('reverberation') given by $a(t)\cos[\omega_0 t + \psi(t)]$, where $a(t)$ and $\psi(t)$ are the amplitude and the phase of the signal respectively, which are both assumed to be slowly varying functions of time in comparison with $\cos\omega_0 t$. Our method uses $a(t)$ only and yields numerical features that are invariant under the linear transformation of $a(t)$ and hence independent of the signal d.c. level and gain.

We denote by $a_i(t)$ the signal amplitude within the ith rectangular window ($i = 1, 2, \ldots, n$) of a fixed time duration T_W ($\gg T$). The minimum value of the signal amplitude is set equal to zero so that $a_i(t) \geq 0$. The windows should have no temporal overlaps and can be taken from any number of pings. We further denote by $w(t)$ the time window function (other than rectangular) such that $w(t) = 0$ for $t < T_D$ and $t > T_D + T_W$, where T_D is the initial delay (measured from the instant of transmission). The resulting windowed signal can be written as $g_i(t) = w(t)a_i(t)$.

If the signal is digitized so that N samples are taken in each window with sampling interval Δt, we have $T_W = N\Delta t$. The Nyquist frequency is equal to $\pi/\Delta t$; if ω_B is the highest angular frequency of interest, the Nyquist sampling theorem implies $\Delta t \leq \pi/\omega_B$.

Performing the Fourier transform (operator $\mathcal{F}$) on the windowed amplitude $g_i(t)$ and taking the modulus squared of the resulting complex quefrency amplitudes, the ith power spectrum is obtained as $P_i(\omega) = |\mathcal{F}\{g_i(t)\}|^2$. By averaging n power values at each frequency, we obtain the averaged power spectrum $\langle P(\omega)\rangle = n^{-1}\sum_{i=1}^{n} P_i(\omega)$, where it is assumed that the system

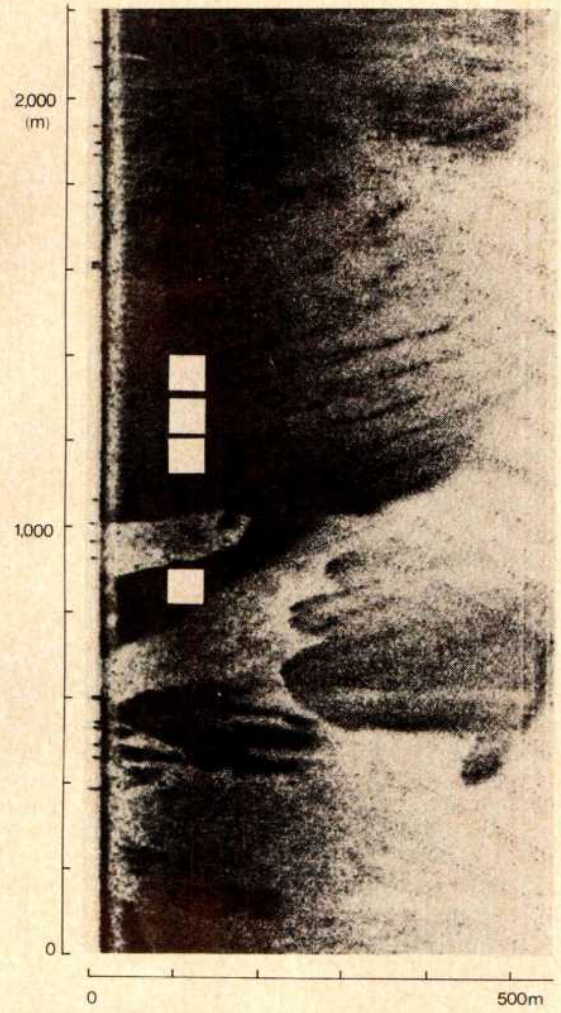

Fig. 1 Side-scan sonar paper record of sand and gravel sea-bed region. Blank squares indicate the approximate locations of four sample areas. The record width corresponds to 550 m range, the zero range being on the left-hand side. Sand and gravel appear as light and dark patches, respectively.

gain remains unaltered during the time taken to receive all n windows.

Performing the Fourier transform on the logarithm of the averaged power spectrum and taking the modulus squared of the resulting complex quantities, the power cepstrum (or simply 'cepstrum') is obtained $C(\tau) = |\mathcal{F}\{\log\langle P(\omega)\rangle\}|^2$, where the time-lag variable τ is called quefrency. The cepstrum, applied to various seismic, speech analysis and machine vibration problems, appears to be more useful in certain cases[6,7] than either the power spectrum or the auto-correlation function. However, we believe it has never been applied to side-scan sonar signals of 'reverberation' type not separating into 'echo' and 'noise'.

We define the power cepstrum integral (cumulative power cepstrum) by $I(\tau') = \int_0^{\tau'} C(\tau)\,\mathrm{d}\tau / \int_0^{T_W} C(\tau)\,\mathrm{d}\tau$, with the variable τ' in the range $\tau_0 \leqslant \tau' \leqslant T_W$, where τ_0 ($\leqslant T$) is a fixed interval.

We introduce two further parameters to characterize the power cepstrum integral, namely, the intercept and the slope at τ_0 given by $D_1 = 1 - I(\tau_0)$ and $D_2 = (\mathrm{d}/\mathrm{d}\tau')I(\tau')|_{\tau'=\tau_0}$, respectively, the cepstrum integral features, which both tend to zero when the cepstrum $C(\tau)$ contracts to the initial quefrency range $0 \leqslant \tau \leqslant \tau_0$.

The side-scan sonar, used for data acquisition, is a standard medium range system operating at 48-kHz carrier frequency, 1-ms pulse length, 2-kHz nominal receiver bandwidth and the usual time-varied gain. The amplitude envelope is recorded on magnetic tape in analog form with 48-dB dynamic range. Hardware for data processing consists of an 8-bit A/D converter and a standard 32 K microcomputer with a dual disk drive. The amplitude envelope is digitized at a sufficiently high rate and

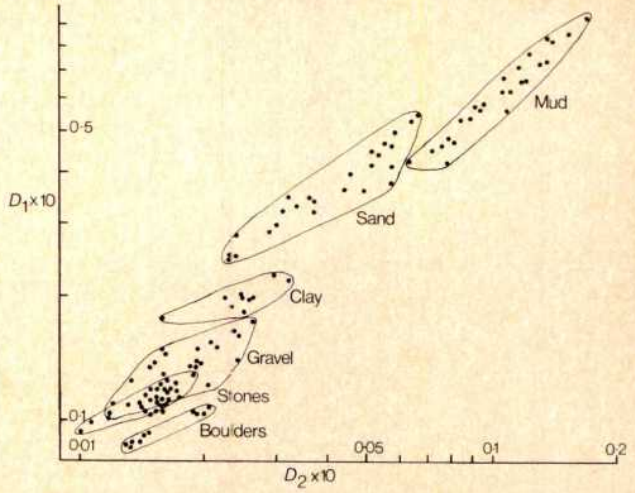

Fig. 2 Cepstrum integral features plane representation of all 120 sample areas. The boundaries to each sea-bed type are drawn by hand for clarity of display only. The time window $w(t)$ is chosen to be of the Hanning (cosine-squared) type. All Fourier transforms are performed according to the fast Fourier transform algorithm. The cepstrum is integrated numerically with a step equal to τ_0 and a straight line is interpolated through the first four points by the least-squares method in evaluating D_1 and D_2. The gain independence of D_1 and D_2 as evaluated by our software has been tested numerically; change in gain by a factor of up to four causes deviations in D_1 and/or D_2 that are at most 5%. The numerical values of D_1 and D_2 for a given sea-bed type depend on the number of windows n, especially when n is small; both sequences (for D_1 and D_2) that correspond to $n = 1, 2, 4, 8, 16, 32$ converge relatively fast so that little can be gained by going to the values of $n > 32$.

integer values in the range 0–255 saved on disk for further processing. A typical side-scan sonar paper record is presented in Fig. 1.

All of our 120 sample areas are homogeneous as far as could be ascertained in real sea beds, are from regions familiar from previous surveys and are free from noise and interference. Based on records (like that in Fig. 1), as well as other knowledge of the regions, any one of the sample areas is assigned to only one of the six classes: mud, sand, clay, gravel, stones and boulders. The sample areas are geographically distributed as follows: mud (25 from the South Baltic Sea), sand (5 from Land's End, 10 from the Outer Hebrides and 10 from the western English Channel), clay (10 from the southern North Sea), gravel (10 from southern North Sea and 15 from western English Channel), stones (10 from South Baltic Sea and 15 from the Outer Hebrides) and boulders (10 from South Baltic Sea).

Table 1 contains the arithmetical mean and standard deviation of the two cepstrum integral features (D_1 and D_2 multiplied by 10) for the six sea-bed types. Numerical values for all 120 sample areas are presented graphically (log–log scale) in Fig 2; each sample area corresponds to a single point in the two-dimensional plot of D_1 against D_2. Each sea-bed type corresponds to an area in (D_1, D_2) plane and the only overlap occurs between gravel and stones areas. Lower values of D_1 and D_2 generally

Table 1 Arithmetical mean and standard deviation of the cepstrum integral features for six sea-bed types

Sea-bed type	No. of sample areas	$D_1 \times 10$ Mean	$D_1 \times 10$ Dev.	$D_2 \times 10$ Mean	$D_2 \times 10$ Dev.
Mud	25	0.619	0.142	0.107	0.027
Sand	25	0.368	0.085	0.042	0.014
Clay	10	0.197	0.014	0.025	0.004
Gravel	25	0.135	0.018	0.018	0.004
Stones	25	0.111	0.007	0.015	0.002
Boulders	10	0.097	0.009	0.017	0.003

correspond to 'harder' sea-beds and the six sea-bed types span a factor of ~10 in the values of D_1 and D_2.

Judging by our results, it seems certain that the cepstrum and its integral features must have an important role in the classification of sea beds. The dependence of the discriminatory ability of the method on pulse length and carrier frequency is presently being investigated especially with respect to the classification of non-homogeneous sea-bed regions (for example, sand with gravel).

We thank H. O. Berktay for stimulating discussions and the British Telecom Research Centre, Ipswich, UK, for support.

Polarity reversal in the Solomon Islands arc

Patricia A. Cooper & Brian Taylor

Hawaii Institute of Geophysics, University of Hawaii, 2525 Correa Road, Honolulu, Hawaii 96822, USA

McKenzie[1] proposed that the direction of subduction beneath an island arc will reverse following arc–continent collision. Dewey and Bird[2] suggested that such an arc polarity reversal occurred in northern New Guinea; Johnson and Molnar[3], however, proposed two alternative models of plate convergence that could explain the observed seismicity. We present here a spatial seismicity study of the Solomon Islands region which has revealed the existence of two juxtaposed Wadati–Benioff (W–B) zones of opposite polarity. Shallow and intermediate foci define a north-east-dipping W–B zone associated with active subduction along the New Britain and San Cristobal trenches and a south-west-dipping W–B zone associated with the inactive North Solomon trench (NST). These data provide the first direct seismic evidence of a reversal in subduction polarity at an island arc.

The Solomon Islands arc forms a linear double chain of islands north-east of the New Britain and San Cristobal trenches. The arc-trench system is part of the convergent boundary between the westward-moving Pacific Plate and the northward-moving Indo-Australian Plate (Fig. 1). Arc volcanics provide evidence of convergence between the Pacific and Indo-Australian plates in this region since the early Eocene. The polarity of the subduction is thought to have varied and a number of different models of the tectonic evolution have been proposed[4–7]. Bathymetric and seismic reflection data indicate a relict subduction zone dipping south from the North Solomon and Vitiaz trenches[8,9]. The abnormally thick lithosphere of the Ontong Java Plateau collided with the NST sometime during the Miocene, although the exact timing remains controversial[4,7,9]. Following the collision, the arc polarity reversed and the present regime of north-east subduction at the New Britain, San Cristobal and Vanuatu trenches began by 10 Myr BP. The hiatus in island arc volcanism lasting from late-early to early-late Miocene observed throughout the Solomon Islands[7,10] may be evidence of a temporary cessation of subduction during the polarity reversal.

Earthquake hypocentres, volcano locations and major tectonic features of the Solomon Islands region are illustrated in Fig. 2. Hypocentres covering the period 1 January 1964 to 30 June 1984 are taken from the International Seismological Centre (ISC) catalogue and include all events with body-wave magnitude ≥4.7 and recorded by more than 15 stations. Three primary features are evident from Fig. 2. First, the spatial density of earthquake foci changes along strike; shallow (<70 km) and intermediate (70–300 km) activity is concentrated in two zones of greatest density under the northwestern and southeastern parts of the arc. Second, a zone of low-density shallow seismicity is associated with the active spreading system extending east across the Woodlark Basin. The low density of seismicity in the central Solomon Islands (from 156–159 °E) coincides with the site of subduction of the young Woodlark Basin lithosphere. Third, diffuse shallow and intermediate seismicity is also observed north-east of New Georgia and Guadalcanal, extending to Santa Isabel and Malaita, which provides evidence of lithosphere previously subducted at the NST.

Four representative seismicity cross-sections located in Fig. 2 and one longitudinal section are shown in Fig. 3. The top of the subducted lithosphere is assumed to extend from the topographic trench axis downward along the upper limit of the concentrated seismicity. Both the dip and the depth-extent of the north-east-dipping W–B zone associated with subduction at the New Britain and San Cristobal trenches vary significantly along strike (Figs 2, 3). North of Bougainville, Fig. 3A shows a well-defined seismic zone dipping at an initially shallow angle, then steepening rapidly until becoming almost vertical below 100 km. Teleseismic activity is virtually absent in the overriding

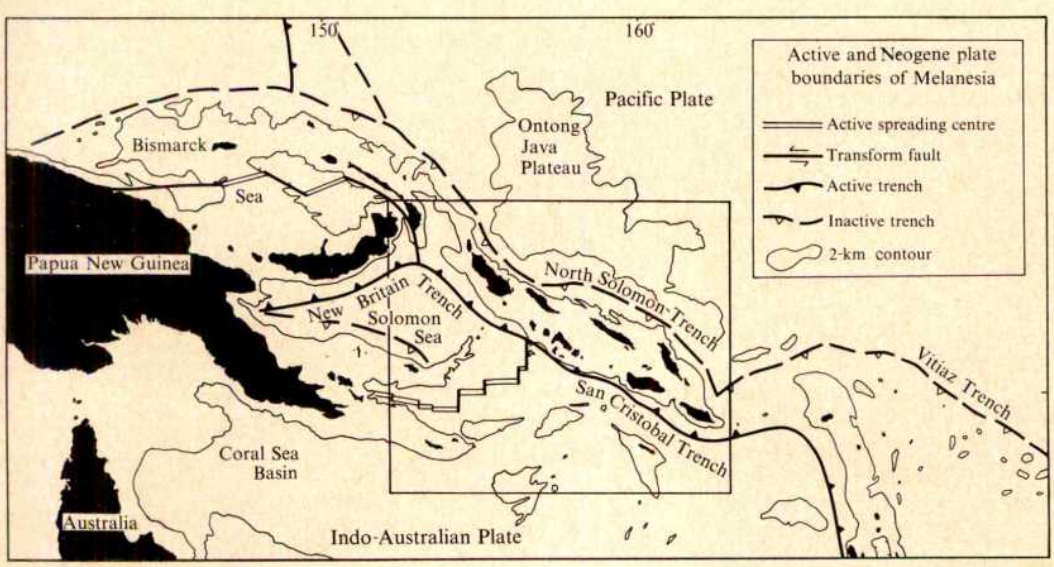

Fig. 1 Summary of active and Neogene plate boundaries of Melanesia (after ref. 19). Box shows location of Fig. 2.

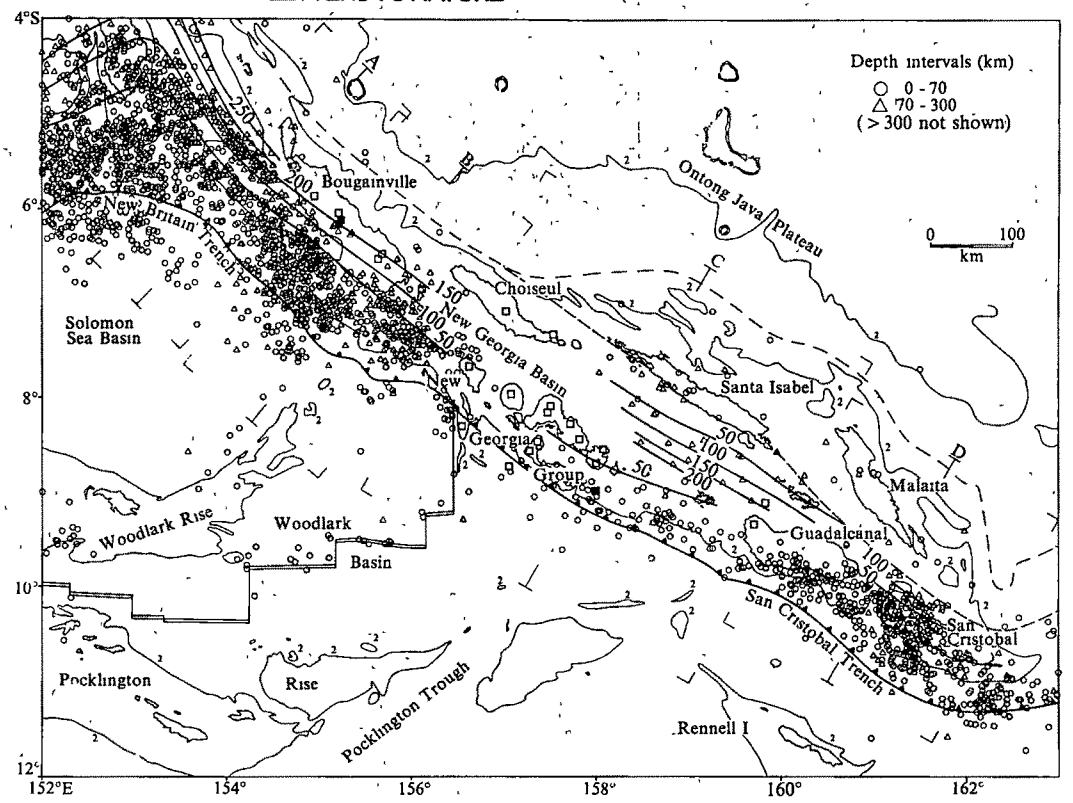

Fig. 2 Regional seismicity (ISC > 4.7 M_b, 1 January 1964 to 30 June 1984) and Wadati–Benioff zone contours (at 50-km intervals) for the Solomon Islands. The Woodlark spreading system is shown following Taylor[13] by double lines (spreading segments) and single lines (transforms). The dashed-dotted line marks the North Solomon trench; the dashed line indicates the Kaipito–Korighole fault. Large squares locate Plio-Pleistocene volcanoes; filled squares are active volcanoes.

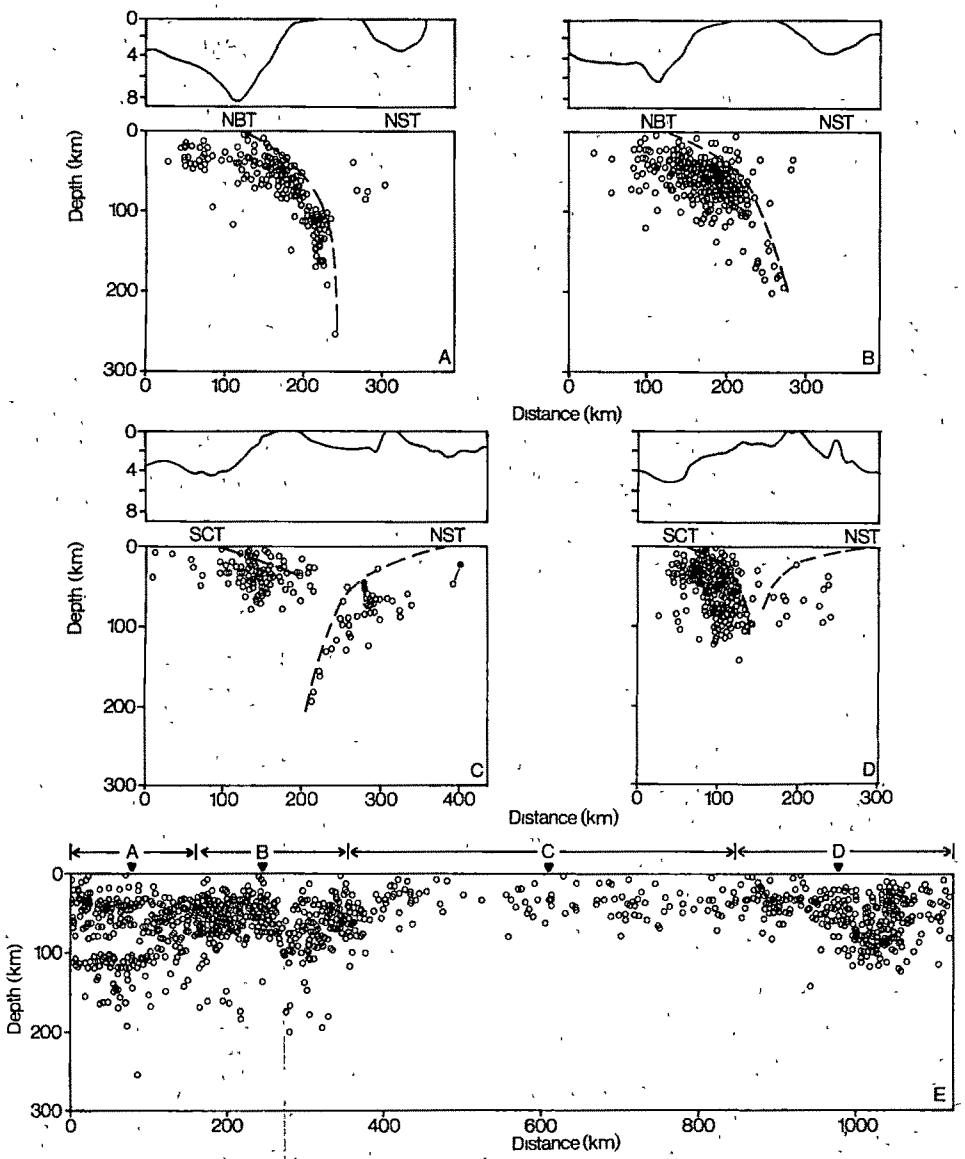

Fig. 3 Projections on vertical planes (located in Fig. 2) of ISC seismicity. The solid circle in C (top right, ○—●) represents a relocated earthquake. Dashed lines locate the inferred top of subducted lithosphere. Profile E is subparallel to the strike of the Solomon Islands, extends from 5.5° S, 153.5° E to 11.0° S, 162.0° E with a width of 425 km, and excludes the hypocentres associated with the south-west-dipping W–B zone. The New Britain, San Cristobal and North Solomon trenches are indicated by their initials.

plate. Near Bougainville (Fig. 3B) the dip of the seismic zone is less steep and the zone has become more diffuse. The W-B zone in these two profiles is continuous to just over 200 km, below which there is a seismic gap. The active volcanoes on Bougainville occur about 150 km above this W-B zone. Deep earthquakes occur throughout the Solomon Islands in cigar-shaped zones at depths of 400 ± 20, 500 ± 20 and 535 ± 10 km, although there is little indication that the presently active W-B zone includes the deep seismicity.

Profile C (Fig. 3C) traverses the New Georgia Group. Subduction of the young lithosphere and active spreading system of the Woodlark Basin is characterized by shallow diffuse low-magnitude seismicity. Similar seismicity characteristics are observed in the region where the Chile Rise is being subducted beneath South America[11]. There, the spreading segments trend parallel to the trench axis and, adjacent to the triple junction, there is a 3° gap in the chain of active volcanoes[12]. In contrast, in the Solomon Islands the spreading segments trend sub-parallel to the convergence direction and, adjacent to the triple junction, there is a maximum in the volcanism of the island arc[13]. Although the seismicity east of the Woodlark Basin does not extend below 80 km, voluminous eruptions of Plio-Pleistocene lavas have formed the New Georgia Group and the active submarine volcano, Kavachi, within 30-90 km of the trench. Fig. 3D shows a north-east-dipping almost vertical seismic zone, continuous to just over 100 km, beneath San Cristobal. A relict south-west-dipping slab, discussed below, may force the presently subducting lithosphere into its almost vertical attitude.

A number of events in Fig. 3C, D define a south-west-dipping W-B zone that we attribute to the relict slab of Pacific Plate lithosphere formerly subducted at the NST. Several hypocentres in the shallow part of this zone were relocated by a joint hypocentral determination technique[14] to depths significantly shallower than those reported by ISC and we note a similar systematic mislocation of events beneath the Japan Trench[15]. We have therefore drawn the top of the W-B zone above the apparent upper level of concentrated seismicity. Figure 3C clearly shows a south-west-dipping W-B zone. Curtis[16], using data spanning 1961-70, noted that diffuse seismicity south of Santa Isabel seemed to form a south-west-dipping zone, but that it could conceivably be incorporated into a north-east-dipping W-B zone if the foci near New Georgia were included. Denham[17] suggested that the Pacific Plate is underthrusting Santa Isabel; there are no cross-arc seismicity zones, however, to indicate that it is connected to the active plate boundaries to the south. Either the seismicity is entirely relict[18], or the presently subducting lithosphere may be pushing the old slab deeper into the asthenosphere, forcing re-equilibration. It may be that the lack of intermediate earthquakes associated with the subduction of a spreading system beneath the central Solomon Islands affords us the unusual clarity in observing the relict slab.

The recognition that this relict slab is present has significant implications also for current petrological studies. Recent volcanism on Savo is located 100-150 km above the relict W-B zone and the Plio-Pleistocene volcanoes of Choiseul (Mt Matambe and Kamboro Peak) are in a similar tectonic position along the strike of this W-B zone, from Savo (Fig. 2). These volcanoes may be evidence of a reactivation of magmatism associated with the relict slab.

A 'northern oscillation' relating northern hemispheric pressure anomalies and the Indian summer monsoon?

C. R. V. Raman* & J. A. Maliekal†

* University of Mysore, Mysore 570 006, India
† Department of Meteorology, University of Hawaii, Honolulu, Hawaii, USA

Analysis of the causes of the Indian monsoon have concentrated on climatological phenomena in the southern hemisphere, such as El Niño and the Southern Oscillation. By contrast, we have examined meteorological records for the northern hemisphere (0°–180°) spanning much of this century. We find that zonally-integrated mean sea-level pressure anomalies across Eurasia during January to April exhibit a statistically significant negative correlation between values for higher and sub-tropical latitudes. We further find that there is an association between above-normal activity of the Indian monsoon and a steep poleward-directed pressure anomaly gradient, which tends to persist through the summer and may indicate a strong zonal flow in the circumpolar westerlies. On the other hand, when this pressure anomaly gradient reverses, zonality is disturbed and the Indian monsoon tends to be drier than usual. Under these conditions, the circumpolar flow becomes persistently meridional as a result of a predisposition to blocking and splitting of the jet.

Exner[1] identified an inverse relationship between mean sea-level pressure in winter (December, January and February) over the northern hemispheric Eurasian Arctic and that in the central Mediterranean. Although he visualized a possible relationship with tropical precipitation, Exner did not pursue further analysis owing to the paucity of data. Through extensive correlation analysis, Walker[2,3] related anomalies in the global centres of action, especially Icelandic and Aleutian, a few months (even a season) ahead with subsequent performance of the summer monsoon over India. Although Walker recognized the importance of Exner's analysis, he emphasized the pressure anomalies

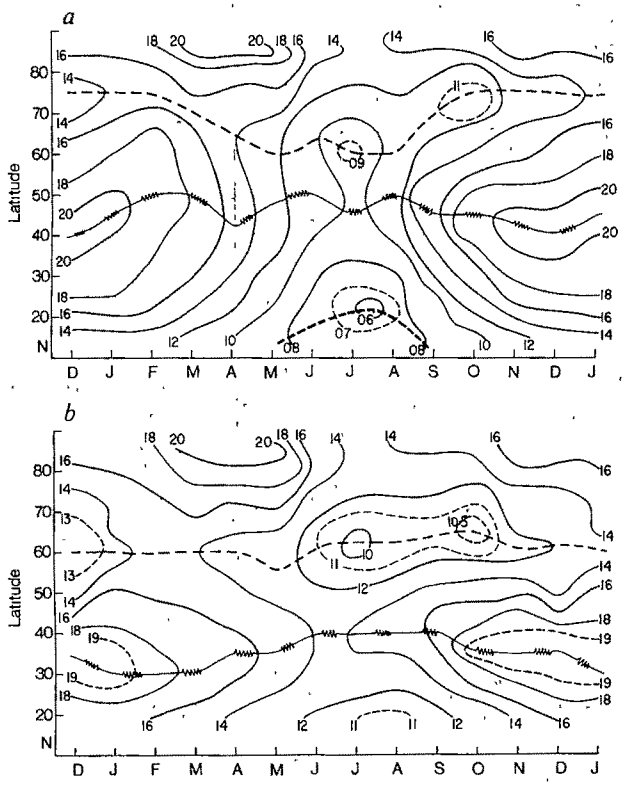

Fig. 1 Annual variation of the profile of mean sea-level pressure (mbar, first two digits omitted) over the northern hemisphere, zonally integrated: *a*, across Eurasia (0–180°; predominantly continental); *b*, around the northern hemisphere (oceanic and continental). Average for 85 yr (1900–84). ——·——·——, Axis of sub-Arctic trough; ——∿——∿——, axis of sub-tropical ridge; --------, axis of tropical trough.

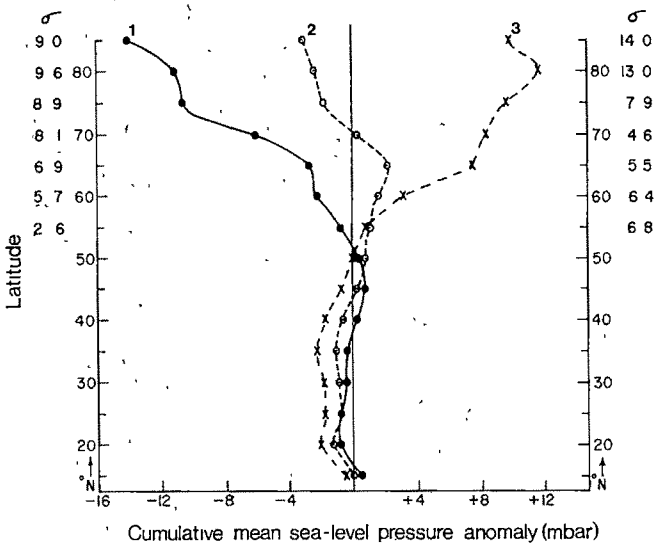

Fig. 2 Latitudinal profile of cumulative anomaly of mean sea-level pressure (January–April), zonally averaged across Eurasia (0–180°) and composited for three categories of performance of the Indian summer monsoon (1) above normal (≥+6%), 12 yr; (2) normal (≥−5%–≤+5%), 18 yr; (3) below normal (≤−6%), 12 yr. Standard deviation (σ) of the two contrasting samples is given with respect to the latitude, on either side. The two samples are significantly different. Note the following: (i) rainfall departures are available for north-west India and the Peninsula for the period 1940–81. (ii) In the almost 100-yr data set supplied by the UK Meteorological Service, data gaps have been reported over USSR between 1916 and 1921 and 1938–39. Hence, the data-gap-free period of 42 yr (1940–81) was chosen for preparation of the composites. (iii) 5% is half of the standard deviation of long-term rainfall of India.

in the centres of action of the southern hemisphere—the Southern Oscillation—and their teleconnections with Indian monsoon rainfall. Thereafter, particularly after Bjerknes[4], more emphasis has been laid on the relationship between the Southern Oscillation/El Niño and the activity of the Indian summer monsoon. Ramage[5] has drawn attention to the limitations of correlation analysis, in which a centre of action undergoes a significant change of location, resulting in a change of the sign of correlation. Therefore, we re-examine here the northern hemispheric pressure anomalies, especially those of continental Eurasia, with an analysis procedure that not only offsets distortions arising from positional changes in the centres of action but also filters sub-synoptic scale noise.

Mean sea-level pressure data for 26 yr (1951–76) received from the Chinese Academy of Sciences (Tao Shi Yan, personal communication), followed subsequently by more extensive data for 85 yr (1900–84) from the UK Meteorological Service formed the principal data sources for the study. Profiles of the monthly march of mean sea-level pressure, zonally integrated across Eurasia (0–180°; predominantly continental) and around the northern hemisphere (0–360°; oceanic and continental) in 5°-lat. steps from 85° N to 15° N are presented in Fig. 1. In the Eurasian profile (Fig. 1*a*), the sub-Arctic trough moves towards the Equator from 75° N in January to 60° N in July and has a higher value of mean pressure in winter compared with that in summer and autumn. The sub-tropical ridge located around 50° N in February/March shifts to 45° N in July and thence to 40° N in December. Again, the mean pressure values are higher in winter than in summer. In the average profile, the sub-tropical high is substantially effaced and is seen as a weak ridge in summer at sea level. The axis of the sub-Arctic trough approaches the position of the weak sub-tropical high belt during May–August. The tropical trough is sharply delineated, traversing from 15° N in May to near 25° N in July/August and shifting equatorward thereafter. In contrast, the axes of the sub-Arctic trough and the sub-tropical ridge in the hemispherical profile (Fig. 1*b*) are about 5–15 degrees of latitude equatorward. The tropical trough is relatively less well defined.

Space-time sections of Eurasian and hemispherical averages of mean sea-level pressure anomalies (January 1900–April 1984) gave the first indication of periodic reversals of pressure anomalies, particularly in winter and early spring, over the Arctic, poleward of 55° N. To express this quantitatively, a correlation matrix (Table 1) compiled with pressure anomaly values from January to April, serially and cumulatively is presented. A marked inverse relationship is noticed between pressure anomalies over higher/middle latitudes and those of the sub-tropics/tropics. The relationship is statistically significant at the 0.1% level. The negative association is striking between 70°/60° N and 30°/25° N. The matrix further suggests that a similar inverse relationship exists between pressure anomalies of the tropics of the northern and the southern hemispheres respectively.

To look for an association with the performance of the summer monsoon over India, the 42-yr data-gap-free period 1940–81 was chosen from the almost 100-yr sample. Monsoon seasonal rainfall departures (June–September) from the long-term norm for the plains of India, north-west India and the Peninsula are used to group the 42-yr period into three categories of monsoon performance over India, namely, 12 yr each of above normal (≥+6%) and below normal (≤−6%) and 18 normal years (≥−5% to ≤+5%). (Note that 5% represents half the standard deviation of long-term monsoon rainfall.)

The composited cumulative pressure anomaly profiles (January–April) display contrasting characteristics (Fig. 2). During this season, preceding above-normal monsoon performance, a distinct negative anomaly exists, with a steep gradient of ~15 mbar directed poleward from the domain of the sub-tropical

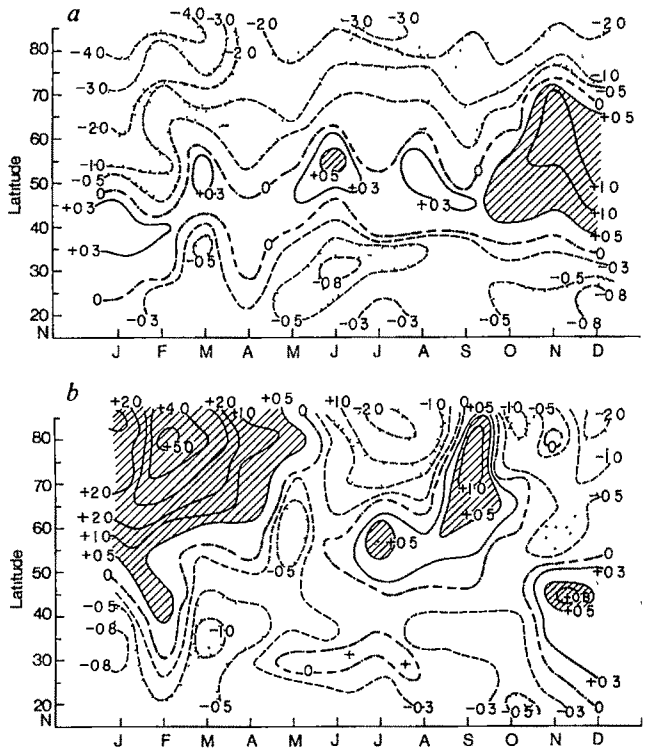

Fig. 3 Monthly march of mean sea-level pressure anomaly, zonally averaged across Eurasia (0–180°) and composited for: *a*, above normal monsoon (≥ +6%, 12 yr); *b*, below normal monsoon (≤ −6%, 12 yr). Note the following: (i) in *a* isopleths of negative and positive anomaly run zonally; in *b* isopleths of pressure anomaly display a meridional orientation. (ii) Positive rainfall anomaly during above-normal (good) monsoon years is ~+6–+8%, the largest being +18% in 1961. However, during below-normal (aberrant) monsoon years, rainfall departure is appreciably negative, ranging from −12% to −33%. (iii) Positive mean sea-level pressure anomaly over the Arctic poleward of 45° N is conspicuously large during January–April in highly aberrant monsoon years with rainfall anomaly < −16% of normal. (iv) Note the contrasting pressure anomaly distribution in summer, equatorward of 40° N, in relation to the opposing pressure anomaly over middle and higher latitudes during January–April.

ridge (45° N). On the other hand, when the summer monsoon performance is below normal, the antecedent anomaly pattern reverses and is diametrically opposite; the gradient of pressure anomaly of ~13 mbar, is now directed equatorward from the Arctic to 45° N. The curve antecedent to normal monsoon behaviour lies in-between the two contrasting profiles. The standard deviation (σ) of the two 12-yr samples, noted on either side of Fig. 2, shows a general decreasing tendency from the Arctic (85° N) to the middle latitude (55° N); the associated standard error is small. The mean $\pm\sigma/2$ values show that the two samples retain their significantly dissimilar characteristics. Application of 'Students' t test confirms that the two samples are statistically significant, poleward of latitude 60° N, with $P < 0.05$.

Using the entire series (1900–84), profiles were constructed with pressure anomalies averaged across Eurasia and around the northern hemisphere corresponding to 19 above-normal and 19 below-normal monsoon years. These two sets of profiles display characteristics essentially similar to those in Fig. 2 as well as statistical tests that are significant.

Figure 3 presents a composite of monthly march of pressure anomaly across Eurasia for extremes of monsoon performance. In the above-normal monsoon composite (Fig. 3*a*), a conspicuously large negative pressure anomaly is observed over the Arctic region poleward of 40° N in the preceding winter and early spring (January–April), persisting through the summer months and even thereafter. Immediately equatorward, the sub-tropical high is enhanced, but in the tropical trough region, equatorward of 40° N, during the ensuing summer (especially June–August) a negative anomaly, almost reaching ~ −1.0 mbar is observed. Considering that the composite is an average of 12 above-normal years and covers one half of the northern hemisphere, a negative pressure anomaly of this magnitude at low latitude is significant. The associated summer monsoon turns out to be active.

However, in the below-normal monsoon composite (Fig. 3*b*), the pronounced positive pressure anomaly of up to +5 mbar during January–April suggests a weakened Arctic trough. The sub-tropical ridge is totally annihilated and, in the ensuing summer, the tropical trough, equatorward of 40° N, is now characterized by a weak positive pressure anomaly. The associated summer monsoon activity is naturally suppressed.

Composites for contrasting monsoon years, prepared with anomalies of 500-mbar topography integrated across Eurasia (0–180°) and around the northern hemisphere, using data for the period 1951–79[6,7], also display characteristics similar to those in Fig. 3. A significantly large positive topographic anomaly overlies a positive mean sea-level pressure anomaly and vice versa.

Blocking, over high latitudes of Eurasia, was recently associated with monsoon droughts over India[8,9]. Arising from dynamical causes, the relatively more-frequent antecedent blocking, over west Eurasian high latitudes, was observed to extend from the lower stratosphere to sea level. Painting[10] reported increased blocking during winter in association with a positive mean sea-level pressure anomaly over high latitudes of the northern hemisphere. The positive pressure anomaly during January–April (Fig. 3*b*) could, therefore, be attributed to persistent high-latitude blocking over Eurasia. Marked differences were reported in hemispherical circulation characteristics over higher latitudes and the tropics during August, the typical summer month, in years of contrasting monsoon performance[8]. Thus, contrasting winter and early spring abnormality in pressure at mean sea level and in the overlying troposphere of the middle and higher latitudes of Eurasia seems to predetermine, to a great extent, the probable pressure anomaly distribution over low-latitude tropics of south Asia in the ensuing summer and the associated monsoon performance. A simple linear relationship does not, however, emerge between the magnitudes of the negative/positive pressure anomalies before the monsoon and subsequent monsoon rainfall departure. Work in progress to compile a suitable pressure oscillation index for the Eurasian region with the long-time pressure data series may provide further insights into this complex problem.

This study does not presume to preclude the apparent effects of El Nino or the Southern Oscillation on the behaviour of the summer monsoon over the Indian subcontinent. The role of soil moisture over high ground of south Asia and the contribution of sensible heat could be among the other factors leading to the organization of the monsoon trough (D. E. Jones and C. K. Folland, personal communication). This investigation just suggests that interaction may exist between antecedent pressure anomalies over middle and high latitudes of the northern hemisphere—the Northern Oscillation?—and the Indian summer monsoon. Much further work remains to be done.

C.R.V.R. thanks Dr A. Gilchrist of the UK Meteorological Service and his colleagues for giving valuable data and for useful suggestions. We also thank Dr S. K. Roy, Mr V. Srinivasan and Mr Y. P. Rao for helpful discussions.

Stable isotope data and depositional environments in the late Quaternary Arctic Ocean

Rainer Zahn*, Berit Markussen† & Jørn Thiede*

There has been much speculation about the history of the Arctic Ocean, particularly its response to the late Quaternary climatic fluctuations[1–8]. As a result, considerable data have been gathered from Arctic Ocean sediment cores to reconstruct glacial and interglacial Arctic Ocean palaeoenvironments[8,9]. But even with these data the reconstructions and the correlations with the Quaternary chronostratigraphy have been unsatisfactory, mainly because of the lack of detailed stratigraphical data such as those provided by stable oxygen-isotope stratigraphy[10]. Here we present stable isotope records from Arctic Ocean sediment cores which can be correlated convincingly with corresponding data from the North Atlantic. Together with lithostratigraphical data, they provide new evidence on Arctic Ocean history in relation to global late Quaternary climatic fluctuations.

Our two sediment cores were collected during the Fram-I expedition[11]. Core Fram-I/4 was raised from the Fram Basin (84°29′56″ N, 08°58′39″ W, water depth 3,820 m) and core Fram-I/7 from the northern flank of Nansen Ridge (83°52′38″ N, 06°57′17″ W, water depth 2,990 m) (Fig. 1). The stable isotope measurements were made on planktonic foraminiferal shells of sinistrally coiled *Neogloboquadrina pachyderma*, with samples containing 55 individuals on average. Measurements followed standard procedures described elsewhere[12,13]. The O-isotope records in the upper parts of both cores (Fig. 2) offer clear evidence of the last glacial–interglacial transition, called Termination I (ref. 14), which is subdivided into Terminations I_A and I_B as defined by Duplessy *et al.*[15]. Additionally, the marked increase in $\delta^{18}O$ in core Fram-I/4 just below Termination I_B may correspond to the Younger Dryas[16]. The difference between the $\delta^{18}O$ shifts at the level of Terminations I_A and I_B in the two cores (Table 1) may be a result of different sampling intervals, that is, the larger sampling intervals of core Fram-I/7 may have resulted in a smoothing of the $\delta^{18}O$ record. On the other hand, bioturbation effects cannot be excluded. Nevertheless, the absolute shifts in $\delta^{18}O$ of ~2.7‰ for the whole of Termination I in both cores exceed the actual 'ice-effected' value of 1.6–1.8‰[17]. This ~1‰ excess may indicate a temperature increase of 4 °C. More probably, however, we may assume there was a direct supply of meltwaters derived from the Arctic ice during deglacial warming, which would indicate a decrease of salinity of ~0.6‰[18].

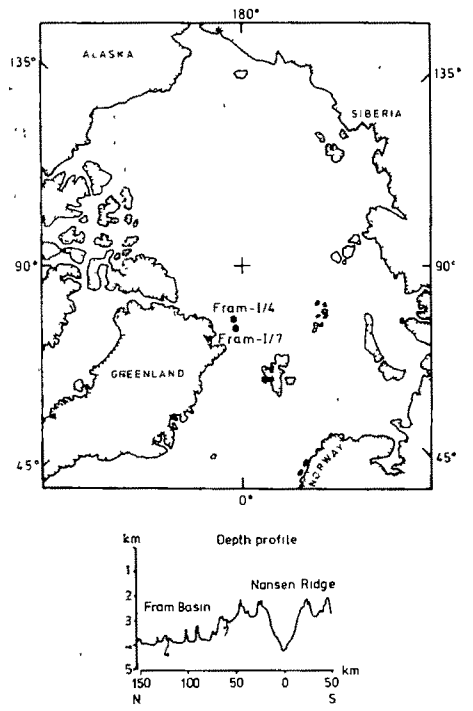

Fig. 1 Locations of cores Fram-I/4 and -I/7 The depth profile traces the bathymetry under the drift of ice station 'FRAM-I'

Furthermore, both cores exhibit a pronounced trend towards lighter $\delta^{18}O$ values in their lower parts, which may represent the O-isotope stage boundary 2/3. The strongly negative $\delta^{18}O$ peak during stage 2 in core Fram-I/7, however, is hard to explain in terms of global warming and its absence from the $\delta^{18}O$ record of core Fram-I/4 may indicate the presence of displaced sediments. Such sediments may have been brought in by turbidity currents, which are likely to occur on flanks of submarine ridges like the one from which core Fram-I/7 was raised (Fig. 1).

At present there are no ^{14}C data for either Fram core, but the O-isotope records resemble those of cores from low-latitude locations[10,19]. Therefore, because of this and the relatively short oceanic mixing time, it seems feasible to transfer the chronostratigraphical fixpoints from ^{14}C-dated low-latitude cores[15,20–22] to the O-isotope analogues of cores Fram-I/4 and Fram-I/7 (Fig. 2, Table 1). The average sedimentation rates between the top of Termination I_B and the stage boundary 2/3, which can be calculated from these fixpoints, are ~1.8 and ~2.6 cm × 10^{-3} yr for cores Fram-I/4 and Fram-I/7, respectively, and

Table 1 Chronostratigraphy, $\delta^{18}O$ shifts and sedimentation rates of cores Fram-I/4 and -I/7

Termination I		Fram-I/4			Fram-I/7

				(for stage 2)			(for stage 2)

Data for Termination I are from refs 17, 22.
* Stage 2 sedimentation rates in core Fram-I/7 were estimated without a section between 54 and 65 cm, which is suggested to represent displaced sediments (see text).

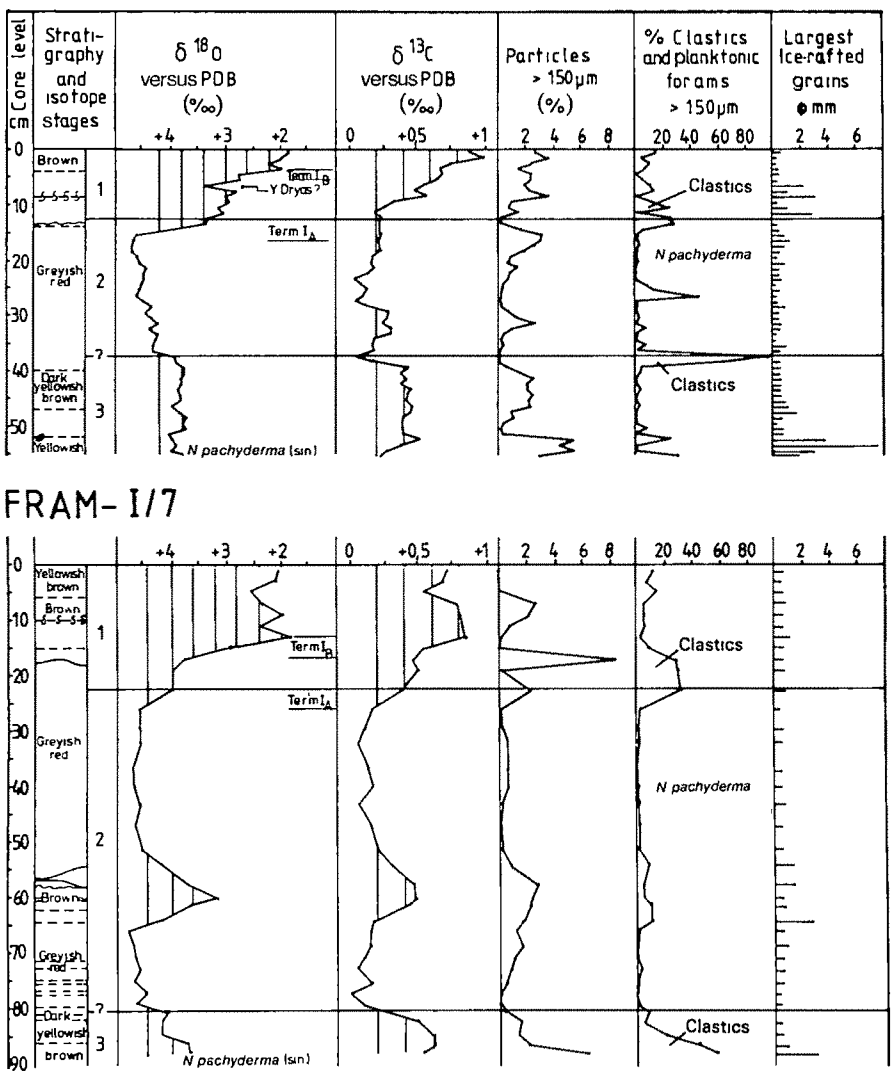

Fig. 2 Stable isotope records and lithostratigraphies of cores Fram-I/4 and -I/7. $\delta^{18}O$ values are shown relative to the PDB reference standard.

much higher than those previously reported for central Arctic Ocean sediments[23,24]. However, sedimentation rates of a similar order of magnitude have been reported recently[25].

Finally, the similarity in O-isotope data between our Arctic Ocean cores and those from the adjacent Norwegian-Greenland Sea[26,27] should be mentioned (Fig. 3). During stage 2 the O-isotope curves actually coincide without any significant difference, suggesting similar surface-water conditions in both deep-sea basins. During O-isotope stages 3 and 1, the Arctic cores tend towards lighter $\delta^{18}O$ values, perhaps because of a more pronounced meltwater effect in the Arctic Ocean than in the Norwegian-Greenland Sea.

The most prominent feature in the $\delta^{13}C$ records of both cores is the steady increase towards heavier values during Termination I (Fig. 2). This increase seems to start somewhat earlier in core Fram-I/7 than in core Fram-I/4, probably because of the different sampling intervals applied on the cores; stage 3 also exhibits heavier values than stage 2. The distinct increase in $\delta^{13}C$ in core Fram-I/7 during stage 2, as well as the $\delta^{18}O$ decrease in the same core section described above, does not occur in the $\delta^{13}C$ record of core Fram-I/4; this may support the assumption that this part of the section has been affected by sediment displacement.

Because $\delta^{13}C$ variations generally follow variations in hydrological parameters such as O_2 content[28], the increasing ^{13}C content in planktonic *N. pachyderma* (sin) shells may indicate the penetration of comparatively well-oxygenated surface-subsurface waters into this general region. This suggests that present-day circulation patterns in the Arctic Ocean may have begun during Termination I, a suggestion strongly supported by $\delta^{13}C$ values of *N. pachyderma* (sin) from Norwegian Sea cores[29] where a similar increase starts somewhat before Termination I. This may reflect the retreat of the glacial-stage ice cover with succeeding inflow of temperate North Atlantic Drift water into the Norwegian-Greenland Sea and, with respect to the $\delta^{13}C$ signal in our cores, into the Arctic Ocean through the Fram Strait[30]. Even the strong $\delta^{18}O$ shift in both cores during Termination I may in part be attributable to an increase in water temperature, indicating the influence of these warm waters.

The sediment compositions of the two cores correspond closely with their stratigraphy, permitting a correlation of their lithostratigraphies also. The lithologies may briefly be characterized as follows: the Upper Holocene sediments contain small amounts of $CaCO_3$ and coarse-grained ice-rafted material, whereas in the sediments, which were deposited during Termination I, that is, the global deglaciation, concentrations of these components are markedly increased. In the deposits corresponding to O-isotope stage 2, that is, fully glacial conditions, coarse ice-rafted material is less abundant, whereas concentrations of $CaCO_3$ are equal to or even higher than those in the Holocene sediments. Only in the section of core Fram-I/7, which has already been suggested to represent displaced sediments, are amounts of both components increasing. In the assumed O-isotope stage 3 sediments, the proportions of the coarse fractions and the amounts and grain sizes of ice-rafted material are clearly increasing, whereas concentrations of $CaCO_3$ are decreasing. The coarse fractions throughout both sediment cores consist mainly of planktonic foraminifers (mainly *N. pachyderma* (sin))

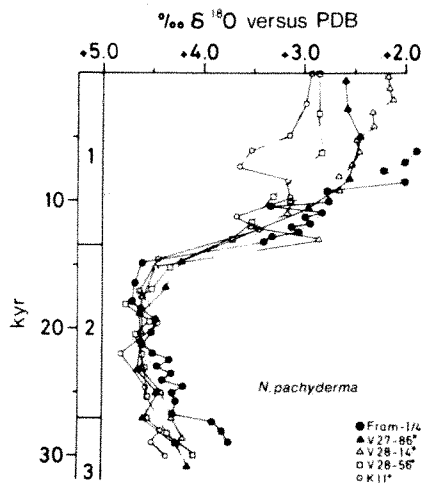

Fig. 3 O-isotope curves of cores from Norwegian-Greenland Sea[26,27] and of core Fram-I/4. A better comparison has been obtained by replotting the O-isotope data on a timescale defined by well-established radiocarbon ages[15,20-22].

hroughout all units, with smaller amounts of benthic fossils uch as foraminifers, sponges and ostracods. The sedimentologi- al and micropalaeontological data will be presented in more letail elsewhere[31].

The most important results and implications from the present tudy may be summarized as follows. (1) Sedimentation rates n the Arctic Ocean may be an order of magnitude higher than vas previously assumed. (2) Increased amounts of ice-rafted naterial accumulated during transitions towards both colder nd warmer climates, but during fully glacial and interglacial limates the supply of this component was strongly diminished. 3) The presence of planktonic foraminifers throughout both ores records a modest productivity of surface-subsurface vaters even during fully glacial conditions. (4) The reddish- rown colours of the sediments, as well as the benthic fossils ound throughout both cores, may be evidence of an efficient enewal of bottom water masses in the eastern Arctic Basin hroughout the late Quaternary. In contrast, however, the $\delta^{13}C$ ecords suggest a distinct change in oceanic circulation during ermination I towards present-day circulation patterns. (5) The bvious correspondence of the O-isotope records presented here vith those from low-latitude sediment cores may indicate an ctive and efficient exchange of Arctic Ocean water masses with hose of the global ocean throughout the late Quaternary. Fur- hermore, the close agreement in O-isotope data from our Arctic)cean cores and those from the Norwegian-Greenland ea[26,27] during stage 2 suggests similar hydrographies of surface- ubsurface waters in both deep-sea basins during fully glacial onditions.

Fram-I cores were collected under the supervision of Y. Kristoffersen. Isotope measurements were made at the ^{14}C aboratory of the University of Kiel. We thank M. Sarnthein, I. Erlenkeuser, G. Miller and N. Shackleton for discussions. his study was supported by the US Office of Naval Research, he Norwegian Polar Institute and the German Research Pro- ram on Climate.

Microhabitats of benthic foraminifera within deep-sea sediments

Bruce H. Corliss*

Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543, USA

Benthic foraminifera are protozoans found throughout the deep-sea environment, secreting a test of calcium carbonate or constructing a test of cemented sediment particles (agglutinated or arenaceous foraminifera). In typical deep-sea sediments, the organic cement of agglutinated taxa degrades upon burial in the sediment and, consequently, few specimens survive in the fossil record. In contrast, calcareous species are well preserved in most oceanic sediments, except at abyssal depths where most carbonate sediment is dissolved because of high levels of carbonate undersaturation of the bottom waters. Although benthic foraminifera have been widely used in studies of Cenozoic palaeoceanography, little is known about the ecology of deep-sea species. I present here an analysis of living (stained) benthic foraminifera within the upper 15 cm of deep-sea sediments, which reveals species-specific microhabitat preferences, with distinct morphological features found with epifaunal and infaunal species. The existence of infaunal habitats suggests that the distribution of certain foraminifera is not directly controlled by overlying bottom-water conditions, but by physicochemical conditions within the sediments. The microhabitat preferences may also explain interspecific carbon isotope differences, as existing data show that infaunal foraminifera generally have lower $\delta^{13}C$ isotope values than epifaunal species.

Early distributional studies demonstrated that deep-sea benthic foraminiferal assemblages are depth related[1] and this information was used in palaeoenvironmental studies of marine sedimentary sequences to estimate past water depths[2,3]. More recent studies have shown that deep-sea benthic foraminiferal faunal assemblages are related to the distribution of distinct water masses in the deep ocean, although the variables which control the faunal patterns are largely unknown[4]. In addition to faunal distribution studies, oxygen and carbon isotope analyses of benthic foraminifera have been used extensively to estimate polar ice volumes[5,6] and to study regional palaeocirculation conditions in the deep ocean[7-9].

A number of unanswered questions remain which limit the usefulness of the faunal and isotope data. Although significant correlations between bottom-water hydrographic variables (for

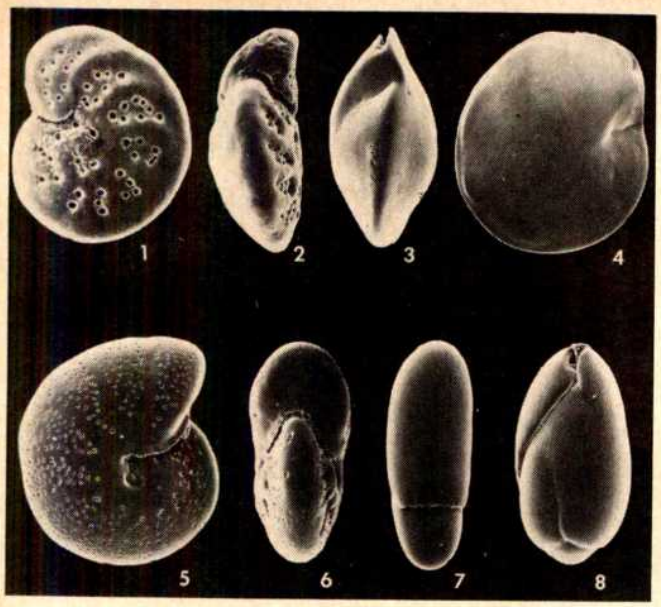

Fig. 1 Illustrations of important living deep-sea benthic foraminifera in OC-86/2-7-4. (1) *Planulina wuellerstorfi*, umbilical view (×103); (2) *P. wuellerstorfi*, edge view (×79). Pores can be seen on the umbilical side but are absent from the spiral side. (3) *Hoeglundina elegans*, edge view (×55); (4) *H. elegans*, umbilical view (×44); (5) *Melonis barleeanum*, side view (×82); (6) *M. barleeanum* edge view (×72); (7) *Chilostomella oolina* (×51); (8) *Globobulimina affinis* (×51). Small pores are present over most of the test surface of *C. oolina* and *G. affinis*. The epifaunal species (1–4) have plano-convex or biconvex shapes with surface pores on only one side or absent, whereas the infaunal species (5–8) have more rounded tests with surface pores evenly distributed over most of the test surface.

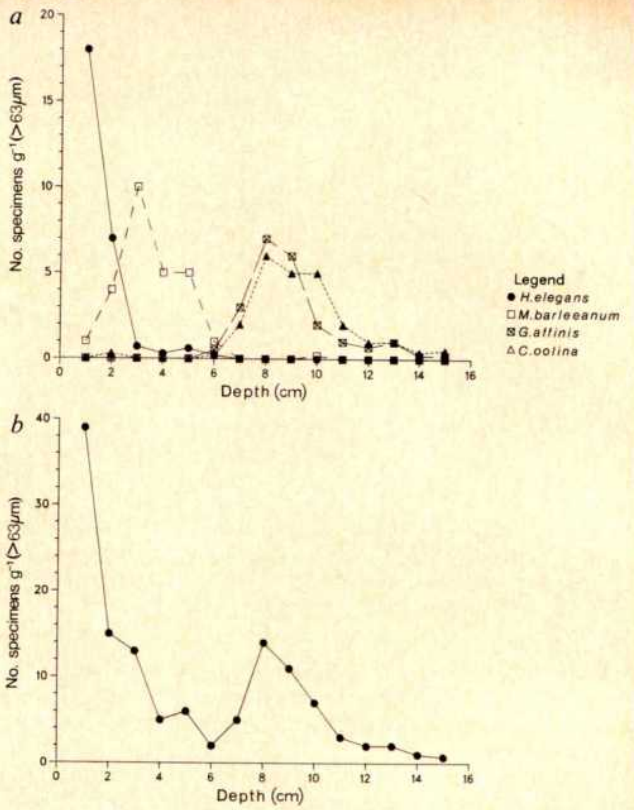

Fig. 2 Summary of benthic foraminiferal data from OC-86/2-7-4. *a*, Number of specimens (>150 μm) per g of >63-μm sediment of four dominant species; *b*, total number of specimens (>150 μm) per g of >63-μm sediment. The species are vertically stratified within the deep-sea sediments with a majority of the living fauna (73%) found below 2 cm.

example, temperature, salinity, dissolved oxygen) and faunal data do exist in regional studies, these correlations are not consistent over broad areas of the ocean, indicating that other variables are controlling faunal patterns. Analysis of the carbon isotope composition of benthic foraminiferal species shows that there are differences (frequently referred to as 'vital effects') between species, with some species secreting calcium carbonate in carbon isotope disequilibrium with the overlying bottom water[10–13]. Interspecific differences in $\delta^{13}C$ have led to speculation that certain species of deep-sea benthic foraminifera have infaunal microhabitats within the sediment where pore-water $\delta^{13}C$ influences carbonate $\delta^{13}C$ (refs 10–12). Palaeoceanographic studies often use time-series data from more than one species with disequilibrium factors applied to correct for species differences, with the assumption that these interspecific differences are constant through time. However, a number of studies have shown that for some species these fractionation factors are variable in the Cenozoic record[14,15].

To gain insight into these questions, two box cores were taken from the western North Atlantic on R/V *Oceanus* cruise 86, leg 2 (OC-86/2), in September 1980, using an Ocean Instruments Mark III box corer (0.25-m^2 surface area) divided into 25 10-cm × 10-cm subsamples. OC-86/2 box core 7-4 (OC-86/2-7-4) was taken at 38°12.9′N, 71°30.4′W in 3,000-m water depth on the eastern US continental rise and *Oceanus* 86/2 box core 5-3 was taken at 35°22.8′N, 65°20′W in 4,800-m water depth on the Bermuda Rise. Both box cores had clear water above the surface indicating the surface sediments were undisturbed during the coring process. Slices (1 cm thick) of two subsamples from OC-86/2-7-4 were taken from the sediment/water interface to 15 cm depth, and from one subsample in OC-86/2-5-3 to 9 cm depth. Each 100-cm^3 sample was preserved in 150 ml of buffered 4% formalin solution and the samples were treated with Rose Bengal stain to identify benthic foraminifera living at the time of collection. In the laboratory, each sample was washed over a 63-μm sieve, the >63-μm fraction was dried, weighed and dry sieved over a 150-μm sieve. All of the living (stained) benthonic foraminifera were picked from the >150-μm sample, sorted by species and counted. Rose Bengal is a biological stain that absorbs on the surface of protoplasm and has been widely used in studies of living benthic foraminifera. This method does have limitations (see ref. 16). A living individual is recognized by the presence of a bright red or violet coloration, within at least one chamber of the test, that can be seen in species with a hyaline test wall. Agglutinated foraminifera with test walls composed of cemented particles or miliolids that have an opaque porcellaneous calcareous wall were not considered here because it was difficult to observe stained protoplasm within the interior portion of the test. Some specimens had a tint of pink colour owing to the presence of an organic membrane, or spots of red colour reflecting particles of organic matter, but these were not counted as living specimens.

The dominant living species in one subsample of core 7-4 are illustrated in Fig. 1 and plotted in Fig. 2*a*, where the data are expressed as the number of living specimens (>150 μm) per gram of >63-μm dry sediment (Table 1). (Results from a second subsample are almost identical and are not presented here.) In the top 2 cm of sediment, *Hoeglundina elegans* (d'Orbigny) is the dominant species and is rare at 2–5 cm. Additional species within the top 1 cm include *Cibicidoides kullenbergi* (Parker), *Oridorsalis tener* (Brady) and *Planulina wuellerstorfi* (Schwager). Within the 1–6-cm interval, *Melonis barleeanum* (Williamson) is the dominant species with a maximum of 8 specimens per g in the 2–3-cm interval. From 6–7 cm to the bottom sample (14–15 cm), two species, *Globobulimina affinis* (d'Orbigny) and *Chilostomella oolina* (Schwager), are dominant, reaching maxima of 6–7 specimens per g in the 7–9-cm interval. The total number of living specimens per gram of >63-μm sediment (Fig.

The number of specimens (>150 μm) of each species, the total number of specimens and the weight of the >63-μm fraction examined are shown for each sample interval.

2*b*) shows a maximum of 39 specimens per g in the 0-1-cm interval and a secondary maximum of 14 specimens per g at the 7-8-cm interval. The faunal data reveal that 73% of the living faunal assemblage was below 2 cm in OC-86/2-7-4. The presence of living benthic foraminifera at depth was verified by picking a few specimens of *G. affinis* from a wet subsample, dissolving the test in a 0.01 M EDTA solution and observing the stained protoplasm. The results from OC-86/2-7-4 differ from OC-86/2-5-3 data, which show that the majority of the living fauna (84%) are confined to the 0-1-cm interval. The number of living specimens per gram in the 0-1-cm interval is 13, with *Epistominella umbonifera* (Cushman) the dominant species, and 1 specimen per g in the 1-2-cm interval. Four specimens were found scattered within the 2-9-cm interval. The data from the two cores show that foraminiferal distributions within the sediments vary with water depth.

The foraminifera are vertically stratified in OC-86/2-7-4, with species-specific microhabitat preferences within the upper 15 cm of sediment. An infaunal habitat for calcareous benthic foraminifera within deep-sea sediments has not been noted previously, although it has been documented for some shallow-water calcareous species[17-24]. Based on the OC-86/2 data, *M. barleeanum*, *C. oolina* and *G. affinis* have infaunal microhabitat preferences. The species confined largely to the top 1 cm, *P. wuellerstorfi*, *C. kullenbergi* and *O. tener*, are more likely to have an epifaunal preference, although these species may be stratified within the 0-1-cm interval. A sampling interval of <1 cm is necessary to determine whether vertical stratification occurs within this interval. *H. elegans* is found throughout the top 2 cm, indicating that this species may have both an epifaunal and infaunal microhabitat, or that its distribution may be influenced by bioturbation moving living species downward from the surface. Bioturbation cannot be used, however, to explain the distribution of species below 2 cm, as *C. oolina* and *G. affinis* are not found in the 0-1-cm interval and these species and *M. barleeanum* have subsurface maxima.

A correlation between benthic foraminiferal morphology and environment was noted by Bandy[1] in continental margin surface sediments; surface area and ornamentation of a number of species were shown to vary with water depth. Although several phenotype studies of benthic foraminifera have followed these initial observations, little is known about the functional adaptive morphology of the benthic foraminiferal test. The test morphologies of the benthic foraminifera in OC-86/2-7-4 show a distinct pattern with sediment depth (Fig. 1). Species found in the 0-2-cm interval, *H. elegans*, *P. wuellerstorfi*, *O. tener*, *C. kullenbergi* and *Cibicidoides* spp., have plano-convex or biconvex shapes, with wall pores found only on the spiral side or completely absent from the entire test. Of species found living below 2 cm, *M. barleeanum* has planispiral coiling with a rounded periphery, *C. oolina* is planispiral and cylinder shaped and *G. affinis* has triserially arranged chambers with a globular to ovate test. In contrast to the species found in the upper 2 cm, the dominant subsurface species have pores evenly distributed over most of the test.

The correlations between test shape, pore distribution and sediment depth suggest that these morphological variables are related to the microhabitat preference of the individual species. The plano-convex or biconvex shapes of the surface species may be advantageous for attachment to the bottom during times of bottom turbulence and for stability in traveling on or near the surface. For example, in shallow-water turbulent environments, *Cibicides* spp., which have plano-convex shapes, are attached to the substrate to resist transport or destruction in these high-energy regions. The plano-convex or biconvex shapes that would be advantageous for stability and mobility at or near the surface would be unnecessary within the sediment and these shapes are indeed absent.

Leutenegger and Hansen[25] noted that a number of species from low-oxygen (<0.3 ml l^{-1} O_2) environments, including *Globobulimina pacifica*, a species closely related to *G. affinis*, had a lower density of mitochondria that were concentrated near pore openings within the cell, than specimens from higher-oxygen environments that had concentrations of mitochondria more evenly distributed throughout the cell. The concentration of mitochondria below the pore entrances was suggested to increase the diffusion of oxygen into the cell in low-oxygen environments. It was also found that an osmiophilic organic lining of *G. pacifica* did not cover the pore entrance, which was interpreted to allow a faster rate of molecular transport in low-oxygen environments. These observations support earlier conclusions[16] that pores are important for gas exchange in foraminifera.

If gas-exchange morphological adaptations are significant, the distribution and density of pores should be distinctly different in epifaunal and infaunal species, because the microenvironments in which they live would be expected to have significantly different dissolved-oxygen levels. The infaunal species (*M. barleeanum*, *C. oolina*, *G. affinis*) have pores evenly distributed over most of the test surface, which should be desirable for enhancing gas exchange in a low-oxygen environment. The pores found in *Cibicidoides* spp. and *P. wuellerstorfi* are found only on the spiral side and may be for protoplasmic streaming as well as for gas exchange, as these openings are much larger (~10 μm) than those found in other species (~1 μm). One species, *E. umbonifera*, which is found in the 0-1-cm interval of OC-86/2-5-3, is different from the other trochospiral species in that it has pores on both sides of the test. The foraminiferal test shapes

may reflect adaptations promoting gas exchange in low-oxygen environments within the sediment as well, as the shapes of species with subsurface maxima have higher surface area/volume ratios than the epifaunal species.

The distribution of live benthic foraminifera within these deep-sea sediments suggests that certain foraminifera with infaunal microhabitats are not directly controlled by overlying bottom-water conditions, but by physicochemical conditions within the sediment, as this environment is geochemically different from the sediment/water interface[26-28]. Some species do not appear to be confined to infaunal habitats, but instead are responding to a set of physicochemical variables independent of sediment depth. For example, *Chilostomella* and *Globobulimina* are found at depth in OC-86/2-7-4, but related species are common in California Borderland surface sediments (based on Rose Bengal stained data) associated with bottom water dissolved-oxygen values of <3 ml l^{-1} and generally <1 ml l^{-1} (ref. 29). The depth distribution of a particular species probably varies regionally in response to different physicochemical conditions within the sediments, ontogenetic differences in microhabitat requirements, or as a result of seasonal cycles in the deep sea.

Recent carbon-isotope data from pore waters in the upper few centimetres of Pacific Ocean and Atlantic Ocean sediments (ref. 30 and F. L. Sayles and W. B. Curry, in preparation) indicate that a $\delta^{13}C$ gradient of $\sim 1‰$ exists in the upper one to a few centimetres. The $\delta^{13}C$ values decrease with depth in the sediment because of the oxidation of ^{12}C-enriched organic matter, which results in a decrease in the $\delta^{13}C$ of the pore waters. The demonstration from the OC-86/2 data that a number of deep-sea benthic foraminifera do have infaunal microhabitats, together with the existence of $\delta^{13}C$ gradients within deep-sea sediments, indicate that the $\delta^{13}C$ disequilibrium of some benthic foraminifera can probably be explained in part by the $\delta^{13}C$ composition of the pore waters. Benthic foraminiferal carbon-isotope data[10,11,13,31] show that plano-convex or biconvex forms, inferred to be epifaunal species, are generally nearest to isotope equilibrium, whereas species with shapes suggesting infaunal habitats are depleted in ^{13}C. For example, a species of *Globobulimina* was highly variable with $\delta^{13}C$ up to 2-3‰ below equilibrium of the overlying bottom water in the California Borderlands[12]. One notable exception to this pattern, however, is *O. tener*, which has consistently lighter values than other biconvex forms. The existing data suggest that a relationship exists between carbon isotope composition and test morphology, which would be expected if the pore-water geochemistry of the microenvironment influences the benthic foraminiferal carbon-isotope data.

I thank L. D. Keigwin Jr, W. B. Curry, S. Honjo and F. L. Sayles for discussions on the research; W. A. Berggren, W. B. Curry, S. R. Emerson, L. D. Keigwin Jr and G. Vilks for reviewing the manuscript; E. L. Grossman for a preprint of his isotope work; J. W. Farrington, B. W. Tripp and C. H. Clifford for obtaining box-core subsamples; M. H. Jeglinski for picking the foraminifera; E. Evans and Joyce Graves for typing the manuscript; T. A. L. Corliss for assistance in verifying the living specimens. Weak neutral currents and the origin of biomolecular chirality

D. K. Kondepudi & G. W. Nelson

Center for Statistical Mechanics and Thermodynamics, The University of Texas, Austin, Texas 78712, USA

It has long been known that Earth's biochemistry is overwhelmingly dissymmetric or chiral[1-4]. In model chemical systems[5-7] that spontaneously evolve to a state dominated by either the L or the D enantiomer, parity violation in β-decay and that attributable to weak neutral currents (WNC) in molecules[8,9] is thought to be too small to have any significant influence on the emergent chirality[10,11]. Other conceivable systematic chiral influences are generally even weaker[12-14]. We show here that there is a simple and extremely sensitive mechanism by which a minute but systematic chiral interaction, no stronger than the WNC interaction in amino acids, can, over a period of ~15,000 yr, determine which enantiomer will dominate. Such a mechanism is especially interesting when considering the origins of terrestrial biochemistry, particularly in view of the work by Mason and Tranter[15], who found that it is the terrestrially dominant L amino acids that are favoured by the WNC interaction.

The process occurs in a randomly fluctuating environment. Chemical systems that, in conditions that are thermodynamically far from equilibrium, can evolve spontaneously to a chirally asymmetric state—that is 'break chiral symmetry'—exhibit a universal behaviour that is a consequence of the symmetry properties of the system[14,16-18]. The amplitude α of the chiral dissymmetry, with the inclusion of fluctuations, obeys the stochastic (Langevin) equation

$$\frac{d\alpha}{dt} = -A\alpha^3 + B(\lambda - \lambda_c)\alpha + Cg + C'\eta f_2(t) + \varepsilon_1^{1/2} f_1(t) \quad (1)$$

in which A, B and C are constants that depend on the kinetics[14,16]; $g \equiv (\Delta E/kT)$, where k is the Boltzmann constant and T the temperature, is the factor by which the Arrhenius reaction rate constants for the L and the D enantiomers differ because of a small difference, ΔE, in their reaction barrier energies caused by an extremely weak chiral interaction[14]—such as WNC. In addition to such systematic effects, there is the fluctuating chiral influence from the environment, such as that attributable to circularly polarized ultraviolet light, represented by $C'\eta f_2(t)$, where $f_2(t)$ is assumed to be a normalized gaussian white noise. We estimate the numerical value of $C'\eta$ from the best known data on circularly polarized light. The intrinsic

thermodynamic fluctuations[19,20] are represented by $\varepsilon_1^{1/2} f_1(t)$; again $f_1(t)$ is assumed to be a normalized gaussian white noise; $\varepsilon_1 = (Q/VN_A)$, where Q can be calculated from the chemical kinetics; V is the volume over which the concentration of the reactants may be assumed homogeneous and N_A is the Avogadro number. The most general stochastic equation must include fluctuations in A and B but, as they have no significant effect on the mechanism[21,22], we ignore them.

As an example and for later numerical considerations, we shall consider the following model scheme of reactions studied in detail in ref. 14

$$S + T \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} X_{L(D)} \qquad \text{(i)}$$

$$S + T + X_{L(D)} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} 2X_{L(D)} \qquad \text{(ii)}$$

$$X_L + X_D \xrightarrow{k_3} P. \qquad \text{(iii)}$$

In this scheme, the chiral species X in the two enantiomeric forms X_L and X_D is produced from the achiral substrate S and T directly through reaction (i) and autocatalytically through reactions (ii). With a suitable supply of S and T (to maintain their concentrations at a fixed level), and the irreversible removal of X through reaction (iii), the system can be driven far from thermodynamic equilibrium. The variables of equation (1) for this system are: $\lambda \equiv [S][T]$ and $\alpha \equiv ([X_L]-[X_D])/2$ (where [] denote concentrations). When λ exceeds a certain critical value λ_c, the steady-state value of α switches from zero to either $\alpha > 0$ or $\alpha < 0$ (ref. 14). If the small chiral interaction influences reactions (i) and (ii) so that the rate constants of the L and D enantiomers are unequal, $k_{1L} = k_{1D}(1+g)$ and $k_{2L} = k_{2D}(1+g)$, then $C = [k_1 + k_2\beta_c]\lambda_c$, where $\beta \equiv ([X_L]+[X_D])/2$, k_1 and k_2 are rate constants when $g = 0$, and the subscript 'c' denotes values at the critical point. Similar, but more involved, expressions may be obtained for A and B (ref.14).

In contrast to the earlier studies[23-25] that mainly examined such systems for $\lambda > \lambda_c$, we study the system as it slowly evolves through the critical point. The macroscopic steady states (when the fluctuations are ignored) and a sample fluctuating trajectory for the time evolution of α of equation (1) are shown in Fig. 1. When λ is well below λ_c, there is only one steady state, $\alpha \simeq Cg/B(\lambda - \lambda_c) \ll 1$, which becomes unstable when λ goes beyond λ_c; for $\lambda > \lambda_c$, the system has two new supercritical branches, $\alpha \simeq \pm\sqrt{B(\lambda - \lambda_c)/A}$, to which it can evolve. In the absence of g, the two supercritical branches emerge symmetrically (as a parabola) from the point λ_c and, as the system evolves through the critical point, the fluctuations make both states equally probable. When $g \neq 0$ this is no longer true; one branch is favoured. The effect of g is most marked in the vicinity of the critical point where it separates the two stable supercritical branches by a minimum of $S = (3/2)(4/A)^{1/3}(Cg)^{1/3}$; in contrast, well above and below the critical point the shift is proportional to Cg. As $Cg \ll 1$, the fractional exponent indicates the enhanced sensitivity of the system near the critical point. However, in this region the α fluctuations are also large. Our aim is to obtain the probability of the system evolving to the favoured branch as λ goes through the critical point at a given rate.

An important factor in calculating this probability is $\varepsilon_1 = Q/VN_A$, which is derived assuming the system is homogeneous over the volume V. We estimate V by considering the homogenization that occurs through diffusion and, for prebiotic considerations, large-scale mixing as might occur in an ocean or a lagoon.

The evolution of the system may be considered in four stages (see Fig. 1). In stages I and IV, the system is well below and well above the critical point respectively; during stages II and III, it is in the vicinity of the critical point where the selection of branches takes place. In stages I and II, there is only one stable steady state and hence the system can be homogeneous over limitlessly large volume. In stage II, if $\alpha \ll 1$ and $\lambda \simeq \lambda_c$, α

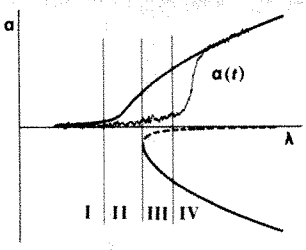

Fig. 1 A sample trajectory of α in equation (1) as λ increases through the critical point (fluctuations exaggerated). Solid line, stable steady states; dashed line, unstable steady state. Stages I–IV are explained in the text.

begins to grow slowly, essentially at an average rate Cg. In stage III, however, the system has two possible steady states and hence the volume over which it may be assumed homogeneous has an upper limit. In this stage, in a small volume δV, the autocatalysis of the chemistry (reflected in the term $B(\lambda - \lambda_c)$, $\lambda > \lambda_c$) will cause a fluctuation in α to grow; this growth, however, is curtailed by diffusion and large-scale mixing which transport the excess of α out of δV. As the rate of growth of α due to the chemical reactions is proportional to δV, whereas depletion is proportional to the surface area of δV, there is a 'nucleation volume' V_c below which α cannot grow. Within this volume V_c, homogeneity is maintained. Diffusion alone can maintain homogeneity over a length scale $l_D \simeq \sqrt{D/B(\lambda - \lambda_c)}$, D being the diffusion coefficient[26,27]. In our numerical simulation, in stage III, $B(\lambda - \lambda_c) \leq 10^{-11}\ s^{-1}$, and with $D \sim 10^{-5}\ cm^2\ s^{-1}$ we see that $\lambda_D \sim 10^3$ cm. Also, stages II and III are traversed in ~6,000 yr, during which we may expect homogenization due to large-scale mixing to be on an oceanic scale. We assume this volume V_c to be at least 4×10^9 l (1 km × 1 km × 4 m) for our estimate of ε_1. As indicated by the fluctuating trajectory in Fig. 1, by the time stage IV is reached, if the system is already well within the region of attraction of the favoured (upper) branch, it becomes increasingly improbable for a fluctuation in α, occurring at least over a volume V_c, to be large enough to reach the unfavoured (lower) branch.

To obtain the probability for the selection of branches, we study the Fokker–Planck[28,29] equation associated with equation (1), which describes the evolution of the probability density $P(\alpha, t)$ of α:

$$\frac{\partial P}{\partial t} = -\frac{\partial}{\partial \alpha}(-A\alpha^3 + B(\lambda(t) - \lambda_c)\alpha + Cg)P(\alpha, t) + \left(\frac{\varepsilon}{2}\right)\frac{\partial^2}{\partial \alpha^2}P(\alpha, t) \qquad (2)$$

where $\varepsilon = \varepsilon_1 + (C'\eta)^2$. We suppose, at $t = 0$, λ is well below the critical point and is gradually increasing. Fluctuations in λ have an insignificant role in the process of selection[21], so we ignore them in our theoretical discussion, though not in our numerical simulation of the above model shown in Fig. 2. From equation (2) it follows that, for λ well below λ_c, $P(\alpha, t)$ is essentially a gaussian whose centre is at $\bar{\alpha} \simeq Cg/B(\lambda_c - \lambda)$, very close to zero (stage I in Fig. 1). As λ increases at a reasonable rate ($\sim 10^{-5}\ M^2\ (10^4\ yr)^{-1}$ for the model) in the vicinity of the critical point, $P(\alpha, t)$ is still a gaussian, but it begins to relax very slowly to the stationary distribution. Thus, in this stage (stages II and III in Fig. 1), $P(\alpha, t)$ is vanishingly small for large α and hence the $-A\alpha^3$ term may be neglected in comparison with the other terms.

For selection, then, we need only consider

$$\frac{\partial P}{\partial t} = -\frac{\partial}{\partial \alpha}(B(\lambda(t) - \lambda_c)\alpha + Cg)P(\alpha, t) + \left(\frac{\varepsilon}{2}\right)\frac{\partial^2}{\partial \alpha^2}P(\alpha, t) \qquad (3)$$

When $\lambda \simeq \lambda_c$, the term $B(\lambda - \lambda_c)\alpha$, for $\alpha \ll 1$, also becomes small compared with Cg. Here we have a gaussian whose peak is shifting at a constant rate Cg, but whose width is also increasing

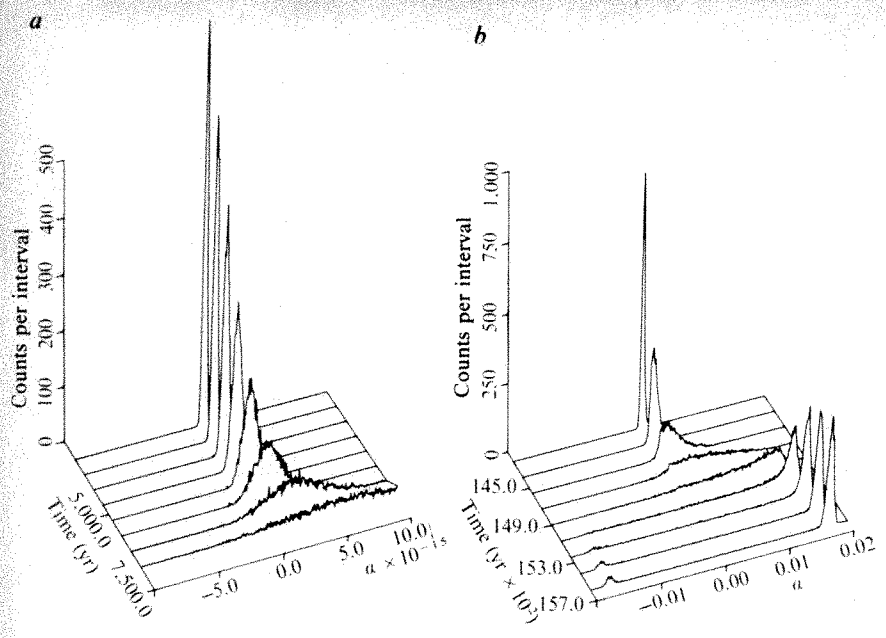

Fig. 2 Results of simulation of equation (2) by 5,000 sample trajectories of equation (1), with $\lambda(t) = \lambda_0 + \gamma t + 0.05 \times \lambda_c \times f(t)$, where $\lambda_0 = 0.8 \times 10^{-5}\ M^2$, $\gamma = 3.171 \times 10^{-17}\ M^2\ s^{-1}$, and $f(t)$ is normalized gaussian noise; t goes from 0 to 15,600 yr. Other parameters are as given in the text. Each curve is a histogram of the number of times $\alpha(t)$ fell within an interval 1/400 of full α scale for the given t. *a*, $P(\alpha)$ drifting and spreading while λ is near λ_c, which here occurs at $t = 3{,}000$ yr. *b*, $P(\alpha)$ spreading and splitting for $\lambda \gg \lambda_c$. Note the change of scale in α by 10^{12} between *a* and *b*, because of which the number of trajectories per interval has sharply increased in *b*.

because of the 'diffusion term' containing ε. In a time interval T, the drift of the peak will be CgT, while the increase in the width will be $\sqrt{\varepsilon T}$. Thus, for sufficiently large T, even when $Cg \ll \sqrt{\varepsilon}$, CgT can exceed $\sqrt{\varepsilon T}$, which implies that much of $P(\alpha, t)$ will drift into the region $\alpha > 0$ (for $Cg > 0$). This is the heart of the selection mechanism. Now, as λ goes beyond λ_c (stage IV in Fig. 1), the term $B(\lambda - \lambda_c)$ is positive and will cause $P(\alpha, t)$ to spread out rapidly on either side. $P(\alpha, t)$, thus split into two parts, will accumulate around the macroscopic steady states because of the term $-A\alpha^3$; note, however, that by the time this term becomes important, how much of $P(\alpha, t)$ will have evolved into $\alpha > 0$ and $\alpha < 0$ regions will already have been determined. Thus, equation (3) is all we need to calculate the probability of branch selection—an approximation well supported by the numerical solution of the complete equation.

The solution to equation (3), well known[29,30] for constant λ, can be extended to time-dependent λ. With $P(\alpha,0) = \delta(\alpha - \alpha_0)$, the solution $P(\alpha, t|\alpha_0)$ is a gaussian that is drifting and spreading

$$P(\alpha, t|\alpha_0) = \frac{1}{[\pi z(t)]^{1/2}} \exp\left[\frac{(\alpha - \bar{\alpha}(t))^2}{z(t)}\right] \tag{4}$$

where

$$\bar{\alpha} = \alpha_0 \exp(w(t)) + Cg \exp w(t) \int_0^t \exp(-w(t'))\mathrm{d}t'$$

in which

$$w(t) = \int_0^t B(\lambda(t') - \lambda_c)\,\mathrm{d}t'$$

and

$$z(t) = 2\varepsilon \int_0^t \exp\left(2\int_{t'}^t B(\lambda(t'') - \lambda_c)\,\mathrm{d}t''\right)\mathrm{d}t'$$

For the probability of selection of the $\alpha > 0$ chiral steady state, P_+, we have: $P_+ = \mathrm{Lt}_{t\to\infty} \int_0^\infty P(\alpha, t/\alpha_0)\,\mathrm{d}\alpha$. Because $P(\alpha, t|\alpha_0)$ is a gaussian and $\alpha_0 \approx 0$, we may write

$$P_+(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{N} \mathrm{e}^{-x^2/2}\,\mathrm{d}x \tag{5}$$

where

$$N = Cg\left[\exp w(t) \int_0^t \exp(-w(t'))\,\mathrm{d}t'\right] \Big/ \sqrt{z(t)/2} \tag{6}$$

gives the number of standard deviations by which the peak of $P(\alpha, t)$ has drifted from the origin. Now, if we let $\lambda = \lambda_0 + \gamma t$ (λ_0 well below λ_c), for $t \to \infty$, we get

$$N = Cg(\varepsilon/2)^{-1/2}(B\gamma/\pi)^{-1/4} \tag{7}$$

Thus, equations (7) and (5) give the required probability for the selection of a branch resulting from a chiral interaction.

For the biomolecular context we consider the above model with kinetic constants $k_1 = 5 \times 10^{-5}\ M^{-1}\ s^{-1}$, $k_2 = 2.5 \times 10^{-5}\ M^{-2}\ s^{-1}$, $k_3 = 10^{-3}\ M^{-1}\ s^{-1}$, $k_{-1} = 2.5 \times 10^{-10}\ s^{-1}$ and $k_{-2} = 1.25 \times 10^{-10}\ M^{-1}\ s^{-1}$. With these values the coefficients of equation (1) are: $A = 1.7 \times 10^{-7}\ M^{-2}\ s^{-1}$, $B = 2.5 \times 10^{-5} M^{-2}\ s^{-1}$, $C = 2.5 \times 10^{-10}\ M\ s^{-1}$ and $\lambda_c = 1.0 \times 10^{-5}\ M^2$; all concentrations are $\sim 10^{-3}$ M or less during the process of selection and $[X] \sim 10^{-2}$ M well above λ_c. If we suppose [S] and [T] are increasing slowly so that $\lambda \equiv [S][T]$ increases from $0.5\,\lambda_c$ to $1.5\,\lambda_c$ in 10,000 yr, then $\gamma = 3.2 \times 10^{-17}\ M^2\ s^{-1}$. For $\varepsilon_1 = Q/VN_A$, $Q = (k_1\lambda_c)/2$ for the model [14], and we take $V = 4 \times 10^9$ l as explained above, so that $\varepsilon_1 \simeq 10^{-43}\ M^2\ s^{-1}$. Using the results of Mason and Tranter for WNC[15], we take $g = 10^{-17}$, which makes $Cg = 2.5 \times 10^{-27}$. For the magnitude of the random chiral influences, we take $C'\eta = 3 \times 10^{-22}$, an estimate explained below. Using these values in equation (7) we get $N \simeq 2.0$, which implies $P_+ \simeq 0.98$, a 98% chance that the enantiomer favoured by WNC will emerge dominant even though the r.m.s. values of the random chiral influences are five orders of magnitude larger. Such sensitivity cannot be realized if the system does not evolve through the critical point.

To check the validity of our approximation of using equation (3) instead of equation (2), we numerically modelled the stochastic equation (1), with $\lambda = \lambda_0 + \gamma t + 0.05\,\lambda_c f(t)$, $f(t)$ being a gaussian noise. The results are shown in Fig. 2. For easier graphical visualization, we set $\varepsilon = 3.9 \times 10^{-43}$. Then, according to equation (5), $N = \sqrt{2}$, implying $P_+ = 0.921$ selectivity. Figure 2 is the result of averaging 5,000 trajectories and gives a $P_+ = 0.916$ in good agreement with the analytical result. If λ evolves extremely slowly, the approximation of using equation (3) is not valid. In the limit of infinitely slow λ_D, the results in refs 14, 16 can be used; for the intermediate region no analytical results exist.

For the estimate of the r.m.s. value of the random environmental factors, we take circularly polarized light in the ultraviolet range to be typical. (Hardly any reliable data exist for other effects.) Chirally selective photochemical effects of circularly polarized light are well known[31–33]. In our model, let us assume that chirally selective degradation of X (back reaction of reaction

(i)), at a rate $k'[X]$, occurs with a mean life of about 3,000 yr, that is $k' \simeq 10^{-11}\,s^{-1}$ for the average solar intensity. (Note, this is also the racemization rate.) For 100% circularly polarized light, the rate of decay of one of the enantiomers is faster by a factor $s \simeq 10^{-3}$ or less for most molecules[32,33], although there are exceptions[34]. Only a fraction $q \simeq 10^{-3}$ of the solar intensity at dawn and dusk is found to be circularly polarized in the infrared frequencies and is at least an order of magnitude smaller for the ultraviolet[35]. The sense of polarization depends on the direction and on the average it is zero. Considering the reduction of q for daylight intensities and attenuating factors in a large body of water, we may take $q_{rms} \simeq 10^{-6}$ with a correlation time $\tau \simeq 10^3$ s. On the evolutionary timescale of 10^{10}–10^{12} s considered here, this may be considered white noise of strength $\sqrt{2\tau}\, q_{rms}$ (equivalent to diffusion constant of $(1/2\tau)$ steps per unit time, each of length $2\tau q_{rms}$). Thus, the rate of asymmetric synthesis is $k'[X_{L(D)}]qs$; when q is a fluctuating quantity it may be represented by a gaussian white-noise term $C'\eta f_2(t)$, with $C'\eta = k'[([X_L]+[X_D])/2]s\sqrt{2\tau}\, q_{rms}$. By analogy with Cg, we may define $C' \equiv k'([X_L]+[X_D])/2$ and $\eta = s\sqrt{2\tau}\, q_{rms}$. With the above numerical values and $[X] \simeq 10^{-3}$ M, $C'\eta \simeq 3 \times 10^{-22}$, the value used in our numerical estimates.

Presynaptic neurones may contribute a unique glycoprotein to the extracellular matrix at the synapse

Pico Caroni, Steven S. Carlson, Erik Schweitzer & Regis B. Kelly

Department of Biochemistry and Biophysics, University of California, San Francisco, California 94143, USA

As the extracellular matrix at the original site of a neuromuscular junction seems to play a major part in the specificity of synaptic regeneration[1–5], considerable attention has been paid to unique molecules localized to this region[6–11]. Here we describe an extracellular matrix glycoprotein of the elasmobranch electric organ that is localized near the nerve endings. By immunological criteria, it is synthesized in the cell bodies, transported down the axons and is related to a glycoprotein in the synaptic vesicles of the neurones that innervate the electric organ. It is apparently specific for these neurones, as it cannot be detected elsewhere in the nervous system of the fish. Therefore, neurones seem to contribute unique extracellular matrix glycoproteins to the synaptic region. Synaptic vesicles could be involved in transporting these glycoproteins to or from the nerve terminal surface.

Cholinergic synaptic vesicles have been purified to near homogeneity from the electric organs of elasmobranchs[12,13] and have been used to generate nerve-terminal-specific antiserum[14,15]. Using synaptic vesicles purified from the electric organ of *Discopyge ommata* as antigen, we have generated monoclonal antibodies to unique vesicle components copurifying with synaptic vesicle contents during size fractionation. The vesicle-specific monoclonal antibodies define at least four different antigenic determinants (SV1–SV4). The SV1 region is part of the same proteoglycan-like molecule that binds monoclonal antibody tor70 (ref. 16). The other three sites have not yet been described. SV2 is fully accessible to antibody in intact vesicles, whereas the rest become accessible only after sonication or detergent treatment, and so are presumably exposed on the inside of the vesicle[17].

The relative concentration of each antigenic determinant was measured by quantitative immunoblotting of synaptic vesicles (Table 1). All four antigens are present in electric organ synaptosomes at about one-tenth of the concentration in vesicles, which is as expected because acetylcholine and ATP in the vesicles have ~10 times higher concentrations per mg protein[12] than in synaptosomes[18]. When the relative concentrations of all four determinants were measured on homogenates of electric organ (Table 1), SV2 and SV3 had low specific activities, as expected from earlier calculations[12]. The specific activity in the electric organ of the SV4 antigenic sites, however, was ~10 times higher than expected, suggesting that ~90% of it is not in synaptic vesicles. The SV4 site, unlike the other three, is found in high concentrations in an extracellular matrix fraction of the electric organ, where the specific activity is higher than in synaptic vesicles (Table 1). As 77% of the total SV4 (but only 2.1% of the total protein) is recovered in the extracellular matrix, most of the SV4 antigen in electric organ may not be in synaptic vesicles, but in the matrix.

The molecules carrying SV4 and SV1 are highly restricted in their location, whereas the SV2 and SV3 antigens occur in all nerve terminals of the electric fish. In homogenates of brain and spinal chord SV4 and SV1 were less than 2% of the value predicted from the amount of SV2 and equal to background levels measured using liver homogenates. By immunofluorescence the cell bodies of the electromotor nucleus contain large amounts of the SV2, SV1 and SV4 sites, whereas synapses in other brain regions have SV2 but no detectable SV4 or SV1 (K. Buckley, unpublished observations), hence the SV4 and SV1 antigens are restricted to electromotor nucleus neurones.

The molecule in synaptic vesicles carrying the SV4 site has a heterogeneous mobility and its antigenicity is destroyed by exposure to conditions[19] that remove carbohydrate side chains from proteins (Fig. 1). The molecule thus has the properties of a glycosylated protein whose antigenicity is associated with oligosaccharides. The SV4 antigen from the extracellular matrix fraction shows the same heterogeneous electrophoretic mobility, and the same susceptibility to mild proteolysis and sensitivity

Table 1 Relative amounts of unique antigenic determinants

	SV4	SV1	SV2	SV3
	(c.p.m. per μg protein) $\times 10^{-2}$			
Synaptic vesicles	111 ± 4	366 ± 12	170 ± 2	87 ± 2
Synaptosomes	17.4 ± 0.4	35 ± 1	14.8 ± 0.5	6.7 ± 0.5
Extracellular matrix	158 ± 3	18.4 ± 0.7	2.1 ± 0.9	1.2 ± 0.8
Electric organ homogenate	4.4 ± 0.4	3.8 ± 0.5	0.54 ± 0.1	0.32 ± 0.08

The concentration of antigenic sites was determined by an indirect solid-phase radioimmunoassay[16]. Samples were solubilized in 0.2 M NaCl, 10 mM HEPES, 1% SDS pH 7.0 and spotted on nitrocellulose filters. After saturating nonspecific sites with carrier protein (5% bovine serum albumin) monoclonal antibody was added in excess (1/100 dilution of hybridoma supernatants). Bound antibody was detected with affinity-purified iodinated goat anti-mouse IgG. The region where binding was linear with protein concentration was used to calculate antigen concentration by linear regression, ±s.e.m. Although the data from only one experiment are given, the relative ratios of antigen concentration have been confirmed at least four times. The extracellular matrix fraction was purified from the electric organ of *D. ommata* by the procedure of McMahan and his colleagues[11], except that detergent extraction was carried out at *p*H 10.5 to remove adventitiously adsorbed protein.

to deglycosylation as its vesicle counterpart, although the matrix-derived material seems to have an even slower electrophoretic mobility on polyacrylamide gels. Thus, the vesicle and extracellular matrix forms of the antigen are similar, but not identical.

Molecules bearing the SV4 antigen must form a tight association in the extracellular matrix fraction, as <10% is released by detergent extraction during matrix isolation. In contrast, >82% of the synaptic vesicle form is solubilized under identical conditions. The SV4 antigen can be solubilized completely from the extracellular matrix by high salt extraction (4M guanidinium chloride). Treatment of sonicated synaptic vesicles with either high salt or *p*H 11 buffer in the absence of detergents solubilizes <2% of the SV4 antigenic site, suggesting that it is part of an integral membrane protein.

Localization of the antigenic material in the synaptic extracellular matrix was confirmed by a combination of immunoelectron microscopy and biochemical data. Buckley *et al.*[20] have described an antibody to synaptic vesicles (tor70) which also binds to the outside of nerve terminals in the region where they face the electrocytes. SV1, SV3 and SV4 sites are also restricted to this extracellular domain (K. Buckley unpublished observations). To examine extracellular binding sites, we gently sheared electric organ to give large sheets of membrane covered with intact terminals[21,22].

To demonstrate that the SV4 antigenic sites in the extracellular matrix fraction correspond to those seen in the synaptic cleft in immunoelectron microscopy studies, antibodies were bound to the intact nerve terminals as before, except that ^{125}I-labelled goat anti-mouse second antibodies were used instead of fluorescent or peroxidase-labelled ones. With antibodies to the intravesicular antigens (SV1, SV3, SV4), the sheets became heavily labelled. When such sheets, labelled indirectly with antibodies to the SV4 antigen, were subjected to the standard fractionation procedure, 75% of the radioactivity occurred in the extracellular matrix fraction. In contrast, 3% of SV3 and 11% of SV1 were recovered in that fraction. (In this experiment the extracting buffer was at *p*H 7.5, not 10.5, to avoid dissociating antigen/antibody complexes.)

The SV4 antigenic site seems to be generated in the neuronal cell bodies; all four antigenic determinants could be measured in the axons and in the electromotor nucleus. To investigate whether these antigenic sites are generated in the periphery, the axons from this nucleus to the electric organ were cut. Three weeks later, the relative concentrations of the SV4 antigenic site in the electromotor nucleus had increased slightly (Table 2), suggesting that it is not derived by retrograde transport from the nerve terminals. Although SV2 and SV3 increased to the same extent, SV1 fell to 17% of its original concentration. To

Fig. 1 SV4 antigen exists on a glycoprotein. Synaptic vesicle proteins were deglycosylated by an acid hydrolysis procedure that specifically cleaves polysaccharide chains from glycoproteins[19]. Proteolytic digestion was performed for 5 min at 4 °C in the presence of 0.5% Nonidet P-40 with a twofold excess of trypsin over vesicle protein and was interrupted by boiling the sample in final sample buffer. Equivalent amounts of synaptic vesicle protein were run on an 8 M urea/8% SDS polyacrylamide gel and then transferred to nitrocellulose[27]. The nitrocellulose filters were then exposed to monoclonal antibody (1/100 dilution) and subsequently to ^{125}I-goat anti-mouse antiserum using standard washing procedures. Filters were then dried and exposed to Kodak X film with an intensifying screen for 15 h at −80 °C. Lane 1, untreated synaptic vesicles (2 μg protein); lane 2, deglycosylated synaptic vesicles (5 μg protein); lane 3, trypsin-digested synaptic vesicle proteins (2 μg vesicle protein, 4 μg trypsin). S, start of stacking gel; R, start of running gel; T, trypsin present in sufficiently high quantities to bind goat anti-mouse antibodies nonspecifically. The deglycosylation procedure[19] increased the electrophoretic mobility of a glycoprotein standard ovomucoid and did not destroy the antigenicity of the SV2 antigen but increased its relative molecular mass (data not shown).

show that the antigenic sites generated in the electromotor nucleus are transported to the nerve terminals, the nerves from the electromotor nucleus to the electric organ were crushed and the accumulation of antigens at the crush measured. SV1 accumulated only distally, implying that the SV1 antigenic site is probably generated at the nerve terminal (Table 2). SV4, on the other hand, increased three- to fourfold on the proximal side of the crush, implying anterograde transport, and also increased on the distal side, indicating retrograde transport.

As anterograde transport has been associated only with movement of newly synthesized material from the perikaryon[23], we propose that, unlike SV1, the SV4 antigen is made in the cell body. Direct support for a presynaptic origin of the SV4 antigen was obtained by injecting ^{35}S-methionine into the right lobe of the electromotor nucleus. Although the total concentration of label in the ipsi- and contralateral electric organs was indistinguishable (presumably because of systemic leakage of ^{35}S-methionine), immunoadsorption with anti-SV4 specifically precipitated 10–20% of the labelled protein from an extracellular matrix fraction of the right (injected) electric organ. In contrast, only 0–5% was precipitated from the contralateral extracellular matrix. Immunoprecipitation with a monoclonal antibody directed against a non-neural antigen showed no difference between the right and left sides. We therefore conclude that the SV4 antigen is synthesized in the electromotor nucleus and transported to the electric organ, and that the material that accumulated distal to a crush represents antigen that is recycling to the cell body from the nerve terminal. Analogous retrograde transport of vesicle proteins has been observed in vertebrate neurones[24–26] and has been interpreted as the reversal of anterograde flow at the nerve terminal[23].

Table 2 Demonstration that SV4 antigen is made in the cell body

Antigenic site/fraction	SV4	SV1	SV2	SV3
		(c.p.m. per μg protein) × 10^{-2}		
Electromotor nucleus	1.8 ± 0.1	0.83 ± 0.081	2.01 ± 0.2	0.6 ± 0.1
Electromotor nucleus after denervation	2.8 ± 0.2	0.14 ± 0.01	3.0 ± 0.3	1.00 ± 0.2
Nerve	0.33 ± 0.03	0.067 ± 0.009	0.026 ± 0.008	0.013 ± 0.009
Nerve proximal to crush	1.5 ± 0.2	0.09 ± 0.02	0.10 ± 0.01	0.05 ± 0.01
Nerve distal to crush	1.87 ± 0.06	0.52 ± 0.10	0.15 ± 0.02	0.06 ± 0.01

Conditions for operating on electric fish and denervating the electric organ have been described previously[22]. All the nerves to one of the two electric organs were cut and the animal was killed 3 weeks after surgery. The experimental and the control electromotor nuclei were removed separately. In axonal transport experiments, sections of nerves to the electric organ were crushed just proximal to their entry into the electric organ. Three days later the fish were killed and 2-4-mm segments proximal and distal to the crush removed. Samples were prepared by homogenization of tissue in 1% SDS buffer as before, and the antigen concentration measured by dot blotting. Specificity of antibody binding was verified by comparison with synaptic vesicle samples on Western blots.

Two more antigenic determinants shared by the synaptic vesicles and the extracellular matrix have been identified by raising monoclonal antibodies to electric organ extracellular matrix. Twenty-five of these bind to innervated sheets of electric organ membrane in a pattern indistinguishable from that obtained by Buckely *et al.*[20] with specific anti-synaptic vesicle antiserum. Two of these also bind to synaptic vesicle components that co-purify with vesicle contents on permeation chromatography. Both also block binding of ^{125}I-labelled antibody to the SV4 antigenic site on synaptic vesicles and on extracellular matrix, and have Western blot patterns on synaptic vesicle proteins similar to those in Fig. 1. Hence, all three antigenic sites are probably on the same molecule and physically close to each other but are not identical to SV4. The extracellular matrix (ECM)1 antigenic site closely resembled SV4 except that the ratio of extracellular matrix to vesicle binding sites differed by a factor of 2.5. Nerve crush experiments showed that, like SV1, ECM2 was only transported retrogradely and so is also probably generated at the nerve terminal. ECM1 and ECM2 are found only in the cell bodies and at the nerve terminals of the neurones innervating the electric organ. Only one synaptic vesicle component has been found in the extracellular matrix by immunological criteria; the extracellular matrix component is the only one found in vesicles. We conclude that three monoclonal antibodies to different but spatially contiguous antigenic sites bind to a glycoprotein of the synaptic extracellular matrix. The glycoprotein originates in the presynaptic neurone and is modified at the nerve terminal region.

Although the synaptic cleft region of the neuromuscular junction contains unique antibody and lectin-binding sites[6-8], the extracellular matrix glycoprotein recognized by these antibodies may be the first shown to be transported down the axon to the nerve terminals. Using the nerve cell to synthesize extracellular matrix precursors is an attractive solution to the problem of how to create synapse-specific domains in the extracellular matrix.

We thank Dr K. Buckley for participation in the generation and screening of monoclonal antibodies to synaptic vesicles, our colleagues for comments on the manuscript and Leslie Spector for typing the manuscript. This work was supported by an EMBO long-term fellowship (ALTF 57-1982) to P.C. by the Muscular Dystrophy Association of America, and by NIH grant NS 09878 and NS 16033 to R.B.K. and S.S.C.

Carbon-dioxide-induced exocytotic insertion of H^+ pumps in turtle-bladder luminal membrane: role of cell *p*H and calcium

Christopher Cannon, Janet van Adelsberg, Sean Kelly & Qais Al-Awqati

Department of Medicine and Physiology, Columbia University, College of Physicians and Surgeons, 630 W 168th St, New York, New York 10032, USA

The contents of endocytic vesicles and other intracellular organelles (such as Golgi and microsomes) are acidified by an electrogenic proton-translocating ATPase that is remarkably similar to that found in urinary epithelia[1-10]. We recently found that the number of H^+ ATPases in the apical plasma membrane of these epithelia is regulated by exocytotic insertion of endocytic vesicles whose membranes contain this H^+ pump[2,10]. Carbon dioxide, a major stimulus for urinary acidification, causes rapid fusion of these vesicles with the luminal membrane, thereby inserting these pumps there and increasing the rate of net transepithelial H^+ secretion; CO_2 also inhibits endocytic retrieval of the pumps from the luminal membrane[11]. Such reciprocal regulation of endocytosis and exocytosis by a physiological modulator makes this system particularly attractive for studying the cellular events regulating membrane fusion. Here we present evidence that CO_2 induces exocytosis by a cascade of events, the first step of which is cytoplasmic acidification. Cell acidification then increases calcium activity, which causes the fusion event.

The epithelial layer of the turtle urinary bladder is comprised of two cell types, one of which, the mitochondrion-rich cell, is enriched in carbonic anhydrase and in vesicles containing proton pumps; hence, it is thought to be the cell responsible for transepithelial H^+ transport[2,12]. When these bladders are mounted in Ussing chambers, H^+ secretion can be measured as the short-circuit current obtained when sodium transport is inhibited by ouabain[12]. To investigate whether CO_2 causes exocytotic insertion of H^+ pumps by acidifying the cytoplasm, we added 5 mM butyrate or acetate to the luminal medium and found that they stimulated the H^+ current in these bladders and that their effect became greater as the *p*H of the medium was reduced. At *p*H 7, butyrate increased the H^+ current by 33%, at *p*H 6 the H^+ current increased by 116%, whereas at *p*H 5 it increased by 179% ($n = 7$ experiments). Quantitatively similar results were obtained with acetate. Because the *p*K of butyrate and acetate is ~4.8 and the undissociated acid is more permeant, these results suggest that the species of the molecule that is

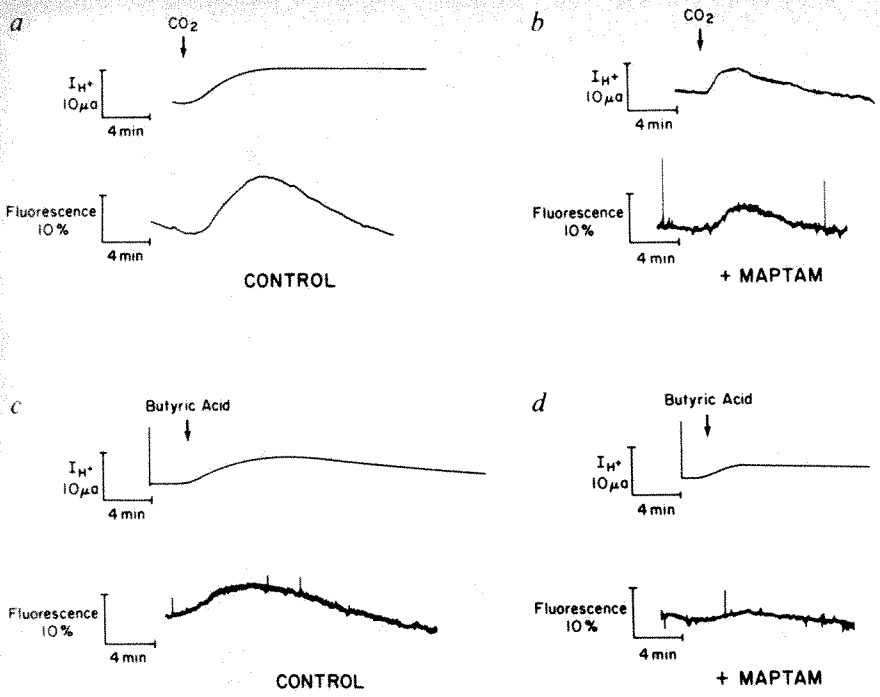

Fig. 1 Exocytosis of fluorescent dextran simultaneously with an increase in H^+ secretion in the turtle urinary bladder. The bladders were perfused on both sides by continuously circulating freshly aerated Ringer's solution with a peristaltic pump. The bladder was initially exposed on the luminal side for 1 h with a 5% CO_2 Ringer's (*p*H 7.5) with FITC dextran (relative molecular mass 70,000) dissolved at 100 mg ml^{-1} followed by 1 h of CO_2-free FITC dextran Ringer's. The luminal solution was then changed to CO_2-free Ringer's without FITC dextran *p*H 6.0 and was passed through a flow cell in a ratio fluorometer (Farrand Optical). After 1 h, both the H^+ current and the fluorescence fell to a low steady-state level. The luminal perfusate was then changed to one containing 5 mM butyric acid, *p*H 6.0 (*a*, *b*), causing a broad peak in the fluorescence tracing and an increase in the H^+ secretion. The solution was then changed to 5% CO_2 Ringer's *p*H 6.0 (*c*, *d*) and a similar rise in H^+ secretion and release of FITC dextran was found. *b*, *d* Show the effect of pretreatment of the luminal side of the bladders with 0.1 mM MAPTAM (Calbiochem) for 1 h.

Table 1 Effect of colchicine (*a*) and MAPTAM (*b*) on H^+ current in paired turtle hemibladders

a	Control	Colchicine-treated
Butyrate ($n=7$)	24±6	13±4*
Acetate ($n=7$)	10±3	4±4*
b	Control	MAPTAM-treated
CO_2 ($n=5$)	11.8±4.6	1.7±5*
Butyrate ($n=8$)	11.2±5	2.9±1.7*
Acetate ($n=3$)	3.0±0.8	0.8±0.6*

Paired hemibladders from freshwater turtles were mounted in Ussing chambers, bathed with CO_2-free Ringer's solution and continuously short-circuited using an automatic voltage clamp. The media were circulated by a gas-lift device using CO_2-free air. Ouabain (0.5 mM) was added to the serosal side in all experiments. The *p*H of the luminal solution was 6.0. The composition of the CO_2-free Ringer's solution was 85 mM NaCl, 3.5 mM KCl, 0.3 mM NaH_2PO_4, 1.65 mM Na_2HPO, 0.5 mM $MgSO_4$, 1 mM $CaCl_2$. *a*, Colchicine (0.1 mM) was added to one member of a pair and 2 h later 5 mM Na-butyrate or Na-acetate was added to the luminal side. The peak increase in the H^+ current is given. Current is given as μA per 8 cm^2 ± s.d. *b*, MAPTAM (50 μM dissolved in dimethyl sulphoxide) was added to one member of a pair whereas the other received diluent only. Two hours later, CO_2 was added isohydrically to both media. In other experiments, butyrate or acetate (5 mM each) was added to the luminal side only. In these experiments, the addition of CO_2 or the weak acids frequently resulted in rapid inhibition of the H^+ current.

*$P<0.05$ compared with the control value.

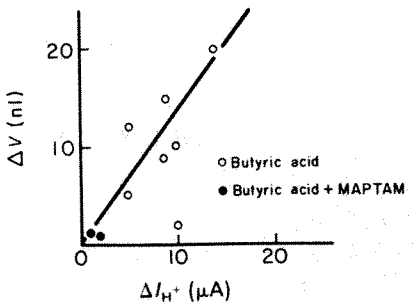

Fig. 2 Correlation of the volume of fluorescent dextran released with the rise in H^+ secretion. Known volumes of the fluorescent dextran loading solution were injected into the perfusion stream. The changes in the fluorescence signal were plotted against the volume injected to obtain a calibration curve from which the secreted volume was calculated.

increasing the transport rate is the undissociated weak acid, which would be expected to cause cytosolic acidification. The increase in H^+ secretion induced by butyrate or acetate was significantly reduced by pretreatment of the bladders with 0.1 mM colchicine (Table 1*a*), an agent that reduces the effect of CO_2 on exocytosis[2,10].

To provide direct evidence for exocytotic fusion induced by the weak acids, we measured their effect on the secretion of fluorescent dextran (fluorescein isothiocyanate (FITC) dextran) previously endocytosed by the bladder (see Fig. 1 legend for assay details). Addition of 5 mM butyrate stimulated secretion of FITC dextran simultaneously with an increase in H^+ secretion (Fig. 1*b*). As with CO_2 (Fig. 1*a*), the fusion event was transient whereas the increase in H^+ transport was constant, implying that the stimulation of H^+ transport was a result of the insertion of H^+ ATPases which continue to turn over and pump protons.

There was excellent correlation between the secreted volume, a function of the number of vesicles which fused, and the increase in H^+ current, which is some function of the number of pumps in the membrane (Fig. 2). These results provide strong evidence that butyrate, like CO_2, increases H^+ pumps in the membrane. Similar studies (not shown) showed that acetate also causes fusion of vesicles.

To measure the cell *p*H of individual mitochondrion-rich cells, we mounted turtle bladders on the stage of a fluorescence microscope and stained them with 6-carboxyfluorescein diacetate (6-CF). Because these cells are enriched in carbonic anhydrase, which is a potent esterase, they preferentially take up the dye and hence appear brighter than the other cell type (Fig. 3*e*). Measurement of the cell *p*H (using a microspectrofluorometric method described in Fig. 3 legend) showed that these cells are more alkaline by ~0.5 *p*H units than the principal cells, as might be expected from H^+-secreting cells. Addition of CO_2 or butyrate acidified the cytosol with a similar time course to that of the effect of these agents on fusion and H^+ transport (compare Figs 1 and 3). That these cells can maintain concentrations of H^+ and 6-CF different from their neighbours implies that they do not have patent gap junctions, a finding that suggests a separate developmental history of the two cell types.

Fusion of vesicles is frequently mediated by changes in cell calcium and recent studies suggest that CO_2 can alter cell calcium activity[13-16]. However, the effect of CO_2 varies in different cell types; in some cells there is an increase[14] while in others CO_2

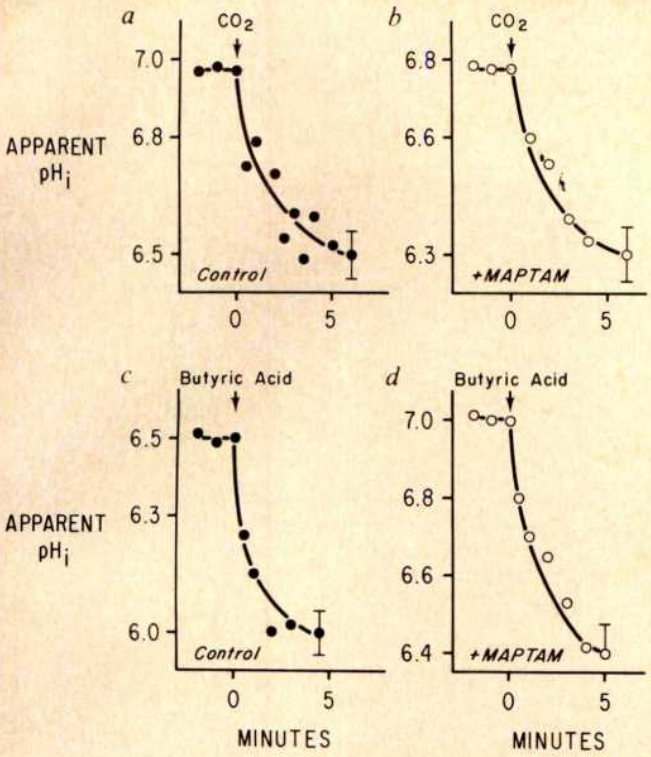

Fig. 3 *a–d*, Graphs showing the average drop in intracellular *p*H when the serosal perfusate was changed from CO_2-free Ringer's *p*H 7.5, to 5% CO_2 *p*H 7.5 (*a*, *b*) or 5 mM butyric acid Ringer's *p*H 7.5 (*c*, *d*). In *b* and *d*, the bladders were preincubated with 50 μM MAPTAM for 1 h. *e*, Turtle bladder epithelium stained with a *p*H-sensitive-fluorescent dye, 6-carboxyfluorescein diacetate (6-CF). Pieces (1 cm^2) of bladder were stretched across cut-off micro-centrifuge tubes. The luminal side of the bladders was stained for 4 min in 20 μM 6-CF in CO_2-free Ringer's *p*H 7.5. The cylinders were placed luminal side down on a glass coverslip on a Zeiss epifluorescence microscope equipped with a mercury lamp and a ×40 objective. The serosal side of the bladder was perfused continuously during microscopy. To measure the *p*H of the cytoplasm, we used a microfluorometer attached to the microscope (Farrand Optical)[2]. Single cells were centred in the aperture of the fluorometer and were excited alternately with 490-nm and 458-nm light using interference filters. The fluorescence emission intensity was measured at 530 nm with the microfluorometer; aperture, 22 μm. A calibration curve of the ratios of fluorescein intensities at the two exciting wavelengths against *p*H was obtained using 1 μM 6-CF dissolved in 0.14 M KCl, 1 mM $MgCl_2$ from *p*H 5.5 to 8.0. There were 7–12 experiments for each condition. The standard deviation, although shown only for the extremes, was the same for all points. The measurement of *p*H in a single cell by our method is subject to several problems relating largely to light scattering and background subtraction. Because each bladder has a different thickness, it is not possible to draw conclusions about the absolute value of the *p*H. However, changes in an individual cell were highly reproducible.

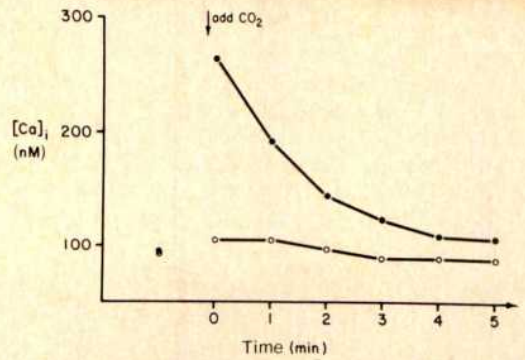

Fig. 4 Effect of CO_2 on intracellular calcium. ●, CO_2; ○, no CO_2. To measure intracellular calcium, turtle bladder epithelial cells were isolated by the method of Rossier *et al.*[23], except that no collagenase digestion was used. Cells were incubated for 1 h in 40 μM Quin 2 AM (Amersham) in CO_2-free Ringer's without calcium, *p*H 7.5. Cells were then washed and resuspended in CO_2-free Ringer's with 1 mM calcium. Fluorescence at excitation 340 nm with emission at 480 nm was measured with a Farrand spectrofluorometer using a 2.5-nm slit width. For each experiment, 1.5 ml of either CO_2-free Ringer's or 5% CO_2 Ringer's were added to 1.5-ml aliquots containing ~1.5×10^6 cells suspended in CO_2-free Ringer's, and the cuvette was sealed. Controls and experiments were always performed on the same cell suspension. Fluorescence was measured for 5 min, at which time calibration of measured Quin 2 fluorescence to concentration of calcium was performed by the method of Tsien[16,17] ($n = 7$, $P < 0.05$ for all points).

educes cell calcium[13,15,16] and in squid axon the effect appears o be biphasic[13]. To measure the changes in cell calcium, we ised the fluorescent calcium indicator Quin 2 in isolated uspended turtle bladder epithelial cells. Quin 2 is an EGTA nalogue which fluoresces when it binds calcium[17,18]; its ester s permeable and the active form is liberated in the cell by cytoplasmic esterases. In unstimulated cells, intracellular calcium is 95 ± 12 nM (±s.e.). Addition of CO_2 by diluting suspended cells with CO_2-saturated buffer causes an increase in cell calcium to a peak of 264 ± 92 nM ($n = 7$, $P < 0.05$), which declines with time towards control concentrations (Fig. 4).

Although these experiments were performed in suspensions containing both cell types, we believe that the signal observed mainly results from the mitochondrion-rich cells, as they were preferentially loaded with Quin 2 through the esterase activity of carbonic anhydrase. Pretreatment of this suspension with acetazolamide, an inhibitor of carbonic anhydrase, substantially prevents the loading of these cells by Quin 2 and 6-CF. Further, acetazolamide, which increases cell *p*H in these cells, reduces the resting calcium level[19]. However, studies in individually identified mitochondrion-rich cells are needed to provide conclusive evidence for the CO_2-induced increase.

To study whether the increased cell calcium is necessary for exocytotic insertion of H^+ pumps, we loaded the epithelium with the calcium buffer 1,2-*bis*-5-methyl-aminophenoxylethane-*N,N,N'*-tetraacetoxymethyl acetate (MAPTAM), another esterified but non-fluorescent EGTA derivative[17,18]. Addition of MAPTAM decreased the H^+ current slightly but considerably blunted the expected increase in H^+ secretion in response to CO_2 and butyrate (Table 1*b*). However, the response was quite variable; in some bladders there was still a small increase (Fig. 1*b*, *d*), while in others there was a rapid decline in the rate of H^+ secretion. On average (Table 1*b*), MAPTAM prevents the increase in H^+ secretion caused by CO_2 and butyrate. This effect is due to inhibition of fusion (Fig. 1*b*, *d*). MAPTAM has no effect on the cytoplasmic acidification caused by CO_2 or butyrate (Fig. 4*b*, *d*).

These results show that CO_2 causes exocytotic insertion of H^+ pumps initially by lowering cell *p*H, which in turn increases cytosolic calcium. The MAPTAM experiments suggest that the increased cell calcium is necessary for exocytosis. In preliminary experiments, we find that the cell *p*H, when lowered by CO_2, relaxes back to the original level in control cells but not in cells where the fusion event has been inhibited by removal of extracellular calcium. These results and the ubiquity of this H^+ ATPase in eukaryotic cells suggest that rapid insertion may be a new mechanism of cell *p*H regulation in addition to the well-studied one mediated by Na/H exchange[20]. In acid-transporting epithelia, this process would be modified only to the extent that

fusion occurs at one cell membrane. Further, recent studies on glucose-mediated insulin release[21] and the effects of CO_2 on vasopressin-induced water permeation[22] suggest that cell acidification may be a more widespread stimulus for exocytosis than previously thought.

Celltech Ltd, 244-250 Bath Road, Slough, Berkshire SL1 4DY, UK
† Department of Biochemistry, University of Oxford, South Parks Road, Oxford OX1 3QU, UK

The yeast *Saccharomyces cerevisiae* can synthesize, process and secrete higher eukaryotic proteins[1-5]. We have investigated the expression of immunoglobulin chains in yeast and demonstrate here (1) the synthesis, processing and secretion of light and heavy chains, (2) the glycosylation of heavy chain, (3) the intracellular localization of these foreign proteins by immunofluorescence, and (4) the detection of functional antibodies in cells co-expressing both chains. This may provide the basis of a microbial fermentation process for the production of monoclonal antibodies. The co-expression of light and heavy chains in *Escherichia coli* has been reported but functional antibodies were not assembled *in vivo*[6,7]. Furthermore, only low-level assembly of these chains was found *in vitro*.

The immunoglobulin λ and μ complementary DNAs used here were isolated from the mouse hybridomas S43 and B1-8, respectively[8,9]. Both hybridomas were raised against the hapten 4-hydroxy-3-nitrophenyl acetyl (NP). The λ and μ cDNAs were placed under the control of the yeast 3-phosphoglycerate kinase (PGK) promoter, on pMA91 bearing the *LEU2* selectable marker[10] (Fig. 1), to form pYλ for the expression of pre-λ, and pYμ for the expression of pre-μ. For co-expression of λ and μ on different plasmids in the same cell, another selectable marker was needed. pLG89 contains two selectable markers, *URA3* and *hph* (ref. 11), therefore the λ coding sequence and PGK promoter from pYλ were excised and inserted into pLG89, to produce pLGλ.

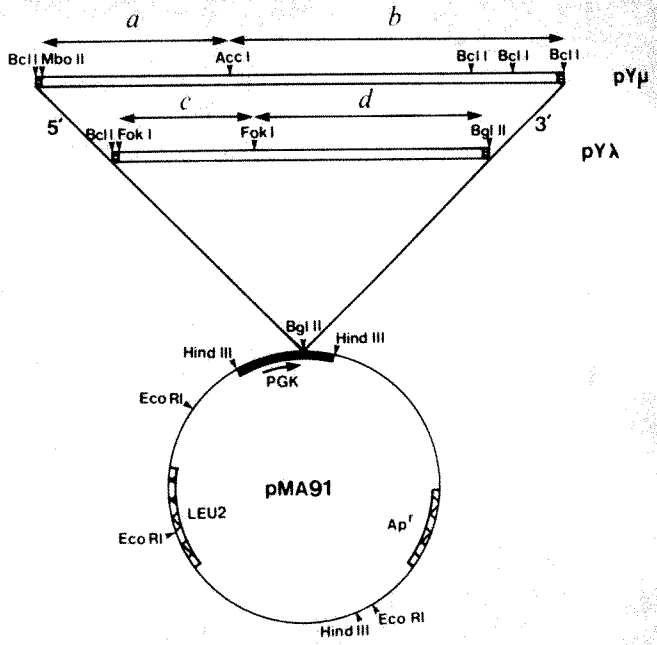

Fig. 1 Plasmids for the expression of immunoglobulin λ and μ chains in yeast. The figure shows the μ and λ inserts of pMA91 which were used to form pYμ and pYλ respectively. Solid bar, PGK sequences; the *LEU2* and Ap^r marker genes are cross-hatched. Sequences derived from synthetic oligodeoxyribonucleotides are indicated by horizontal bars. An arrow indicates the direction of PGK transcription.

Methods. All DNA manipulations were carried out as described elsewhere[22]. For construction of pYλ, the *Hin*dIII fragment of pATλ 1-15 (ref. 6) bearing the λ cDNA was isolated, and cut with *Fok*I; 307-base pair (bp) *Fok*I and 512-bp *Fok*I-*Hin*dIII fragments were isolated (fragments *c* and *d*, respectively). Both oligodeoxyribonucleotides[23]: R162 (5′GATCAATGGCCTG-GATT 3′) and R163 (5′GTGAAATCCAGGCCATT 3′) and pCT54 (ref. 24) cut with *Bcl*I and *Hin*dIII, to form pCTYλ. R162/R163 recreate the 5′ coding sequence, and place a *Bcl*I site immediately upstream of the initiation ATG. pCTYλ was digested with *Hin*dIII, blunted with S_1 nuclease and filled-in with T4 DNA polymerase (P-L Biochemicals); the product was ligated with *Bgl*II linkers (5′AGAGATCTCT 3′), then digested with *Bcl*I and *Bgl*II. The fragment bearing the λcDNA was isolated and ligated with *Bgl*II-cut pMA91, to form pYλ. The 5′ λ coding sequence of pYλ was isolated and shown to be correct by nucleotide sequencing. The λ coding sequence and PGK promoter were excised from pYλ on a *Hin*dIII fragment, and ligated with *Hin*dIII-cut pLG89 to form pLGλ. For construction of pYμ, the μ cDNA was excised from pCT54μ[25] on a *Hin*dIII fragment, blunted (as for pCTYλ) and ligated with linker R107 (5′TTTTGATCAAAA 3′) which contains an internal *Bcl*I site. The ligation product was digested with *Bcl*I and *Acc*I, and the fragment containing the 3′ end of μ coding sequence isolated (*b*). Only the *Bcl*I site created by R107 will cut, for internal sites were *dam*-methylated. pCT54μ was cut with *Mbo*II, ligated with R121 (5′GATCAATGGGATGGAGCTGT 3′) and R112 (5′CAGCTCCATCCCATT 3′) and digested with *Acc*I. The 276-bp *Bcl*I-*Acc*I fragment (fragment *a*) generated was isolated from a 5% polyacrylamide gel. pMA91 cut with *Bgl*II was ligated with both *a* and *b*, to form pYμ. The proximal end of the μ gene was isolated and shown to be correct by nucleotide sequencing[26,27]. Yeast transformations were carried out as described elsewhere[28]. pYλ and pYμ were individually transformed into MD46 (*a*/∝ *pep4.3*/*pep4.3 leu2*/*leu2 arg5.6*/+ +/*trp1* +/*rad52 ade1*/+ *his3*/+; Melanie Dobson, personal communication); pYμ and pLGλ were individually transformed or co-transformed into X4003-5B (*a leu2 ade1 his4 met2 ura3 trp5 gal1*; Yeast Genetic Stock Center, Berkeley, California). Cells containing pYλ or pYμ were selected for by growth in the absence of L-leucine, and pLGλ cells selected for by growth in the absence of uracil.

Cell extracts were subjected to Western blot analysis, using antisera to λ or μ proteins. MD46 cells containing pYλ were found to contain an immunoreactive protein (Fig. 2*a*, lane 3) that co-migrates with authentic B1-8 λ (Fig. 2*a*, lane 1) and with the mature λ protein synthesized by *E. coli* cells containing

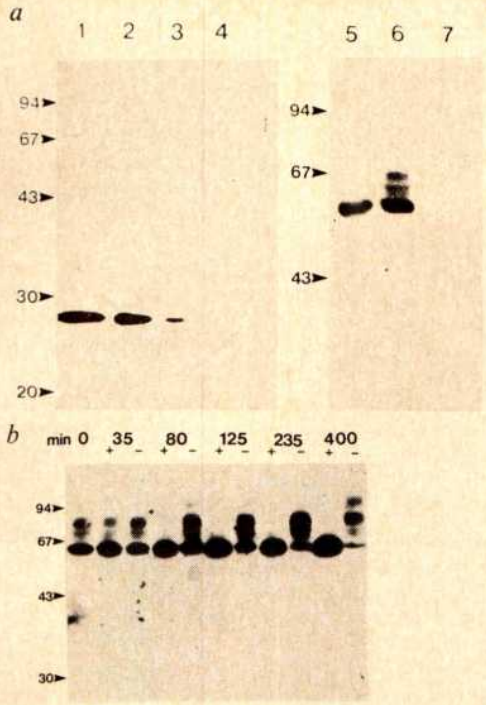

Fig. 2 Analyses of λ and μ proteins in yeast cell extracts. Cells were grown in YMM (2% (w/v) glucose, 0.67% (w/v) Difco yeast nitrogen base without amino acids) to $A_{660} = 1.0$, at 30 °C with shaking, then collected by centrifugation. Cell pellets were disrupted by vortexing with glass beads (40 mesh, BDH) in 50 mM Tris-HCl *p*H 7.6, 1 mM EDTA, and diluted in sample buffer to 1.5% (w/v) SDS, 2.5% (v/v) β-mercaptoethanol, 5% (v/v) glycerol. Samples were subjected to SDS-polyacrylamide gel electrophoresis[29] and transferred to 0.45-μm nitrocellulose and Western-blotted[30,31] with either rabbit anti-mouse λ antibody (Miles) or rabbit anti-mouse IgM (Bionetics), and challenged with affinity-purified iodinated protein A (2 μCi ml^{-1}; Amersham). Migration of yeast λ and μ was compared with that of B1-8 protein and of mature λ and μ synthesized in *E. coli*[6]. ***a***, Lanes 1–4, samples blotted with anti-λ antibody: lane 1, B1-8; lane 2, bacterial λ; lane 3, pYλ/MD46 cell extract; lane 4, MD46 cell extract. Lanes 5–7, samples blotted with anti-IgM: lane 5, bacterial μ; lane 6, pYμ/MD46 cell extract; lane 7, MD46 cell extract. Arrowheads indicate the positions of markers (Pharmacia): phosphorylase *b*, 94 K; bovine serum albumin, 67 K; ovalbumin, 43 K; carbonic anhydrase, 30 K; soybean trypsin inhibitor, 20.1 K. For secretion studies, cells were also grown in YPED (1% (w/v) Difco Bacto yeast extract, 2% (w/v) Difco Bacto peptone, 2% (w/v) glucose) and all cultures were buffered with potassium phosphate *p*H 7.0. In these conditions, we were able to detect the ADH activity in extracts from <0.005 A_{660} units of cells, which would represent lysis of <0.5% of a culture at $A_{660} = 1.0$. At such concentrations, ADH activity remained stable for up to 3 h at 30 °C. Medium supernatants were assayed for ADH by mixing in a cuvette 1 ml of supernatant with 0.3 ml of 500 mM potassium phosphate *p*H 7.0, 100 μl 30 mM NAD (reduced form; Sigma), 0.3 ml 30 mM acetaldehyde (BDH) and 1.3 ml double-distilled water. The decrease in A_{340} was measured with a Gilford spectrophotometer at 30 °C. ***b***, Demonstration of μ glycosylation in yeast. Duplicate 50-ml YMM cultures of MD46 containing pYμ were grown in 250-ml baffled flasks, with shaking at 30 °C to $A_{660} = 1.0$ then split into duplicate 20-ml cultures. To one culture, designated '+', we added tunicamycin[12,32] to a concentration of 15 μg ml^{-1}, in 30 μl of dimethyl sulphoxide (DMSO), and to the other culture, designated '−', we added 30 μl of DMSO alone. Cultures were left shaking at 30 °C, and samples taken at various times from both cultures. Cell extracts were prepared and Western-blotted with rabbit anti-mouse IgM and iodinated protein A. Alternating + and − tunicamycin samples are shown and the times of sampling given above the lanes in min. The 0-min sample was taken immediately before DMSO addition. Cells harbouring pYλ were treated similarly, and no difference was found between cultures with or without tunicamycin, when Western-blotted with anti-λ antiserum (data not shown). This result was expected as λ is a non-glycosylated protein in mammalian cells.

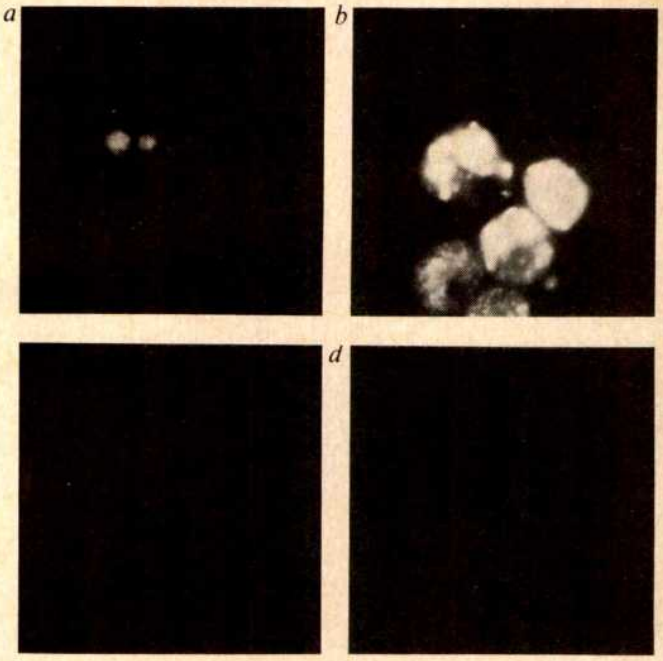

Fig. 3 Intracellular localization of λ and μ protein. The figure shows MD46 cells either untransformed (*c*, *d*), or transformed with pYμ (*a*) or pYMλ (*b*); *a* and *c* were incubated with fluorescein-conjugated anti-μ; *b* and *d* with rhodamine-conjugated anti-λ. ×700.

Methods. Cells were grown in minimal media and converted to spheroplasts with zymolyase 20,000 (50 μg per A_{660} unit in 0.5 ml; Miles), in 1.2 M sorbitol, 50 mM potassium phosphate *p*H 7.0, 15 mM β-mercaptoethanol, 10 mM EDTA, at 30 °C for 30 min. Spheroplasts were washed in 1.2 M sorbitol, and deposited on glass microscope slides using a cytocentrifuge, then fixed in 5% (v/v) acetic acid/95% (v/v) ethanol, at −20 °C overnight. Slides were rehydrated and washed thoroughly in phosphate-buffered saline (PBS), before being stained with 0.1 mg ml^{-1} of fluorescein isothiocyanate-labelled affinity-purified goat anti-mouse IgM or tetramethylrhodamine isothiocyanate-labelled affinity-purified goat anti-mouse λ (both from Southern Biotechnology Associates, Alabama). Slides were washed in PBS, and mounted in glycerol containing 1,4-diazabicylo(2.2.2)octane, before examination by ultraviolet microscopy.

a gene for mature λ (ref. 6) (Fig. 2*a*, lane 2). MD46 cells containing pYμ were found to contain three immunoreactive species (Fig. 2*a*, lane 6). The predominant yeast μ-immunoreactive band had a relative molecular mass (M_r) of ~63,500 (63.5 K) consistent with it being mature, non-glycosylated μ, and co-migrated with the mature μ synthesized by *E. coli* cells containing a gene for mature μ (ref. 6) (Fig. 2*a*, lane 5). In addition, two diffuse bands of greater relative molecular mass were found in MD46 cells containing pYμ (Fig. 2*a*, lane 6). The mature, glycosylated μ of B1-8 has a M_r ~70 K (not shown).

We conclude that the λ immunoreactive species is mature λ, and the ~63.5 K μ species is mature, non-glycosylated μ. On the basis of relative molecular mass, the signal sequences of both proteins have probably been cleaved. The higher-M_r μ bands were shown by two criteria to be glycosylated μ. First, the higher M_r μ was lost from cells treated with tunicamycin, an inhibitor of *N*-linked glycosylation[12]. In cultures without tunicamycin, the amount of higher-M_r μ increased during the time course examined, up to 235-min sample, after which the culture reached stationary phase, and the level of μ decreased (Fig. 2*b*). In cultures containing tunicamycin, the 63.5 K μ species accumulated with this species alone being found after 80 min of tunicamycin treatment. In addition, the higher-M_r form of μ was reduced in size to that of mature, non-glycosylated μ from *E. coli*, when treated with trifluoromethane sulphonic acid, which removes *N*-linked glycosyl groups with high efficiency[13] (data not shown). We conclude that a significant proportion of yeast μ is *N*-glycosylated. However, the yeast

and mammalian μ will probably differ in carbohydrate composition, especially if the yeast μ has outer-chain oligosaccharides[14,15].

Medium supernatants from cultures of MD46 cells transformed with either pYλ or pYμ were found to contain immunoreactive λ or μ protein, respectively. This was shown to be genuinely secreted material, rather than arising from cell lysis, by demonstrating the absence of a cytoplasmic enzyme, alcohol dehydrogenase (ADH), from the supernatants (see Fig. 2 legend). In yeast minimal medium (YMM), up to 10% of λ and 5% of μ in MD46 cultures at A_{660} ~1.0 was found in the medium supernatant, as detected by enzyme-linked immunosorbent assay (ELISA)[25]. In YPED medium (Fig. 2 legend) up to 40% of λ and 15% of μ was found in this fraction. Transformed X4003-5B cells generally yielded higher levels of secreted material. The immunoreactive λ material from the medium supernatants of cultures containing pYλ was shown, by Western blotting, to co-migrate with intracellular λ (data not shown). The secreted μ has not yet been examined.

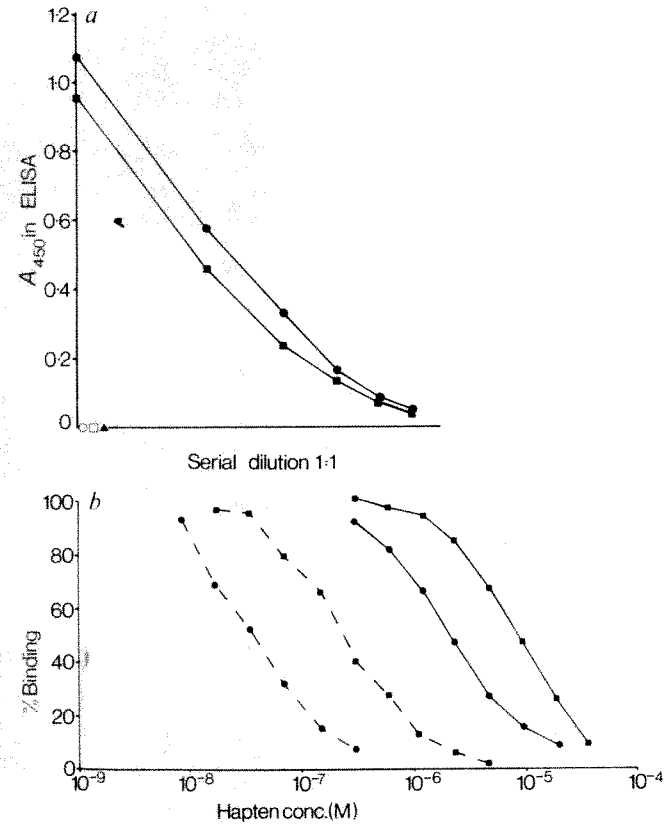

Fig. 4 Analysis of functional antibodies in yeast. Transformed X4003-5B cells were grown in 100-ml volumes of YMM, supplemented with 50 mg l^{-1} of L-tryptophan, L-histidine and L-methionine, and 30 mg l^{-1} of adenine sulphate in 500-ml flasks. Strains not containing pLGλ were supplemented with 30 mg l^{-1} uracil, and those not containing pYμ with 50 mg l^{-1} L-leucine. Cells were collected by centrifugation, then washed and resuspended in 25 mM Tris-HCl *p*H 8.0, 1 mM EDTA, 5% (v/v) glycerol, 0.1% (v/v) Nonidet-P40, 1 mM phenylmethylsulphonylfluoride (extraction buffer), before being lysed by glass bead disruption. 'Insoluble' material was pelleted in a microfuge for 12 min at 4 °C, and the 'soluble' supernatant fraction removed. The soluble fraction was analysed in a two-site sandwich ELISA (NIP assay) which detects μ-chain binding to haptenylated bovine serum albumin (NIP-caproate-BSA)[6]; this assay is sensitive to 60 pg of B1-8 IgM. *a*, Specific hapten binding was examined in the NIP assay of the soluble fraction of pLGλ + pYμ-transformed cells (●, ○), pYμ-transformed cells (▲) and B1-8 (■, □), in the absence (solid symbols) and presence (open symbols) of 30 μM free NIP-caproate. *b*, The heteroclitic nature of yeast antibody activity (●) in soluble fractions from pLGλ + pYμ-transformed cells and B1-8 (■) was examined by comparing binding in the presence of free NIP-caproate (- - -) and NP-caproate (——).

The intracellular locations of λ and μ proteins in yeast were examined by staining fixed yeast spheroplasts with fluorescein or rhodamine-conjugated antisera. We stained both MD46 and X4003-5B strains, harbouring pYμ, pYλ, pLGλ or pYMλ. pYMλ is a pMA91 derivative encoding the mature λ protein, that is, Met-mature λ, not including the signal sequence. Cells containing pYμ (Fig. 3*a*), pYMλ (Fig. 3*b*), pYλ or pLGλ showed a discrete immunofluorescence localized in bodies that appeared on the basis of their morphology to be vacuoles[16,17]. Cells containing pYMλ showed a much greater accumulation of stain than those containing pYλ; this may be explained by the observation that the intracellular concentration of mature λ from pYMλ is up to fourfold greater than that of pre-λ from pYλ, in MD46, by ELISA. Further experiments are required to identify unequivocally the sites of accumulation of immunoreactive λ and μ proteins. If these foreign proteins are being localized in the vacuole, they could be transported there by the secretory pathway[18,19], however, the detection of mature λ from pYMλ in the same structures calls this into question—the cell may be directing these proteins to the vacuole for degradation[20].

Soluble extracts of X4003-5B cells transformed with one or both of pYμ and pLGλ were prepared and analysed by an ELISA that detects binding of B1-8 to solid-phase hapten, in the presence and absence of competing free hapten[6] (Fig. 4*a*); no specific binding was detected for extracts of cells transformed with either pLGλ or pYμ. However, extracts of cells transformed with both plasmids, and expressing both light and heavy chains, showed a strong, specific signal similar to that of the hybridoma B1-8 protein. All detectable solid-phase hapten binding was lost in the presence of 30 μM free hapten. B1-8 is a heteroclitic antibody, and shows greater affinity for the related hapten 4-hydroxy-5-iodo-3-nitrophenyl acetyl (NIP), than for the hapten NP[21]. The yeast antibody activity also showed that higher free NP than free NIP concentrations were required to inhibit binding of antibody to solid-phase NIP (Fig. 4*b*). In addition, the activities of the yeast antibody and B1-8 showed similar specificity ratios (ratio of concentration of NP to NIP at 50% inhibition) of 37 and 47, respectively. The amount of μ protein in the soluble extract of cells containing pLGλ and pYμ was determined by ELISA, and using B1-8 as a standard, the specific activity of the yeast antibody was found to be ~0.5%. ELISA showed that at $A_{660} = 1.0$, there was ~500 ng of B1-8 λ equivalent, and 15 ng of B1-8 μ equivalent per ml. No significant amounts of NIP binding activity have been found in concentrated culture media (data not shown).

On the basis of the specific activity of the soluble-fraction yeast antibodies, the efficiency of assembly of functional antibodies is low, although the antibodies show both specific hapten binding and heterocliticity. It will be interesting to characterize further the yeast antibodies in the soluble fraction and to determine whether or not most of the immunoglobulin protein from the insoluble fraction (~75% of total) is also assembled into functional antibodies.

We thank Drs A. Bothwell and D. Baltimore for supplying plasmids pABλ1-15 and pABμ-11; Drs M. Neuberger and T. Imanishi-Kari for gifts of B1-8 protein; Dr J. E. Davies for the provision of pLG89; and Drs M. Dobson, A. J. Kingsman and S. M. Kingsman (Oxford) for pMA91 and MD46. We thank our many colleagues in Celltech and Oxford, for advice and discussions.

Functional modifications of cytotoxic T-lymphocyte T200 glycoprotein recognized by monoclonal antibodies

Leo Lefrançois & Michael J. Bevan

Department of Immunology, Scripps Clinic and Research Foundation, 10666 North Torrey Pines Road, La Jolla, California 92037, USA

Plasma membrane glycoproteins of cytotoxic T lymphocytes (CTLs) are involved in the binding to and subsequent destruction of appropriate target cells[1–3]. The electrophoretic profile of surface proteins of mature CTLs, particularly those of high relative molecular mass (M_r), is markedly different from that of naive peripheral T cells or non-cytolytic T cells[4–7], suggesting the possible involvement of these molecules in the activation of CTLs and/or in the lytic process itself. By generating monoclonal antibodies to cell-surface proteins of CTL clones, we have now detected CTL-specific modifications in one of these high-M_r membrane proteins, T200. Although forms of T200 are found on a wide variety of cell types, the neoantigenic determinants recognized by our antibodies are present exclusively on activated T cells and in high concentrations only on CTLs. Furthermore, the expression of the modifications recognized by our antibodies is influenced by soluble factors and also seems to have functional significance, as monoclonal antibodies specific for these novel epitopes block cytolytic activity.

Monoclonal antibodies with specificity for CTL surface recognition structures were produced by immunizing BALB.B mice repeatedly (intraperitoneally) with a C57BL/6-derived CTL clone, B3.3, which is specific for a BALB minor histocompatibility antigen in association with H-2K^b. Spleen cells of immune mice were fused to a myeloma partner, P3-X63 Ag8.653, and the resulting hybridoma supernatants were screened for the ability to block specific target lysis by B3.3. Figure 1*a* depicts the blocking activity of two of these monoclonal antibodies, CT1 and CT2, on clone B3.3 in conditions of saturating antibody. CT1 and CT2 (which are both IgM antibodies) efficiently block specific killing of BALB.B target cells by clone B3.3, CT2 being the more efficient of the two antibodies. In this regard, CT2 was as efficient as the anti-Lyt-2 monoclonal antibody, 53.6.72. Antibody I3/2.3, which is specific for the T200 molecule[8], did not significantly affect specific lysis by this CTL clone.

To determine whether CT1 and CT2 were able to block CTL-mediated killing in conditions not requiring antigen-specific recognition on the part of the CTLs, we tested their ability to inhibit lectin-dependent cell-mediated cytotoxicity (LDCC). Both antibodies were highly efficient as inhibitors of

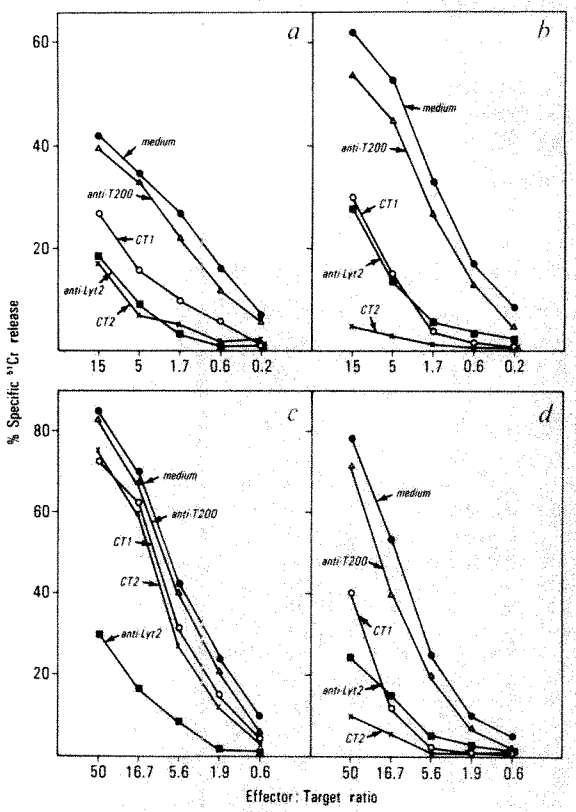

Fig. 1 Inhibition by CT antibodies of cytolysis mediated by cloned CTLs and MLC-derived CTLs. Serial dilutions of effector cells were incubated in 96-well round-bottomed microtitre plates for 30 min at 4 °C with saturating levels of CT1 (○), CT2 (×), I3/2.3 (△, anti-T200, kindly provided by Dr Ian Trowbridge, Salk Institute), 53.6.72 (■, anti-Lyt-2), or medium (●). Effector cells were: *a*, *b*, CTL clone B3.3 (a C57BL/6 clone derived by limiting dilution and specific for a BALB minor histocompatibility antigen in association with H-2K^b); *c*, C57BL/6 spleen cells stimulated for 5 days with irradiated DBA/2 spleen cells (5×10^6 cells of each per well in 24-well plates) in RPMI 1640 culture medium supplemented with 5% fetal calf serum; *d*, MLC cells derived as in *c* but restimulated (5×10^5 responders and 5×10^6 stimulators per well) every 7 days for 4 weeks in medium containing 5% rat Con A supernatant (RCS). ^{51}Cr-labelled target cells (1×10^4) were as follows: *a*, 3-day BALB.B Con A blasts; *b*, P815 H-2^d mastocytoma cells with the addition of 10 μg ml^{-1} PHA; *c*, *d*, P815 cells. After the addition of target cells, the plates were centrifuged for 3 min at 800 r.p.m. to initiate cell contact and incubated at 37 °C for 2 h. Per cent specific lysis was calculated as $100\times$[(c.p.m. released with effectors) − (c.p.m. released alone)]/[(c.p.m. released by detergent) − (c.p.m. released alone)]. Spontaneous release of P815 target cells was 5% and that of BALB.B Con A blasts 18%. No significant lysis was observed of C57BL/6 Con A blasts (*a*), of P815 cells without the addition of PHA (*b*), or of EL4 cells (*c*, *d*).

phytohaemagglutinin (PHA)-dependent killing of P815 tumour cells by clone B3.3 (Fig. 1*b*). CT1 was comparable with anti-Lyt-2 in blocking LDCC, while the anti-T200 antibody did not inhibit lysis (Fig. 1*b*). (Note that CT1 and CT2 do not bind to the target cells used in these assays; see below.) We also found that five out of five independently isolated CTL clones of various target specificities were blocked by both antibodies. Thus, it was apparent that CT1 and CT2 were not clone-specific or anti-idiotypic in their reactivity. More surprising results were obtained when we examined their effect on heterogenous populations of CTLs generated in mixed lymphocyte culture (MLC). When the effects of these antibodies on the lytic ability of a primary MLC were tested (Fig. 1*c*), only minimal inhibition of specific lysis was observed using CT1, CT2 or the control antibody I3/2.3 (anti-T200), while 53.6.72 (anti-Lyt-2) significantly inhibited lysis. However, quite surprisingly, in inhibition assays using as effectors CTLs from a long-term MLC, CT1 and CT2 produced a significant decrease in specific lysis (Fig. 1*d*). This MLC (and others similarly blocked by CT1 and CT2) were

Table 1 CT antigen expression in cytolytic and non-cytolytic T-cell populations and in naive cell populations

Cell source	Strains represented	Reactivity
Cytotoxic T-cell clones and long-term MLC cells (15)	C57BL/6, SJL, BALB.B, BALB/c, B10.D2, B10.BR	++++
Non-cytolytic T-cell clones (11)	C57BL/6, B10.D2, CAF_1, B10.A	+/−
Non-cytolytic T-cell hybrids (10)	B10.A, B10.D2	−, +/−
Primary MLC cells	C57BL/6, BALB.B	++
Thymocytes	C57BL/6, BALB.B	−
Lymph node T cells	C57BL/6, BALB.B	−
Bone marrow	C57BL/6	−
Spleen	C57BL/6	−

Reactivity of CT1 and CT2 was determined by fluorescence flow cytometry or fluorescence microscopy. CTL clones, long-term MLC cells and non-cytolytic T-cell clones were propagated by restimulation with the appropriate irradiated spleen cells in medium containing 5% supernatant derived from Con A-stimulated rat spleen cells (RCS) and 50 mM α-methyl mannoside. Non-cytolytic T-cell hybrids and primary MLC cells were grown in medium without RCS. MLCs were established by co-culturing 5×10^6 responder spleen cells per 2 ml culture with 5×10^6 irradiated (2,000 rad, ^{137}Cs source) stimulator spleen cells. Primary MLC cells were tested for CT reactivity 5 days after stimulation and long-term MLC cells were tested 4 days after the fifth *in vitro* restimulation. Viable cells were isolated by passage over Ficoll-Isopaque, resuspended in phosphate-buffered saline with 0.1% NaN_3 and 0.1% bovine serum albumin at a concentration of 1×10^7 ml^{-1}. Cells (1×10^6) were incubated with 100 µl of a 1:100 dilution of ascites fluid of antibodies CT1 or CT2 at 4 °C for 30 min. After washing, the cells were incubated for 30 min at 4 °C with a fluorescein-conjugated affinity-purified $F(ab')_2$ rabbit anti-mouse reagent (Cappel Laboratories). After washing, the cells were resuspended at 1×10^6 cells ml^{-1} for cytofluorimetric analysis or were placed directly on slides for fluorescence microscopic analysis. Numbers in parentheses indicate the number of individual clones tested. For comparison of relative fluorescence intensities, see Fig. 3.

cultured in the presence of supernatants containing interleukin-2 (IL-2), as were our CTL clones. Only weak blocking of long-term MLC cells was observed without the addition of exogenous IL-2 to the cultures. This dichotomy seems to result from differential expression of CT antigens on MLC cells cultured with or without lymphokine-rich supernatants (see below).

As these antibodies clearly were reacting with CTLs, we also investigated the presence of the antigens recognized on other cell populations. By screening a large panel of T-cell clones for reactivity with CT1 and CT2, we determined that only T cells of CTL lineage expressed significant levels of the antigen(s) recognized by the CT monoclonal antibodies (Table 1). Seventeen independent CTL clones expressed high levels of CT antigen whereas 11 non-cytolytic T-cell clones and 10 non-cytolytic T-cell hybrids either did not express the CT determinants or expressed them only weakly. Importantly, both CTL clones and non-cytolytic T-cell clones were cultured identically in the presence of antigen and IL-2-containing supernatants. Furthermore, the T-cell clones tested represent a wide variety of specificities and strains of origin, indicating that the genetic background of the T cells probably does not influence CT antigen expression. In fact, these antibodies are autoantibodies, as they were produced in BALB.B mice and react with BALB.B-derived CTL. Primary MLC cells express intermediate levels of CT antigen whereas thymocytes, lymph node T cells, spleen cells and bone marrow cells were unreactive with the CT antibodies. Several T-cell lymphoma lines tested also did not express the CT antigens[9].

The characteristics of CT1 and CT2 suggested the presence of a CTL-specific differentiation or activation antigen(s) involved in CTL-induced lysis. The biochemical characteristics of the antigen recognized by these antibodies were explored by radioiodination of the CTL clone B3.3 followed by immune precipitation (Fig. 2). Precipitation with CT1 followed by SDS-

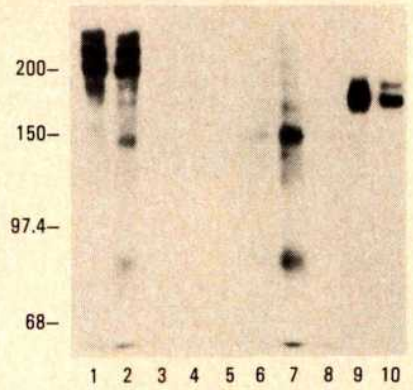

Fig. 2 Radioimmunoprecipitation by anti-T200 and CT1 antibodies. CTL clone B3.3, EL4 thymoma cells or the non-cytolytic M1s-reactive T-cell clone BB5 (kindly provided by Dr Andrew Glasebrook, Salk Institute) were labelled using $Na^{125}I$ (1.0 mCi per 1×10^7 cells) by the lactoperoxidase method[28]. After washing, the cells were resuspended in lysis buffer (phosphate-buffered saline, 1% Nonidet P-40 (NP40), 2 mM phenylmethylsulphonyl fluoride, 20 IU ml^{-1} aprotinin, 10 mg ml^{-1} bovine serum albumin) and incubated on ice for 30 min. The lysates were centrifuged at 13,000 *g* for 5 min and aliquots of the supernatant were incubated with ascites fluid containing CT1 or, in the case of I3/2.3, with the monoclonal antibody directly coupled to Sepharose 4B (a gift of Dr Ian Trowbridge). For precipitations using CT1, protein A-Sepharose 4B coated with rabbit anti-mouse immunoglobulin was used as a second-step reagent. After incubation at 4 °C, the immune complexes were washed extensively with buffer (20 mM Na-phosphate, 0.5 M NaCl, 0.5% deoxycholic acid, 0.5% NP40, 0.1% SDS, 2 mM EDTA) and subsequently analysed by SDS-polyacrylamide gel electrophoresis according to the procedure of Laemmli[29] but using as acrylamide stock a 30% w/v acrylamide, 0.17% bis-acrylamide solution to form 7.5% acrylamide gels. The gels were dried and subjected to autoradiography. Lanes 1–8, CTL clone B3.3. Lane 1, I3/2.3 (anti-T200); lane 2, CT1; lane 3, CT1 after preclearance with CT1; lane 4, I3/2.3 after preclearance with CT1; lane 5, I3/2.3 after preclearance with I3/2.3; lane 6, CT1 after preclearance with I3/2.3; lanes 7, 8, prolonged autoradiographic exposure of lanes 6, 5, respectively. Lanes 9, 10, I3/2.3 precipitates of labelled BB5 and EL4 cell lysates, respectively. M_r markers are shown$\times10^{-3}$.

polyacrylamide gel electrophoresis (PAGE) yielded a series of proteins of high M_r as well as two proteins of relatively lower M_r (Fig. 2, lane 2). The high M_r proteins recognized by CT1 appeared similar to the molecules precipitated from the same lysates by the anti-T200 antibody I3/2.3 (Fig. 2, lane 1). CT1 precipitated proteins with apparent M_rs of 24,000 (24K), 220K and 200K and two proteins with lower apparent M_rs of 140K and 85K. Minor proteins of 190K and 180K were also occasionally observed. Precipitation with anti-T200 antibody followed by PAGE showed nearly the same high-M_r protein profile as that precipitated by CT1, with a greater amount of the 190K protein being precipitated by anti-T200. Interestingly, the 140K and 85K proteins precipitated by CT1 were never observed in anti-T200 immmunoprecipitates. Although CT2 was very inefficient in immunoprecipitation experiments, Western blot analysis with both antibodies showed similar binding profiles (data not shown).

We next investigated whether the determinants recognized by CT1 and the anti-T200 antibody were present on the same molecules. Sequential immunoprecipitations were carried out using CT1 or anti-T200 to preclear lysates from surface -labelled cloned CTLs. Preclearing of the lysate from clone B3.3 with CT1 resulted in the complete removal of the antigens recognized by CT1 (Fig. 2, lane 3) and by anti-T200 (lane 4). Conversely, preclearing with anti-T200 followed by precipitation with anti-T200 or CT1 revealed that most of the high-M_r material reactive with CT1 or anti-T200 had been removed (Fig. 2, lanes 5, 6). However, the two lower-M_r proteins recognized by CT1 were not removed by preclearance with anti-T200 (Fig. 2, lanes 6, 7).

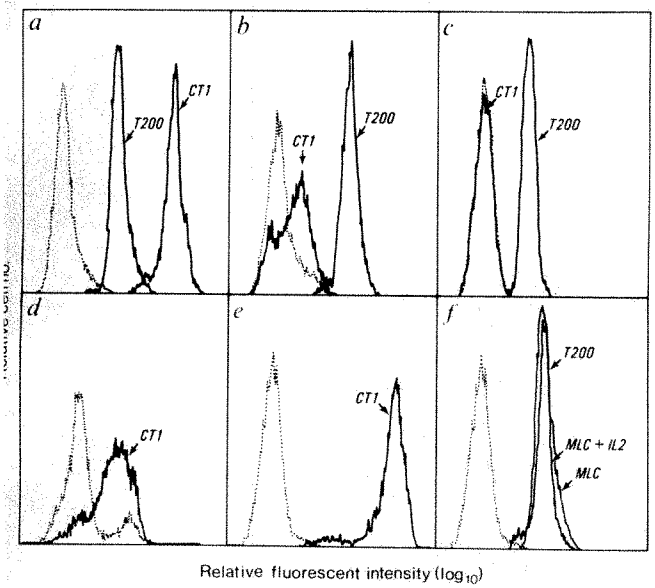

Fig. 3 The preferential reactivity of CT monoclonal antibodies with CTLs is not due to variations in cell-surface T200 concentration. *a*, CTL clone B3.3; *b*, T-helper clone D10.2; *c*, thymocytes; *d*, primary MLC; *e*, long-term MLC cultured with RCS; *f*, long-term MLC with or without the addition of RCS. Viable cells were stained as in Table 1 with CT1 or I3/2.3 (anti-T200) followed by reaction with an $F(ab')_2$ of a fluorescein-rabbit anti-mouse immunoglobulin (CT antibodies) or fluorescein rabbit anti-rat immunoglobulin (I3/2.3). Relative fluorescent intensities of individual cells were measured using the FACS-IV (Becton-Dickinson). Forward angle light scatter was used to exclude dead and aggregated cells. Dotted lines indicate the fluorescent profile of control antibody. Non-cytolytic T-cell clone D10.2 was provided by Dr Susan Webb.

For comparison of the T200 molecule present on CTLs with he T200 protein of other T-cell populations, the non-cytolytic T-cell clone BB5 and the EL4 thymoma were suface-labelled ınd the lysates immunoprecipitated with anti-T200 (Fig. 2, lanes), 10). PAGE analysis showed that two 175K and 190K proteins were precipitated from the surface of EL4 cells (a minor protein of 200K was also sometimes visible) and a heterogeneous protein(s) of 175–195K was precipitated from BB5. The T200 protein profile of EL4 was virtually identical with that of thymocytes ınd lymph node T cells. Immunoprecipitation with CT1 revealed hat a minor amount of T200 ($<1\%$ of total precipitable T200) was precipitated from BB5 cell lysates while no specific precipiation of proteins by CT1 from EL4 lysates was observed[9].

Because the CT determinants are expressed on T200 nolecules, their differential expression could result from disparıte T200 levels on different cell populations. To test this possibilty, we analysed T-cell populations by fluorescence flow ytometry after reactions with CT or anti-T200 antibodies folowed by reaction with a fluorescein-labelled secondary reagent Fig. 3). CTL clone B3.3 expressed high levels of CT deterninants (Fig. 3*a*), whereas an Mls-reactive non-cytolytic T-cell lone D10.2 (which produces IL-2 in response to antigen) xhibited very low reactivity with the CT antibody, ~25% of he cells being weakly CT^+ (Fig. 3*b*). However, the level of ell-surface T200 on these clones was nearly identical. Thynocytes were unreactive with CT antibodies but displayed a evel of T200 similar to that of the T-cell clones (Fig. 3*c*). Primary MLC cells (which were ~85% Thy 1^+ and ~65% Lyt-2^+) xpressed intermediate levels of CT antigen, with ~60% of ells being CT^+ (Fig. 3*d*). In contrast, virtually all long-term MLC cells cultured with exogenous IL-2 (>95% Thy 1^+, $T200^+$ ınd Lyt-2^+) expressed very high levels of CT antigen (Fig. 3*e*). The T200 concentration on long-term MLC cells cultured with ır without exogenous IL-2 remained constant (Fig. 3*f*), indicatng that different levels of CT antigen expression were not the esult of variations in T200 expression. The shift from low to ıigh CT antigen expression is accompanied by marked sequenial biochemical changes in the T200 molecule[9].

The T200 glycoprotein, which carries the Ly 5 determinants[10,11], has been implicated in several immunological mechanisms[12–14] and is a major cell-surface receptor for concanavalin A (Con A)[15,16]. The inhibitory activity of anti-Ly 5 sera or anti-T200 monoclonal antibodies on CTLs has remained a controversial topic[17–21]. (Note that the CT antibodies bind to long-term MLC cells and T-cell clones from both B6 (Ly 5.1) and SJL (Ly 5.2) mice, Table 1.) Our results indicate that the CT antibodies are able to inhibit CTLs expressing high levels of CT antigen but are unable to block CTLs exhibiting relatively low CT antigen levels (long-term MLC cells compared with primary MLC cells; Fig. 3*d*, *e*). However, primary MLC cells do express significant levels of CT antigen whereas naive peripheral T cells and clones of T-helper cell phenotype do not. The inability of CT antibodies to inhibit primary MLC CTLs does not exclude a role for CT determinants in the general mechanism of CTL-induced lysis, as the inhibition assay may be influenced by various parameters, including antigen expression (as shown), the relative affinities of monoclonal antibodies and CTLs, and CTL recycling.

Few antigens have been described that are specific for activated T cells, and no monoclonal antibodies specific for activation determinants of a T-cell subclass have been reported until now. By selectively labelling T-cell surface glycoproteins, Kimura and Wigzell[22] demonstrated the presence of a 145K protein expressed primarily on Lyt 1^-2^+T cells, but drew no conclusions as to the functional role of this molecule. Whether this protein is related to the 140K protein precipitated by CT1 is unknown. The monoclonal antibody HNK-1, which is reactive with carbohydrate, defines a differentiation antigen selectively expressed on human natural killer cells[23,24] and is therefore similar to the CT antibodies in defining a functional subset of lymphocytes. Indeed, our preliminary results suggest the CT antibodies may also be specific for cell-type-specific carbohydrate determinants. Interestingly, a variant of T200, termed T200A, selectively appears on most T cells after activation[25]. However, unlike the antigens described here, the T200A determinants are present on molecules distinct from the T200 glycoprotein and monoclonal antibodies specific for T200A do not inhibit CTL-mediated cytolysis[25]. Recent work has also indicated the presence on human T cells of high-M_r activation antigens distinct from the human T200 molecule[26,27]. Thus, activation of T cells results in the appearance of proteins or antigenic determinants not present on resting T cells which are apparently involved in their subsequent functions. We propose that the maturational modifications of the T200 glycoprotein detected by our antibodies are functionally related to the lytic capability of CTLs. These alterations may act to stabilize further the interaction of CTL and target cells or may represent modifications necessary for the triggering of the lytic mechanism in fully differentiated CTLs.

We thank Dr Lynn Puddington for helpful discussions concerning the biochemistry and Dr Ian Trowbridge for the gift of anti-T200 reagents. This work was supported in part by USPHS grants AII9335 and AII9499. L.L. is a Senior Fellow of the American Cancer Society, California Division, S-23-84.

Construction of chimaeric processed immunoglobulin genes containing mouse variable and human constant region sequences

Shun-ichi Takeda, Takayuki Naito, Kazuaki Hama, Takafumi Noma & Tasuku Honjo

Department of Genetics, Osaka University Medical School, Kita-ku, Osaka 530, Japan

The specificity of monoclonal antibodies provides a powerful diagnostic and therapeutic tool in investigating human neoplasia. Radiological scanning and immunotherapy with mouse tumour-specific monoclonal antibodies have been applied to patients with some success[1-3], but a major problem is the neutralization of the mouse antibody induced by repeated administration of heterologous antibodies. To avoid or reduce such immune reactions, chimaeric immunoglobulins consisting of mouse variable (V) and human constant (C) regions can be synthesized. We have constructed a recombinant retrovirus DNA carrying genomic heavy-chain (H) variable–diversity joining (V_H–D–J_H) and $C_\gamma 1$ genes from different species and show here that the chimaeric intervening sequences are spliced out precisely. This procedure provides a useful method to construct the chimaeric mouse–human immunoglobulin gene to be expressed in *Escherichia coli*, yeast and animal cells. Unexpectedly, a hidden splice donor site in the 5′-flanking region of a human V_H gene is used in place of the donor site of the leader sequence exon, resulting in the formation of the V region without the leader sequence.

We have chosen two pairs of immunoglobulin V_H and C_H genes from different species as models for the chimaeric recombinant immunoglobulin heavy-chain gene. One pair consists of the mouse $C_\gamma 1$ gene[4] and a human V_H gene encoding a V_H region against the surface antigen of hepatitis B virus (HBV). These two genes were inserted into a retrovirus vector plasmid, pTK-2ΔΔter (R)[5] and the recombinant virus plasmid abbreviated as pSNV$_1$·hV$_{HBV}$-mC$_\gamma$1 (Fig. 1*a*). The other pair, consisting of the human $C_\gamma 1$ gene[6] and the mouse V_H gene of TEPC15 myeloma[7], was inserted into pSNVΔTK (ref. 8) and the recombinant virus plasmid abbreviated as pSNV$_2$·mV$_{T15}$-hC$_\gamma$1 (Fig. 1*b*). These two vectors are derived from spleen necrosis virus (SNV). As the removal of the poly(A) addition signal AATAAA of an inserted foreign gene increases the recovery of the SNV vector[5], we removed the sequence 3′ to the *Hin*fI site located 39 base pairs (bp) downstream of the mouse $C_\gamma 1$ coding sequence and the sequence 3′ to the *Hha*I site located 88 bp downstream of the human $C_\gamma 1$ coding sequence.

To recover infectious viruses carrying the immunoglobulin gene, pSNV$_1$·hV$_{HBV}$-mC_γ1 and pSNV$_1$·mV$_{T15}$-hC_γ1 DNAs were used to transfect chicken embryo fibroblasts with or without 1/10th as much DNA of a provirus clone of a non-defective helper virus, reticuloendotheliosis virus strain A (REV-A)[9]. Before transfection, pSNV$_1$·hV$_{HBS}$-mC_γ1 DNA was digested with *Sal*I to remove the pBR322 sequence. Virus production was assayed by reverse transcriptase activity[10]. The enzyme activity of the culture supernatants of the cells transfected with recombinant and helper viral DNAs rose to ~10-fold higher than that of the background on day 5-7 after transfection. We next used viruses in culture supernatants recovered 7-10 days after transfection to infect fresh chicken embryo fibroblasts. Three days later, non-integrated linear viral DNA was isolated and examined for processing of the inserted DNA by Southern blot hybridization.

The parental pSNV$_1$·hV$_{HBV}$-mC_γ1 DNA contains the 3.6-kilobase (kb) *Bgl*II fragment that hybridizes to both human V_{HBV} and mouse $C_\gamma 1$ probes (probes A and B in Fig. 1*a*, respectively). On the other hand, *Bgl*II digestion of the processed pSNV$_1$·hV$_{HBV}$-mC_γ1 DNA should yield a 2.6-kb fragment hybridizing to both probes (Fig. 1). As shown in Fig. 2*a*, viral DNA from chicken embryonic fibroblasts transfected with pSNV$_1$·hV$_{HBV}$-mC_γ1 and helper virus DNA contained the 3.6- and 2.1-kb *Bgl*II fragments hybridizing to both human V_{HBV} and mouse $C_\gamma 1$ probes, suggesting that the viral DNA contains the parental and processed forms. No significant viral DNA was recovered from transfectants without the helper virus DNA (Fig. 2*a*, lanes 2, 3, 7, 8).

The parental pSNV$_2$·mV$_{T15}$-hC_γ1 DNA contains the 1.3-kb *Bam*HI fragment hybridizing to the mouse V_{T15} probe (probe C) and a 3.6-kb *Bam*HI fragment hybridizing to the human $C_\gamma 1$ probe (probe D). *Bam*HI digestion of the processed pSNV$_2$·mV$_{T15}$-hC_γ1 should yield a 1.7-kb fragment hybridizing both to probes C and D. Viral DNA isolated from transfectants by pSNV$_2$·mV$_{T15}$-hC_γ1 and helper viruses contained the 1.7- and 1.3-kb *Bam*HI fragments hybridizing to probe C (Fig. 2*b*, lanes 1-5) and the 1.7- and 3.6-kb *Bam*HI fragments hybridizing to probe D (Fig. 2*b*, lanes 6-10). There are three other potential donor splice sites (J_H2, J_H3 and J_H4) paired with the acceptor splice site of the C_H1 exon. If the donor sites of the J_H2, J_H3 and J_H4 segments were used, we should see the 2.2-, 1.5- and 2.0-kb *Bam*HI bands, respectively, hybridizing to the human $C_\gamma 1$ probe. There were no additional faint bands between 3.6- and 1.7-kb *Bam*HI bands, excluding these possibilities and suggesting that the chimaeric immunoglobulin genes are processed at the expected intron/exon splice sites.

To analyse the structure of the progeny viruses in more detail, the inserts of the progeny viruses were cloned into Charon 28H vector, a derivative of Charon 28 (see Fig. 3 legend). The progeny viral DNAs of pSNV$_1$·hV$_{HBV}$-mC_γ1 and pSNV$_2$·mV$_{T15}$-hC_γ1 were digested with *Bgl*II and *Bam*HI, respectively, and fractionated by agarose gel electrophoresis. DNA fractions containing the 2.1-kb *Bgl*II and 1.7-kb *Bam*HI fragments were ligated into the *Bam*HI site of phage Charon 28H DNA. Recombinant phages were screened by appropriate immunoglobulin gene probes (Fig. 3). Restriction enzyme cleavage analysis indicated that the eight hV$_{HBV}$-mC_γ1 clones and the two mV$_{T15}$-hC_γ1 clones obtained are identical with respect to restriction-site mapping.

The restriction map of the cloned hV$_{HBV}$-mC_γ1 DNA is consistent with that of the processed chimaeric gene of the human V_{HBV} and mouse $C_\gamma 1$ gene except that the left-most *Taq*I/*Xba*I is shortened by 500 bp (Fig. 1*a*). Disappearance of the *Bam*HI site in the 5′-flanking region of the processed hV$_{HBV}$-mC_γ1 agrees with the reduction of the *Taq*I/*Xba*I fragment size, suggesting that segmental deletion occurs in the 5′-flanking region of the V_{HBV} gene. The total length of the cloned hV$_{HBV}$-mC_γ1 insert is 2.1 kb, 500 bp shorter than predicted, in agreement with the size of the *Bgl*II fragment (2.1 kb) observed by Southern blot hybridization (Fig. 2*a*). The 500-bp deletion in *Taq*I/*Xba*I fragment, therefore, does not result from a cloning artefact but from genetic events during virus replication. Restriction-site mapping of the progeny mV$_{T15}$-hC_γ1 clones is consistent with the loss of all introns from the parental mV$_{T15}$-hC_γ1 insert.

Nucleotide sequences surrounding the junctions of the *V* and *C* gene sequences of the progeny clones are aligned with those around the splice sites of the parental *V* and *C* gene exons as shown in Fig. 3. It is clear that the *V*–*C* junctions of pSNV$_1$·hV$_{HBV}$-mC_γ1 and pSNV$_2$·mV$_{T15}$-hC_γ1 are processed precisely according to the GT-AG rule[11], indicating that interspecies pairs of exons easily allow precise removal of introns.

lucleotide sequences of other exon junctions also demonstrate iat all the introns are spliced out exactly as expected (data not iown).

We also read the sequence of the 5′-flanking region of the enomic V_{HBV} gene and find that there is a potential donor splice site, CCGGTGAGA, at 268–276 bp downstream from the *Taq*I site. Comparison of the nucleotide sequences of the parental and progeny V_{HBV} genes and their upstream regions reveals that the region extending from this potential donor site to the acceptor site of the V_{HBV} exon is removed (Fig. 3). Therefore,

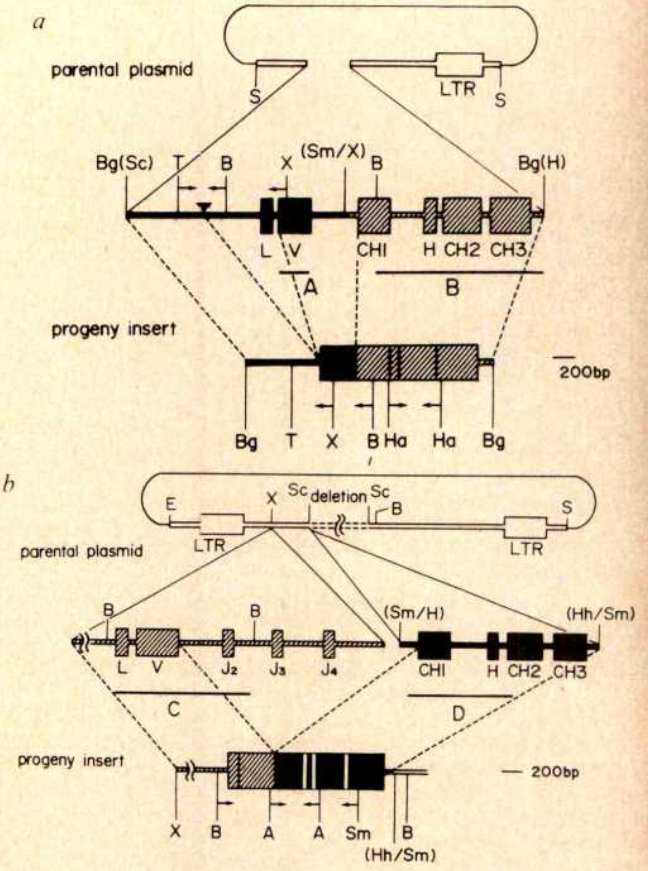

Fig. 1 Structure of parental and progeny recombinant immunoglobulin genes; *a*, $pSNV_1 \cdot hV_{HBV}\text{-}mC_\gamma 1$; *b*, $pSNV_2 \cdot mV_{T15}\text{-}hC_\gamma 1$. Parental recombinant plasmids containing retroviral and immunoglobulin sequences are shown at the top and immunoglobulin gene sequences in progeny retroviruses at the bottom. Retrovirus, mouse and human immunoglobulin sequences are indicated by open, oblique and solid rectangles, respectively. The long terminal repeat (LTR) and exons are shown by wider rectangles and the pBR322 sequence by a solid line. Corresponding DNA segments in parental and progeny viruses are aligned by dotted lines. Solid bars indicate probes used. Directions and ranges of sequences read are shown by horizontal arrows. L, leader exon; V, *V–D–J* exon; H, hinge exon; C_H1, C_H2 and C_H3, exons encoding each domain. Restriction sites are indicated as follows: A, *Ava*II; B, *Bam*HI; Bg, *Bgl*II; E, *Eco*RI; H, *Hin*fI; Ha, *Hae*III; Hh, *Hha*I; S, *Sal*I; Sc, *Sac*II; Sm, *Sma*I; T, *Taq*I; X, *Xba*I. In *a*, fragments A and B indicate the *Sau*3A/*Hha*I fragment of the human V_{HBV} gene and the *Bam*HI/*Bgl*II fragment of the mouse $C_\gamma 1$ gene, respectively. The closed triangle indicates the hidden donor splice site in the *Taq*I/*Bam*HI fragment. In *b*, fragments C and D indicate the *Bam*HI fragment of the mouse V_{T15} gene and the *Sac*II fragment of the human $C_\gamma 1$ gene, respectively.

Methods. Construction of $pSNV_1 \cdot hV_{HBV}\text{-}mC_\gamma 1$. We cloned the V_H gene encoding the V region against the surface antigen of HBV from the Epstein-Barr-virus-transformed cell and determined the nucleotide sequence of the coding region (T. Noma and T. Honjo, unpublished). The 2.2-kb (*Sac*II/*Sma*I) fragment of the human V_{HBV} gene was prepared. The *Sac*I fragment (2.5 kb) including the mouse $C_\gamma 1$ gene sequence was isolated electrophoretically from λgtWES·IgH-2 (ref. 4) and digested separately with *Xba*I and *Sma*I, and with *Sma*I and *Hin*fI. *Hin*fI digests the $C_\gamma 1$ gene 30 bp upstream from the poly(A) addition signal AATAAA. We inserted the 2.2-kb *Sac*II/*Sma*I fragment of the human V_{HBV} gene and the 0.88-kb *Xba*I/*Sma*I and 0.64-kb *Sma*I/*Hin*fI fragments of the mouse $C_\gamma 1$ gene into the *Bgl*II site of pTK-2ΔΔTer (R) (ref. 5). The *Xba*I site of the mouse $C_\gamma 1$ gene was treated with the Klenow fragment of DNA polymerase I to make the blunt end and ligated with the *Sma*I site of the human V_{HBV} gene. The *Sac*II site of human V_{HBV} and the *Hin*fI site of mouse $C_\gamma 1$ gene were filled with Klenow fragment and ligated with *Bgl*II linker (Takara Co. Ltd). The intron between the *V* and *C* exons consists of 460 bp of 3′-noncoding sequence of the V_{HBV}–D–J_H gene and 50 bp of the 5-noncoding sequence of the mouse $C_\gamma 1$ gene. Construction of $pSNV_2 \cdot mV_{T15}\text{-}hC_\gamma 1$. pSNV-TK (ref. 8) was digested with *Sac*II to remove the 1.6-kb *Sac*II fragment in the *tk* gene and then recircularized with T4 ligase to give plasmid pSNVΔTK. The *Hin*dIII fragment of $Ig_\gamma 1$-10-containing human $C_\gamma 1$ gene[6] was first subcloned into pBR322 and the plasmid then digested separately with *Hin*dIII and *Pst*I, and with *Pst*I and *Hha*I. (*Hha*I cleaves the $C_\gamma 1$ gene 15 bp upstream from AATAAA sequence.) Equimolar amounts of the *Hin*dIII/*Pst*I fragment containing the C_H1 exon and the *Pst*I/*Hha*I fragment containing the C_H2, hinge and C_H3 exons were ligated together. The 1.9-kb fragment corresponding to the length of the intact *Hin*dIII/*Hha*I fragment of the human $C_\gamma 1$ gene was purified and the ends of the fragment were filled by the Klenow fragment of DNA polymerase I. The blunt-ended DNA fragment was inserted into the *Sma*I site of pSNVΔTK and the *Xba*I fragment containing the V_{T15} sequence[7] then inserted into the *Xba*I site of $pSNV\Delta TK \cdot C_\gamma 1$. The intron between the V_{T15} and $C\gamma 1$ exons consists of the 3′-noncoding region of the V_{T15} (2 kb) containing the J_H2, J_H3 and J_H4 exons, the 5′-noncoding region of the human $C_\gamma 1$ gene(200 bp) and the *Xba*I/*Sma*I fragment of pSNV-TK (200 bp).

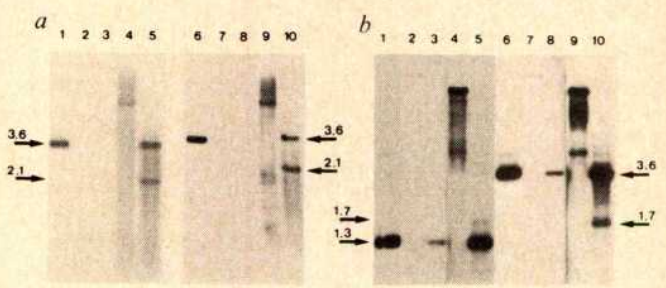

Fig. 2 Structural analyses of nonintegrated progeny viral DNA from chicken fibroblasts infected with recombinant viruses. Non-integrated viral DNA was analysed by Southern blot hybridization using the nick-translated probes indicated. *a*, Progeny virus of $pSNV_1 \cdot hV_{HBV}\text{-}mC_\gamma 1$. DNA is as follows: lanes 1, 6, parental $pSNV_1 \cdot hV_{HBV}\text{-}mC_\gamma 1$; lanes 2, 3, 7, 8, progeny of $pSNV_1 \cdot hV_{HBV}\text{-}mC_\gamma 1$ recovered from chicken fibroblast cells transfected without helper virus DNA; lanes 4, 5, 9, 10, progeny of $pSNV_1 \cdot hV_{HBV}\text{-}mC_\gamma 1$ recovered from fibroblasts transfected with helper virus DNA. DNAs in lanes 1, 3, 5, 6, 8 and 10 were digested with *Bgl*II. Hybridization probes used: lanes 1–5, probe A; lanes 6–10, probe B described in Fig. 1. *b*, Progeny virus of $pSNV_2 \cdot mV_{T15}\text{-}hC_\gamma 1$. DNA lanes 1, 6, parental $pSNV_2 \cdot mV_{T15}\text{-}hC_\gamma 1$; lanes 2, 3, 7, 8, progeny of $pSNV_2 \cdot mV_{T15}\text{-}hC_\gamma 1$ recovered from fibroblasts transfected without helper virus DNA; lanes 4, 5, 9, 10, progeny of $pSNV_2 \cdot mV_{T15}\text{-}C_\gamma 1$ recovered from fibroblasts transfected with helper virus DNA. DNAs in lanes 1, 3, 5, 6, 8 and 10 were digested with *Bam*HI. Hybridization probes used: lanes 1–5, probe C; lanes 6–10, probe D described in Fig. 1. Lengths of hybridized bands are given in kb; arrows indicate the bands derived from the parental or processed hybrid immunoglobulin gene.

Methods. The 8.2-kb *Sal*I fragment of $pSNV_1 \cdot hV_{HBV}\text{-}mC_\gamma 1$ was isolated by agarose gel electrophoresis and ligated with T_4 DNA ligase at 15 °C for 10 h. Homopolymeric $SNV_1 \cdot hV_{HBV}\text{-}mC_\gamma 1$ and circular $pSNV_2 \cdot mV_{T15}\text{-}hC_\gamma 1$ DNA (10 μg each) were introduced separately into chicken fibrobalsts in a tissue-culture flask (25 cm^2) in the presence or the absence of REV-A DNA (1 μg) by the calcium phosphate co-precipitation technique[17]. Virus production was assayed by the reverse transcriptase activity[10]. After 7–10 days, the tissue culture medium containing the recombinant virus was collected and fresh chicken cells in a 100-mm Petri dish were infected with undiluted virus. Three days after infection, non-integrated viral DNA was isolated by the Hirt procedure from the infected cells[18,19]. The non-integrated viral DNAs were digested with *Bgl*II or *Bam*HI and analysed by electrophoresis in a 0.8% agarose gel. Each lane contained DNA from one 100-mm Petri dish. The gel was blotted onto nitrocellulose filter paper and the filter hybridized with the nick-translated ^{32}P-labelled probe indicated.

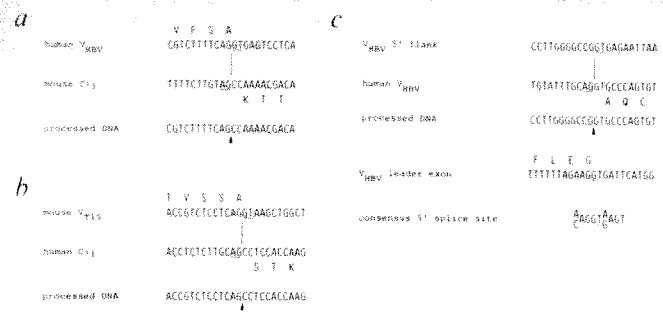

Fig. 3 Nucleotide sequences surrounding processed exon junctions in progeny viruses. *a*, Sequence surrounding the V_{HBV} and mouse C_H1 exon junction in progeny virus of $pSNV_1 \cdot V_{HBV}$-$mC_\gamma1$. *b*, Sequence surrounding the V_{T15} and human C_H1 exon junction in progeny virus of $pSNV_2 \cdot mV_{T15}$-$hC_\gamma1$. *c*, Sequence surrounding the recombination site between the potential donor splice site in the 5′-flanking region of the V_{HBV} gene and the V_{HBV} exon. Nucleotide sequences around the exon/intron junctions in parental virus are shown above the sequence of processed gene. The consensus sequence of the donor splice site[12] and the 5′ splice site of leader sequence of V_{HBV} are also shown. GT and AG are underlined. Splice sites are designated by arrowheads. Nucleotide sequences determined (~200 bp at each junction) are identical to those predicted from parental gene sequences taken from the literature[4,20,21]. **Method.** Virus-infected chicken cells in 12 100-mm Petri dishes were lysed with SDS 3 days after infection. Non-integrated viral DNA was isolated by Hirt's procedure[18,19]. The 1.7-kb *Bam*HI fragment containing the processed mV_{T15}-$hC_\gamma1$ gene and the 2.1-kb *Bgl*II fragment containing the processed hV_{HBV}-$mC_\gamma1$ gene were isolated by agarose gel electrophoresis. These fragments were inserted separately into Charon 28H, a modified Charon 28 vector (described below), with T_4 ligase and packaged *in vitro*. Recombinant phages containing hV_{HBV}-$mC_\gamma1$ and mV_{T15}-$hC_\gamma1$ were screened using probes A and C, respectively. We identified eight phage clones that contained the hybrid hV_{HBV}-$mC_\gamma1$ gene fragment and two phage clones that contained the hybrid mV_{T15}-$hC_\gamma1$ gene fragment. There is an *Eco*RI site in each arm of Charon 28H. We purified the *Eco*RI fragment containing processed hV_{HBV}-$mC_\gamma1$ gene and the *Bam*HI fragment containing processed mV_{T15}-$hC_\gamma1$ gene for restriction enzyme analysis and sequencing. The *Eco*RI fragment containing hV_{HBV}-$mC_\gamma1$ and the *Bam*HI fragment containing mV_{T15}-$hC_\gamma1$ were cleaved with restriction enzymes shown in Fig. 1 and their ends were labelled by polynucleotide kinase. Labelled fragments were isolated and sequenced according to Maxam and Gilbert[22]. We also sequenced the *Taq*I/*Xba*I fragment of the 5′-flanking region of the V_{HBV} gene. Construction of Charon 28H vector. The 6.8-kb *Bam*HI fragment of mouse immunoglobulin $S_\gamma2a$ region gene[23] was cloned in pBR322. The recombinant plasmid was digested with *Bgl*II and inserted into *Bam*HI site of Charon 28 (ref. 24) to construct Charon 28H vector. Charon 28H DNA was digested with *Bam*HI and *Sal*I and the internal fragment derived from pBR322 was removed to prepare arms. Longer and shorter arms of the modified Charon 28H are 4.1 and 2.7 kb, respectively, longer than the original Charon 28.

there is preference of the 5′ potential splice site over the normal donor site of the signal peptide exon. The nucleotide sequences of both the 5′ potential and normal donor sites mismatch at two bases with the consensus 9-base sequence surrounding the donor splice site[12]. Except for GGTGA sequence, there is little sequence homology between the nucleotide sequences surrounding the potential and normal donor sites. There are several examples where mutations in normal splice donor sites have revealed potential donor splice sites in exons[13–16]. The presence of a donor splice site more potent than the normal donor site in the flanking region has not been reported.

We have shown here that the strategy using the retrovirus vector is useful for construction of hybrid immunoglobin genes and will eventually enable expression of the hybrid protein in yeast, *E. coli* and animal cells. Our results demonstrate that the genomic *V* and *C* exons derived from different species are properly fused. We have used the same strategy to construct the hybrid light-chain genes composed of mouse V_K and human C_K genes. Most clinically useful antibodies are made more easily in mouse and are difficult to administer in humans. If the C region of the mouse monoclonal antibody against human cancer cells could be replaced by a human immunoglobulin C region, the clinical advantages would include the facts that the hybric immunoglobulin is less antigenic and the most useful C_H regior could be chosen for treatment.

We thank Ms Y. Utsunomiya, N. Kisogawa and K. Harate for technical assistance and Miss K. Kawabata for her assistance in preparing the manuscript. We also thank Dr Y. Ono for the EBV-transformed B-cell line and Dr K. Shimotomo for the generous supply of retrovirus vectors. T.N. and K.H. are on leave from the Research Institute of Ono Pharamceutical Co Ltd.

Thymic epithelium and the induction of transplantation tolerance in nude mice

R. K. Jordan, J. H. Robinson, N. A. Hopkinson, K. C. House & A. L. Bentley

Department of Anatomy, The Medical School, University of Newcastle upon Tyne, Newcastle upon Tyne NE2 4HH, UK

Immunological tolerance of self has been studied experimentally by the induction of unresponsiveness to antigens of the major histocompatibility complex (MHC) in neonatal mice[1]. The specific unresponsiveness resulting from such neonatal tolerance induction is first demonstrable in the thymus[2,3], suggesting that neonatal tolerance is induced by some cellular component of the thymus, or at some prethymic stage. Recent transplantation studies suggest that thymic epithelium, derived by organ culturing fetal mouse thymus in the presence of deoxyguanosine, survives in an allogeneic host environment despite the continued expression of MHC donor antigens, but fails to induce allotolerance[4]. We demonstrate here that embryonic thymus lobes organ cultured at 24°C, a treatment that deletes the lymphohaematopoietic component of thymus leaving the epithelial matrix intact[5], when transplanted to intact histoincompatible recipients, similarly survive for a prolonged period and do not induce tolerance to donor MHC antigens. However, when such culture-derived thymic epithelium is allografted to athymic nude mice, host-derived lymphocytes from both the epithelial graft and recipient spleen are unresponsive to the MHC antigens of the epithelial donor. The results suggest that, when investigated in a system which precludes the possible involvement of extrinsic mature T cells, processed by the syngeneic host thymus, thymic epithelium may induce transplantation tolerance.

Low-temperature (24 °C) organ culture was first used to deplete passenger leukocytes in studies of pancreatic islet

Table 1 Effect of low-temperature organ culture on the survival of fetal thymus grafts in allogeneic recipients

Duration of grafts (days)	No. of animals with surviving grafts: Low-temperature culture (24 °C)	Conventional culture (37 °C)	Uncultured 14-day thymus
5	5/5	5/5	5/5
10	5/5	0/5	3/5
15	5/5	0/5	1/5
25	5/5	0/5	0/5
40	3/5	0/5	0/5
50	1/5	0/5	0/5

Fetal thymus lobes were isolated from C57BL/6 (H-2^b) embryos on day 14 of gestation and organ cultured for 8 days at either 24 or 37 °C as described previously[6]. Two lobes were transplanted beneath the renal capsule of C_3H (H-2^k) recipients. Uncultured lobes were transplanted to allogeneic recipients immediately following isolation from 14-day donor embryos. Host mice were killed at varying times post-grafting (5–50 days) and the presence or absence of grafts was scored using a dissecting microscope. Successful grafts were readily identified as fleshy, white subcapsular swellings. The absence of grafts was always confirmed histologically. Grafts of fetal thymus, whether low-temperature organ cultured or not, survived indefinitely in syngenic recipients of allogeneic (H-2^d) nude mice (data not shown). The results show that, whilst untreated 14-day thymic lobes and those organ cultured at 37 °C are acutely rejected by allogeneic hosts, low-temperature (24 °C) cultured grafts survive for prolonged periods.

allograft survival[6] and has been shown subsequently to delete selectively the lymphoid component of fetal mouse thymus, leaving the epithelial matrix intact[5,7]. When 14-day fetal thymus lobes, cultured for 8 days at 24 °C, are grafted beneath the renal capsule of intact syngeneic mice, the surviving thymic epithelial matrix is colonized by host-derived lymphoid precursors which differentiate into thymocytes, thus forming an heterotopic lymphoid thymus[5,8]. The regenerating intragraft lymphocyte population is 95% Thy-1^+, 80% TL^+, 95% Lyt 1^+, 90% Lyt 2^+ and includes a cortisone-resistant functional subpopulation responsive to alloantigens in mixed lymphocyte culture (MLC) as well as to T-cell mitogens (refs 8, 9 and R.K.J. and N.A.H., unpublished data).

It has been reported previously that embryonic thymus lobes depleted of their endogenous lymphophaematopoietic cells by deoxyguanosine treatment *in vitro* can be successfully transplanted across major histocompatibility barriers, even though the surviving thymic epithelium continues to express class II MHC antigens[4]. To determine whether low-temperature organ culture would allow the similar survival of fetal thymic allografts, C3H (H-2^k) mice were grafted with thymus lobes from C57BL/6 (H-2^b) embryos of 14 days' gestation, organ cultured for 8 days at 24°C. Survival of these experimental grafts was compared with that of 14-day fetal thymic lobes with and without conventional organ culture at 37 °C. Table 1 shows that, whereas uncultured and conventionally cultured grafts are rejected normally by 15 days post-grafting, fetal thymus lobes cultured at 24 °C escape this acute rejection. Survival of these thymic epithelial allografts, at least in this strain combination (C57BL/6 into C3H), is not indefinite. Although 100% of low-temperature treated grafts were recovered at 25 days, this proportion fell to 60% by 40 days and to 20% by 50 days. Surviving allogeneic epithelial grafts seem to grow in the same way as they do in syngeneic recipients, demonstrating organotypic thymic development and giving a maximal lymphoid cell yield of about 5×10^6 per lobe.

The probable explanation for the observed prolongation of allograft survival is that the low-temperature treatment of fetal thymus not only eliminates the endogenous thymocytes and their progenitors, but also substantially reduces or even deletes the donor class II MHC-antigen-expressing dendritic cells of the thymus, thereby avoiding route 1 rejection as described by Lechler and Batchelor[10]. Thus, when allografted, the thymic epithelium derived by low-temperature organ culture seems to behave in a similar fashion to that obtained by deoxyguanosine treatment[4], except that, over the longer timescale reported here, low-temperature-treated grafts seem eventually rejected. This late rejection may reflect the survival of small numbers of donor-derived dendritic cells[11,12] of haematogenous origin within the graft or it may be a manifestation of the alternative rejection route proposed by Lechler and Batchelor[10] by which graft antigens are processed and presented by the recipients' own accessory cells.

We confirm the findings of Ready *et al.*[4] that lymphocytes recovered from both the epithelial grafts and the spleens of intact allogeneic recipients respond to the MHC antigens of the thymic donor type in MLC (Table 2), arguing against a role for thymic epithelium in the induction of tolerance. However, as the recipients of the thymic epithelial grafts were normal intact histoincompatible mice, it cannot be concluded necessarily that the reactive T cells present in the grafts had, in fact, matured there. Indeed, it is possible that the reactive T cells had matured in the syngeneic recipient thymus and subsequently migrated into the allogeneic thymic epithelial graft. To eliminate this possibility, we also transplanted low-temperature organ-culture-derived thymic epithelium to athymic nude mice, where there was no possibility of host thymic processing.

Athymic BALB/c *nu/nu* (H-2^d) mice were grafted with low-temperature-treated C57BL/6 (H-2^b) fetal thymic lobes. Such

Table 2 MLC responses of spleen and thymus graft cells from C_3H(H-2^k) mice bearing low-temperature organ-cultured C57BL/6 (H-2^b) thymus grafts beneath the renal capsule

Animal no.	Responders	Stimulators: Host type (H-2^k)	Graft type (H-2^b)	Third party (H-2^d)	*P* values
1	Intragraft lymphocytes	564 ± 91	4,815 ± 736	5,392 ± 124	<0.01; <0.001
	Host spleen	16,006 ± 1,079	38,048 ± 312	49,546 ± 1,318	<0.001; <0.001
2	Intragraft lymphocytes	475 ± 40	2,368 ± 178	1,517 ± 231	<0.001; <0.05
	Host spleen	7,807 ± 673	18,780 ± 52	24,250 ± 295	<0.001; <0.001
3	Intragraft lymphocytes	362 ± 40	3,364 ± 143	2,454 ± 155	<0.001; <0.001
	Host spleen	NT	NT	NT	

MLC assays were performed in U-well microtitre plates. Responder cells were prepared by teasing host spleen and thymus grafts and were used at a final concentration of 2×10^5 per well. Stimulators were mitomycin-C-treated (30 μg ml^{-1} for 40 min at 37 °C) spleen cells titrated over the range 4×10^5–2.5×10^4 per well. All cultures were performed in 200 μl of supplemented RPMI 1640 medium with 10% fetal calf serum. Cultures were pulsed with 1 μCi ml^{-1} of ^{3}H-thymidine for 18 h on day 4 of culture and collected with an automatic sample collector. Results are expressed as the mean d.p.m. ± s.e.m. for three replicate wells at the optimal stimulator: responder ratio. *P* values are given for the response to graft-type and third-party stimulators as compared with the response to host-type stimulators. The results show that there are significant responses to both graft-type and third-party stimulators by cells from both host spleen and thymus grafts. NT, not tested.

Table 3 MLC responses of spleen and thymus graft cells from athymic BALB/c (H-2^d) nude mice bearing low-temperature organ culture C57BL/6 (H-2^b) thymus grafts beneath the renal capsule

Animal no.	Responders	Stimulators: Host type (H-2^d)	Graft type (H-2^b)	Third party (H-2^k)	*P* values
1	Intragraft lymphocytes	412 ± 95	326 ± 102	4,338 ± 59	NS; <0.001
	Host spleen	12,261 ± 1,471	16,672 ± 896	25,614 ± 2,348	NS; <0.01
2	Intragraft lymphocytes	258 ± 60	243 ± 53	2,779 ± 159	NS; <0.001
	Host spleen	13,212 ± 1,294	14,417 ± 796	24,212 ± 1,261	NS; <0.01
3	Intragraft lymphocytes	468 ± 114	859 ± 246	2,050 ± 244	NS; <0.01
	Host spleen	16,438 ± 2,615	17,046 ± 1,050	28,793 ± 2,150	NS; <0.01

MLC cultures were carried out as described in Table 2 legend. The results show that while there are significant responses to third-party stimulators by cells from both nude host spleen and thymus grafts, both populations failed to respond to graft-type stimulators. NS, not significant.

thymic epithelial grafts, placed beneath the renal capsule, became recolonized by T-cell precursors to form a fully lymphoid heterotopic thymus. The host derivation of the repopulating lymphoid component was confirmed using monoclonal anti-D^d (supernatant from clone 34-4-21s) and anti-K^b (supernatant from clone 28-13-3s) antibodies (data not shown). By 56 days post-grafting, the peripheral T-cell compartment of the nude recipients was significantly reconstituted as judged by the number of Thy-1^+ cells in the host spleen and the restoration of responsiveness to the T-cell mitogen concanavalin A (Con A) (Table 4). In these nude recipients, we found that host-derived lymphocytes (H-2^d) within the epithelial graft respond in MLC (Table 3) to the MHC antigens of a third party (H-2^k), but not to the MHC antigens of the thymic epithelial donor (H-2^b). Table 3 also shows that spleen cells from the recipient nudes respond to third-party stimulators (H-2^k) but not to graft type (H-2^b); however, the high level of proliferation to host type (H-2^d) obscures a clear demonstration of either reconstitution of the MLC response or tolerance in the spleen population.

Thus, in the nude thymic chimaera, the low-temperature-cultured thymic allografts can be shown to induce tolerance while failing to do so in normal thymus-intact recipients. The simplest explanation for this paradox is that the T cells reactive to donor graft type in the intact chimaera had matured in the syngeneic host thymus and migrated to the allogeneic thymic graft. That mature T cells can indeed recirculate to the normal thymus has been suggested previously by migration studies with labelled effector T-lymphocyte lines[13]. The results suggest that the epithelium remaining in low-temperature cultured grafts can induce tolerance, but that in allogeneic normal recipients this tolerance is masked.

That it is the grafted thymic epithelium which leads to tolerance induction is at this time only a probability, for the involvement of thymic dendritic cells cannot be entirely ruled out. We have been unable to isolate dendritic cells from low-temperature thymic organ cultures before grafting[8], but it cannot be precluded that the low-temperature treatment only reduces the number of dendritic cells rather than eliminating them altogether. However, as low-temperature-treated thymic allografts survive in thymus-intact recipients long after the stage of acute rejection, the presence of functionally significant numbers of dendritic cells is doubtful.

Although there is little question that the tolerance to donor MHC antigens observed in both the grafts and spleens of the nude recipients was induced by the presence of the low-temperature organ-cultured thymic lobes, the present study sheds little light on the nature of the tolerogenic mechanism. While these results are in keeping with the hypothesis that tolerance results from the deletion of clones reactive to graft type[2], the unresponsiveness to donor MHC antigens could be mediated by specific suppressor T cells, as demonstrated for classical neonatal tolerance[14,15].

In conclusion, we suggest that it is premature to exclude thymic epithelium from having a determining effect in tolerance induction, as our results can be interpreted as suggesting that thymic epithelial cells, which are known to express class II MHC antigens[16,17], may have a role in the induction of tolerance in helper T lymphocytes. Whether cultured thymic epithelium tolerizes cytotoxic T lymphocytes remains to be determined, but in this context it is interesting that the thymus appears to impose MHC restriction only for class II- and not for class I-restricted T-cell recognition[18,19].

This work was supported by NIH grant AI 15819. We thank Linda Ferries and Ian Williamson for their technical assistance and Dr E. Simpson, Transplantation Biology, Clinical Research Centre, Harrow for the gift of the monoclonal anti-D^d and anti-K^k antibodies.

Note added in proof: It has recently been shown that thymocytes from deoxyguanosine-treated fetal thymi grafted to allogeneic nude recipients contain cytolytic T-lymphocyte precursors reactive to class I MHC antigens of thymic donor type[20].

Table 4 Thy-1 expression and Con A responsiveness of spleen lymphocytes recovered from BALB/c nude mice with and without C57BL/6 thymic epithelial grafts

Recipient	Graft	No. Thy 1.2 (CI ± s.e.m.)	Con A ($\bar{x}\Delta$ d.p.m. ± s.e.m.)
nu/+ (27)	—	28.2 ± 4.2	61,067 ± 6,427
nu/*nu* (12)	—	0.1 ± 0.6	370 ± 1,354
nu/*nu* (10)	+	9.6 ± 1.5	33,118 ± 6,922

CI, cytotoxic index, using anti-mouse Thy 1.2 (clone 30-H12, Becton-Dickinson) at 1 in 800 and rabbit complement (Low Tox M, Cedarlane) at 1 in 15. Viability was assessed by trypan blue dye exclusion and a total of 400 cells counted. For Con A experiments, 200-μl microcultures in triplicate using 2×10^5 spleen cells and 2 μg ml^{-1} Con A (Miles-Yeda) were incubated for 72 h with a pulse of 1 μCi ml^{-1} for the final 18 h. Numbers in parentheses are the number of mice tested.

Activation of major histocompatibility complex class I mRNA containing an *Alu*-like repeat in polyoma virus-transformed rat cells

Barbara Majello, Girolama La Mantia, Antonio Simeone,* Edoardo Boncinelli* & Luigi Lania†

† To whom correspondence should be addressed.

Class I genes of the major histocompatibility complex (MHC) appear to be activated in mouse cells transformed by the DNA tumour virus simian virus 40 (SV40)[1]. Conversely, suppression of MHC class I genes has been reported in adenovirus-12-transformed baby kidney rat cells[2]. We have now investigated the expression of genes encoded by the rat MHC locus in rat fibroblast cells transformed by polyoma virus (Py). Using a mouse genomic *H-2* clone as a probe in Northern transfer hybridization analysis, we have observed a high level of expression of rat MHC class I messenger RNA in all the transformed rat cell lines analysed. The class I 1.6-kilobase (kb) mRNA activated in Py-transformed rat cells appears to contain an *Alu*-like type II repeat element, as the same 1.6-kb mRNA is detected using either the *H-2* class I sequence or a repetitive *Alu*-like type II element as a probe. High levels of heterogeneous poly(A)$^+$ transcripts of 0.5–0.8 kb are also observed in Py-transformed rat cells using probes containing an *Alu*-like type II repetitive element.

The rat major histocompatibility complex, the *RT.1* complex, comprises the loci encoding the histocompatibility antigens[3]. Three loci, *RT.1 A* (analogues of mouse *H-2K* and *H-2D*)[4], *RT.1 E* (ref. 5) and *RT.1 C* (*Qa* analogue)[6], control the expression of the classical serologically defined class I antigens. Taking advantage of the relatively conserved nature of portions of mammalian MHC genes, we have used a mouse genomic *H-2* DNA probe to investigate the level of *RT.1* class I mRNA expression in Py-transformed rat cells and the parental untransformed cells. Figure 1 describes the structure of the mouse *H-2* clone pL4-7. The 2.7-kb *Bam*HI fragment isolated from a genomic library constructed from mouse DBA/2 seems to be similar, if not identical, to the 3'-end portion of the *27.1* gene isolated by Steinmetz *et al.*[7] from a BALB/c DNA library. As the probe contains the constant (third) domain, it should react with any MHC class I heavy-chain mRNA present in rat cells.

A series of Py-transformed rat cell lines was used to demonstrate the general applicability of the observed phenomena (Table 1). The Rat-1 (ref. 8) parental cell line and the Ag4-rat revertant cell line R3-rat, which has lost the integrated Py early DNA coding sequence (G.L.M. and L.L., unpublished results), were used as untransformed control cells.

Polyadenylated cytoplasmic RNAs from parental, transformed and revertant normal cells were electrophoresed in formaldehyde/agarose gel, transferred to nitrocellulose filter and hybridized with ^{32}P-labelled pL4-7 plasmid DNA (Fig. 2). All the Py-transformed rat cells analysed (Table 1), regardless of their origin, expressed a high level of mRNA of 1.6 kb and a heterogeneous class of transcripts of 0.5–0.8 kb (Fig. 2 and data not shown). The various Py-rat cell lines analysed seemed to express slightly different patterns of the heterogeneous small RNAs. Conversely, the untransformed parental Rat-1 and the normal revertant cells (Fig. 2, lanes 1, 2) expressed a very low level of 1.6-kb mRNA, which was almost undetectable after long exposure of these autoradiograms (2 weeks at −80 °C). The heterogeneous class of RNA transcripts of 0.5–0.8 kb was observed in the normal cells, although at a lower level in Rat-1 cells. Attempts to resolve the hybridization signal observed at 0.5–0.8 kb into discrete bands using different gel concentrations and electrophoresis conditions were unsuccessful.

These results indicate that a high level of expression of MHC class I mRNA is a common characteristic of Py-transformed rat cells, extending to the Py-rat system the notion originally proposed[1] that activation of class I major histocompatibility antigen genes is a general feature of oncogenesis in the mouse. However, the activation of MHC class I gene expression in Py-rat does not appear to be a general phenomenon of transformed rat cells, as it has been reported[2,9] that a MHC gene, *RT.1 A*^{u}, is switched off in adenovirus-12-transformed primary baby rat kidney cells.

To rule out the possibility that the high level of expression of *RT.1* class I mRNA in Py-rat cells is a result of extensive amplification of the corresponding *RT.1* genomic sequences, we have used the Southern[10] hybridization technique to analyse the structure of the *RT.1* locus in Py-rat and in the normal

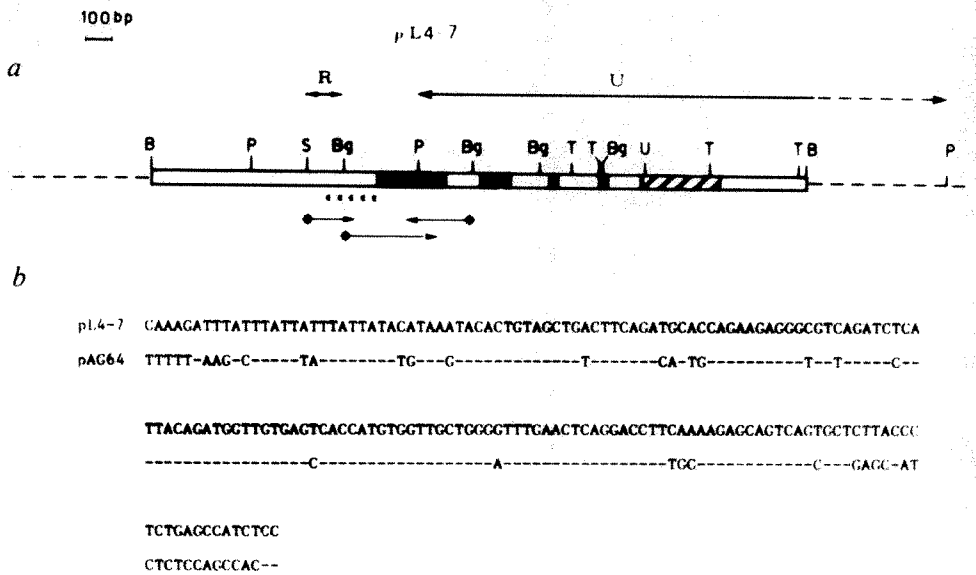

Fig. 1 *a*, Map of pL4-7. This plasmid was isolated originally by A. M. Frischauf, (EMBL) from DBA/2 mouse DNA. Fine restriction mapping and partial DNA sequencing have revealed that the pL4-7 is similar to the 3'-end portion of the 27.1 clone isolated by Steinmetz *et al.*[7]. Black boxes indicate the positions of the exons, a hatched box denotes the 3'-untranslated region as indicated by Steinmetz *et al.*[7]. Partial DNA sequencing was performed across exon 4 and we found no difference from the reported sequence of the 27.1 clone. The arrows indicate the direction and length of the sequences obtained by the chemical degradation method[27]. « « « Indicates the position of an *Alu*-like type II repeat. Subclone 'R' was constructed by inserting the 137-bp *Sal*I/*Bgl*II fragment in the *Bam*HI/*Sal*I sites of plasmid pAT153 (ref. 28). The *Sal*I/*Bgl*II fragment comprises 72 bp of the repetitive element and 65 bp of the adjacent intron sequences as determined by DNA sequencing. Subclone 'U', containing the 3'-end coding region devoid of the repetitive element, was constructed by subcloning the 2.7-kb *Pst*I fragment in the *Pst*I site of pAT153. B, *Bam*HI; Bg, *Bgl*II; P, *Pst*I; S, *Sal*I; T, *Sst*I; U, *Pvu*II. *b*, Comparison of the *Alu*-like repeat present in the pL4-7 and the repetitive element in the plasmid pAG64[1] written in the opposite orientation. -, Identical sequences.

Rat-1. No difference was detected between the Rat-1 and Py-rat cell DNAs (data not shown).

The presence of a type II *Alu*-like repeat within pL4-7 (Fig. 1) raises the question of the relationship between the mRNAs found in the Py-rat and the repetitive element. To answer this question, we have constructed subclones of pL4-7 containing either the repetitive element (subclone 'R'; see Fig. 1) or exclusively the non-repetitive *H-2* sequence (subclone 'U'; see Fig. 1), and have used these as probes in Northern transfer experiments. Figure 3 shows that probe R detects all the RNA transcripts observed with the pL4-7, whereas probe U detects only the 1.6-kb mRNA. These data indicate that the heterogeneous RNA transcripts of 0.5–0.8 kb hybridize only to *Alu*-like repeat, whereas the 1.6-kb mRNA is composed of the *RT.1* class I sequence containing an *Alu*-like type II repeat.

The activation of a MHC class I gene containing a repetitive element has been documented by Rigby's group[1,11,12] in SV40-transformed mouse cells and in two Py-mouse cell lines, where they have characterized sets of genes silent in most normal cells but active in oncogenic transformed mouse cells. The prototype complementary DNA clone of Set 1, pAG64 (ref. 1), encodes a *H-2* class I antigen and contains a dispersed repetitive element in the 3′-untranslated region of the mRNA which is very similar to the repetitive element located in the opposite orientation within one of the introns in pL4-7 (see Fig. 1*b*). Both these *Alu*-like elements are members of the *B2* family originally defined by hybridization to 'fold-back' heterogeneous nuclear RNA[13,14]. The *Alu*-like repeat in pL4-7 diverges 14% from the pAG64 repeat and 12% from the consensus *B2* family sequence[13].

Alu-like type II repetitive elements have been found in the 3′-untranslated region of cDNA clones encoded in the *H-2D* and *H-2L* regions[15–19], whereas cDNA clones encoding the K^b (ref. 20) and K^d (ref. 21) antigens lack repetitive sequences. The presence of *Alu*-like repeats in both mouse and rat MHC class I mRNAs may reflect a similar evolutionary history of their MHC.

Several conclusions can be drawn from our work. First, the elevated level of 1.6-kb mRNA appears to be independent of the expression of Py early large T-antigen [relative molecular mass (M_r) 100,000 (100K)] and small T-antigen (M_r 22K) (Table 1, Fig. 2), indicating that the presence of the 55K middle T-antigen is sufficient to induce a high level of 1.6-kb mRNA. As the 55K middle T-antigen is a non-nuclear protein and as there is no evidence that it can regulate gene transcription directly, one must postulate the presence of cell-encoded factor(s) involved in the activation of MHC class I mRNA in response to viral transformation. Second, the activation of 1.6-kb mRNA appears to be a reversible phenomenon, as low levels of 1.6-kb mRNA are found in the revertant cell line R3-rat. Third, elevated levels of 1.6-kb mRNA are found both in *in vitro* Py-rat cells and in cell lines established from tumours induced with Py-rat cells. Fourth, it appears that in neoplastic mouse and rat cells transformed by two similar oncogenic viruses, SV40 and Py, the activation of MHC class I mRNA containing a similar repetitive

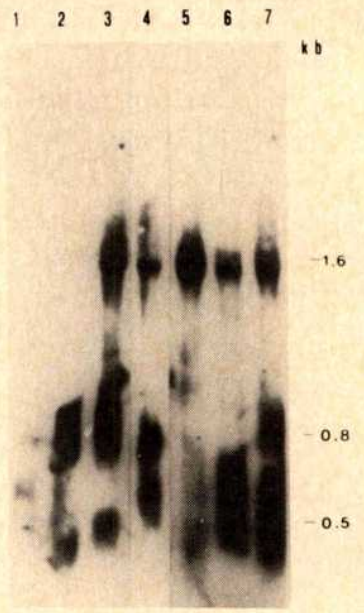

Fig. 2 RNA transfer hybridization analysis of normal and transformed rat cell lines. Polyadenylated cytoplasmic RNA was isolated as described previously[29]. Aliquots (2 μg) of poly(A)$^+$ RNA (selected once) were fractionated by electrophoresis in 1.3% agarose/formaldehyde gels and transferred to nitrocellulose filters[30]. The blots were heated for 2 h at 80 °C and prehybridized for 5 h at 42 °C in a buffer containing 5× Denhardt's solution (0.1% each of Ficoll, bovine serum albumin and polyvinylpyrrolidone), 0.25 mg denatured calf thymus DNA per ml and 50% formamide. Subsequently, the filters were hybridized at 42 °C in the same buffer containing 20 ng ml^{-1} ^{32}P-labelled pL4-7 DNA. The pL4-7 DNA was labelled by nick-translation[31] at a specific activity of 2×10^8 c.p.m. μg^{-1}. After hybridization, the filters were washed three times in 2×SSC, 0.1% SDS at room temperature, then at 50 °C for ~2 h. The filters were then autoradiographed at −80 °C with intensifying screen for 72 h. RNA samples are: lane 1, Rat-1; lane 2, R3-rat; lane 3, 7ax; lane 4, 7axT; lane 5, 82-rat; lane 6, Ag4-rat; lane 7, MT-rat. The gels were routinely calibrated with ribosomal RNA of various sources and with ^{32}P-labelled DNA plasmid size markers (×10^{-3}).

Table 1 Properties of the polyoma-transformed rat cell lines used

Cell lines	Ref.	T-antigen species				Isolation		
		Large-T	Middle-T	Small-T	Others	Foci	Agar	Tumour
7ax	22	+	+	+	−	+		
82-rat	22	−	+	+	63K, 40K, 32K	+		
53-rat	22	−	+	+	−	+		
H-2	23	+	+	+	−	+		
Ag4-rat		−	+	+	70K		+	
MT-rat		−	+	−	−	+		
7axT	8	−	+	+	75K			+
7axB	24	+	+	+	−			+
8aT	25	−	+	+	35K			+
82T	25	−	+	+	63, 40K, 32K			+
53T	25	−	+	+	−			+

The cell line MT-rat was isolated and characterized after DNA transfection of plasmid pPY-MT[26] on Rat-1 cells. The MT-rat cells contain about three copies of integrated Py DNA sequences, and express only the 55K middle T-antigen, as determined by immunoprecipitation with anti-T serum (L.L., unpublished results). The Ag4-rat cell line was isolated using a polyoma mutant Py9-1 which has lost part of the polyoma DNA sequences unique to the 100K large T-antigen coding sequences, but retains the ability to express middle and small T-antigens. The Ag4-rat cells express the 22K, 55K and 70K T-antigens, as determined by immunoprecipitation with anti-T serum (G.L.M. and L.L., unpublished results).

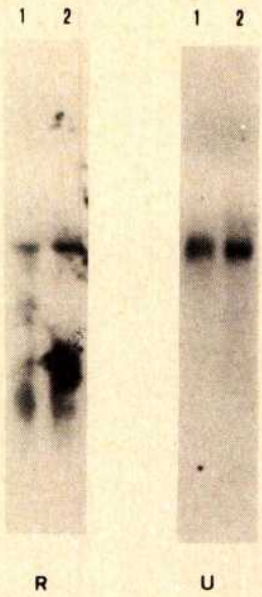

Fig. 3 Northern hybridization analysis of activated transcripts using the 'R' and 'U' probes (Fig. 1). Cytoplasmic poly(A)$^+$ RNA extracted from 7ax cells (lane 1) and 7axT (lane 2) were fractionated in 1.3% agarose/formaldehyde gels, then processed as described in Fig. 2 legend. Aliquots (5 μg) of poly(A)$^+$ RNAs were used. The exposure time was 1 week at −80 °C for blot 'R' and 48 h for blot 'U'.

element takes place. However, until the mRNA activated in the Py-transformed rat cells has been cloned, the homologous MHC class I genes activated in the mouse and rat transformed cells remain undefined.

We thank Drs Harold Varmus, Mike Fried and Sharon Boast for useful discussions and advice in the preparation of this manuscript, and Dr A. M. Frischauf for the gift of pL4-7 plasmid. This work was supported by grants from Progetti Finalizzati CNR 'Ingegneria Genetica', 'Crescita Neoplastica' (core grants to P. Amati) and PF 'Oncologia' and MPI to L.L.

Keratinocytes blocked in phorbol ester-responsive early stage of terminal differentiation by sarcoma viruses

Stuart H. Yuspa*, Anne E. Kilkenny*, John Stanley† & Ulrike Lichti*

* Laboratory of Cellular Carcinogenesis and Tumor Promotion, National Cancer Institute, Bethesda, Maryland 20205, USA
† Uniformed Services University of Health Sciences, Bethesda, Maryland 20814, USA

It has been suggested that the initiation step in mouse skin carcinogenesis involves an alteration in epidermal differentiation, as mouse basal keratinocytes exposed to initiators resist the arrest of cell growth that is normally associated with the induction of terminal differentiation by calcium ions[1-3]. The growth of epidermal basal cells infected by Kirsten (Ki) or Harvey (Ha) sarcoma viruses is, however, arrested in response to calcium ions, although the cells do not progress through their entire maturation programme when a functioning *ras* gene of those viruses is expressed[4]. If continuous proliferation in the differentiating cell layers is a requirement for tumour formation in skin[3,5], the response of sarcoma virus-infected cells seems inconsistent with the suggestion that an activated *ras* gene is sufficient to initiate skin carcinogenesis[6]. We now show that sarcoma virus-infected keratinocytes, when induced to differentiate, are blocked at an early, reversible stage of maturation. Furthermore, the cells respond to phorbol ester tumour promoters by undergoing a phenotypic reversion to a less mature stage. These results suggest that activation of a *ras* gene can produce conditionally initiated cells, in which the full expression of tumorigenicity depends on exposure to tumour promoters.

Mouse basal keratinocytes can be grown selectively in <0.1 mM Ca^{2+} medium (low Ca^{2+}) and induced to stop growing, differentiate terminally and slough from the culture dish by >0.1 mM Ca^{2+} medium (high Ca^{2+})[7]. (By previously published criteria for biological responses, any Ca^{2+} concentration <0.1 mM is considered low Ca^{2+} and >0.1 mM is considered high Ca^{2+}.) Carcinogen treatment of basal cells produces foci that continue to proliferate when challenged with high Ca^{2+} medium. Such studies have formed the basis for the hypothesis that this cellular change represents the initiation event[1-3,8]. It seems likely that cells that have undergone the initiation step possess all the information required to produce papillomas[3,5]. Recently, Balmain *et al.* have reported that Ha-*ras* expression is increased in epidermal papillomas and carcinomas[6] and that more than 60% of papillomas contain an activated *ras* gene when tested by 3T3 transfection studies[6,9]. However, we have been unable to detect elevated levels of *ras* messenger RNA or other mRNAs hybridizable by complementary DNAs for viral oncogenes in putatively initiated epidermal cell lines[29]. Furthermore, studies with sarcoma viruses indicate that an activated *ras* gene produces changes in keratinocytes which differ from those seen in putative chemically initiated cells and which are inconsistent with the expected requirements for papilloma formation[3,4]. To clarify this discrepancy, we made further studies of the properties of keratinocytes expressing an activated Ha-*ras* and Ki-*ras* gene that had been introduced by virus infection.

Two epidermal marker proteins were examined, the pemphigoid and pemphigus vulgaris antigens. Pemphigoid antigen is a protein of relative molecular mass (M_r) 220,000 (220K) found in the basement membrane and it is closely associated with the plasma membrane of the basal cell[10,11]. Pemphigus vulgaris antigen is a 210K glycoprotein containing disulphide-linked chains of 130K and 80K which occurs on the surface of stratifying epithelial cells[12]. Immunofluorescence and immunoprecipitation data have shown that the pemphigoid antigen is synthesized exclusively by basal cells in low Ca^{2+}; within 6 h of switch to high Ca^{2+}, pemphigoid synthesis is

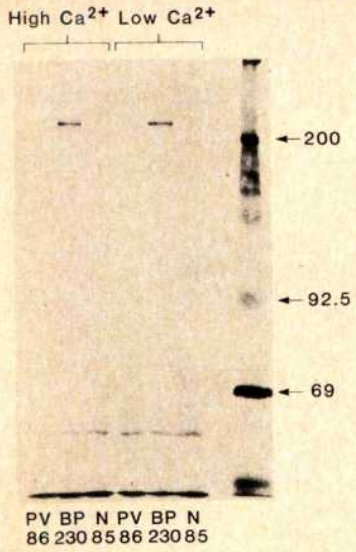

Fig. 1 Synthesis of epidermal antigens by virus-infected and control cells. Approximately 3×10^6 c.p.m. of each sample was immunoprecipitated with specific antisera (N, normal human serum; PV, pemphigus vulgaris antiserum no. 86; BP, bullous pemphigoid antiserum no. 230) and precipitates separated on a SDS-dithiothreitol (DTT) 6% polyacrylamide gel as reported previously[12]. Fluorograms were developed after 3 weeks of exposure. Numbers refer to M_r markers ($\times 10^{-3}$). Only virus-infected cultures are shown.

Methods. Newborn BALB/c mouse keratinocytes were isolated and cultured in Eagle's medium with 8% Chelex-treated fetal calf serum (Reheis), 1% antibiotic/antimycotic mixture (Gibco) and 0.05 mM Ca^{2+} as described previously[7]. On day 3 *in vitro*, cultures were exposed to a virus complex containing Friend murine leukaemia virus (F-MuLV) clone 57 and Kirsten sarcoma virus in the presence of 4 μg ml^{-1} polybrene as reported previously[4]. Viral stocks were titred by xc plaque formation in NIH 3T3 cells[4]. Cells were exposed to 1 : 2 dilution of virus stock (multiplicity of infection of ~0.5) for 1 h and a dilution eightfold further was continued for 72 h. Fresh medium (0.05 mM Ca^{2+}) was added for an additional 24 h after which half of the dishes were switched to medium containing 1.2 mM Ca^{2+}. Cultures were maintained in either 1.2 mM or 0.05 mM Ca^{2+} for 48 h of which the final 16 h included 12.5 μCi ml^{-1} ^{14}C amino-acid mixture (NEN, 55 mCi per mol atom carbon). The cell layer was extracted with 3 ml of 0.5% Nonidet P-40 in Tris-buffered saline (10 mM Tris HCl, *p*H 7.4, 0.15 mM NaCl) with 1 mM phenylmethylsulphonyl fluoride. After centrifugation at 100,000*g* for 1 h, the supernatant was dialysed against 0.3% Nonidet P-40 in Tris-buffered saline.

inhibited by >90%[13]. Similar studies have indicated that pemphigus vulgaris antigen is synthesized exclusively by differentiating cells in high Ca^{2+} (ref. 13). Therefore, we prepared cell lysates from virus-infected keratinocytes that had been labelled with ^{14}C-amino acids for 16 h in low or high Ca^{2+} medium, and examined them by gel separation of immunoprecipitates using specific antisera to pemphigus vulgaris or pemphigoid antigens (Fig. 1). We found that, as occurs with normal cells, pemphigoid antigen was synthesized by infected keratinocytes in low Ca^{2+}, but unlike normal cells, synthesis was unchanged in infected cells maintained in high Ca^{2+} for 48 h. Furthermore, the extremely low levels of labelled pemphigus vulgaris antigen, expected in lysates from low Ca^{2+} cells, were also observed in lysates of virus-infected cells grown in high Ca^{2+} medium, culture conditions which stimulate pemphigus vulgaris synthesis in normal cells. Because the expression of these proteins is strongly linked to the differentiation state of keratinocytes[13], the results suggested that virus-infected cells in high Ca^{2+} maintain basal cell properties.

Additional support for an early differentiative block of virus-treated cells was obtained in experiments in which cells were returned to low Ca^{2+} growth conditions after a period in high Ca^{2+}. Previously, Hennings and Holbrook[14] had shown that

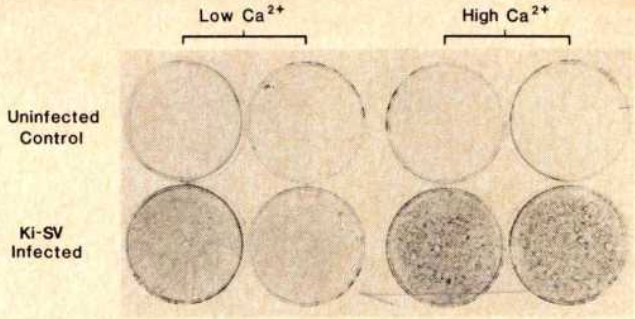

Fig. 2 Reversibility of the differentiation state of sarcoma virus-infected keratinocytes. Newborn BALB/c keratinocytes were isolated, plated and exposed to Kirsten virus as described in Fig. 1 legend. Five days after the start of virus exposure, all cultures were switched from 0.05 mM Ca^{2+} medium to 0.5 mM Ca^{2+} medium and maintained for 2 weeks with twice-weekly medium changes. Control and virus-infected dishes were then either switched back to 0.05 mM Ca^{2+} or continued in 0.5 mM Ca^{2+}, both for an additional 2 weeks. All dishes were then fixed in 10% formalin and stained with 10% Giemsa stain. Uninfected control cultures were exposed to polybrene only. Previously, controls exposed to polybrene only were shown to be identical to F-MuLV-exposed controls[4]. The low Ca^{2+} (0.05 mM) or high Ca^{2+} (0.5 mM) groups refer to the Ca^{2+} level of the final growth medium. Virus-treated cultures in 0.05 mM Ca^{2+} are not as dense as those in 0.5 mM Ca^{2+} and therefore do not stain as darkly, although both culture groups form completely confluent monolayers. Both uninfected control groups contained very few attached cells and thus show little staining.

keratinocytes are irreversibly committed to terminal differentiation by 72 h treatment in high Ca^{2+}. Such cells slough from culture even if switched back to the lower Ca^{2+}. This result is reproduced (Fig. 2) in uninfected control cultures, which were devoid of keratinocytes when maintained in high Ca^{2+} continuously for 4 weeks or when grown in high Ca^{2+} for 2 weeks and then returned to low Ca^{2+} for 2 weeks. The virus-infected cultures (Fig. 2) remained confluent when maintained in high Ca^{2+} conditions (although growth rate was low)[4]. When these cultures were returned to low Ca^{2+} medium, the confluent cell layer persisted and the cells assumed a basal cell morphology once again. These results support the suggestion that the sarcoma virus (and presumably the active *ras* gene) blocks keratinocytes prior to a step of irreversible commitment to terminal differentiation.

The state of epidermal differentiation is known to determine the response pattern to phorbol ester tumour promoters. Proliferative responses, such as the induction of ornithine decarboxylase (ODC), are characteristic of basal cells[15,16], and these responses are rapidly lost as cells begin their maturation programme[15]. Phorbol esters markedly accelerate terminal differentiation of more mature basal cells[16,17], as indicated by the induction of epidermal transglutaminase and an increase in the percentage of cells with cornified envelopes. Modulation of the normal pattern of phorbol ester responses would be expected if virus infection altered the maturation state of keratinocytes. Virus-infected basal cells incubated in low Ca^{2+} medium are highly sensitive to the induction of ornithine decarboxylase by 12-O-tetradecanoyl phorbol-13-acetate (TPA) (not shown). The response kinetics are similar to those of normal basal cells, although the magnitude is several-fold greater. When normal cells were induced to differentiate by Ca^{2+}, TPA was ineffective in inducing ODC within 6 h after shifting to high Ca^{2+} medium[15] (Fig. 3). However, virus-infected cells retained response to TPA for ODC induction even after several days in high Ca^{2+} medium (Fig. 3). These results are consistent with the suggestion that the virus blocks maturation at the basal cell stage.

Epidermal transglutaminase activity increases during Ca^{2+}-induced differentiation in normal cells[18] and virus infection does not block this increase[4]. We found that in normal cells, transglutaminase activity remained high as the cells completed their

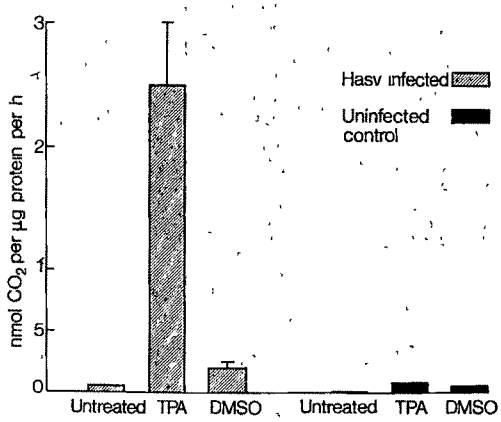

Fig. 3 Ornithine decarboxylase (ODC) response of keratinocytes in 1.2 mM Ca^{2+} medium after exposure to TPA. The viral preparation contained Harvey sarcoma virus with F-MuLV in this experiment, but identical results were obtained with cultures infected with Kirsten sarcoma virus.

Methods. Keratinocytes were plated and exposed to virus as indicated in Fig. 1. Cultures were exposed to virus or polybrene for 72 h in 0.05 mM Ca^{2+} medium and fresh 0.05 mM Ca^{2+} medium for 48 h and then switched to 1.2 mM Ca^{2+} medium for 72 h. Untreated dishes were washed three times with normal saline and frozen on dry ice, while treated cells received fresh 1.2 mM Ca^{2+} medium containing either 0.1% DMSO (Pierce) or 0.1 μg ml^{-1} TPA (Chemical Carcinogenesis, Eden Prairy, Minnesota) and 0.1% DMSO After a 6-h incubation at 37 °C, cells were washed and frozen as above Cells from each dish were scraped twice with 120 μl PBS and 50-μl aliquots of the lysates were assayed for ODC and protein as described previously[15].

Table 1 DNA synthesis in epidermal cells after exposure to TPA

Treatment	Control cells (0.5 mM Ca^{2+}) DNA synthesis (c.p.m. per μg DNA)	Harvey sarcoma virus-infected cells (0.5 mM Ca^{2+}) DNA synthesis (c.p.m. per μg DNA)
0.1% DMSO	511 ± 59	489 ± 73
0.0001 μg ml^{-1} TPA	260 ± 18	616 ± 27
0.001 μg ml^{-1} TPA	264 ± 8	665 ± 52
0.01 μg ml^{-1} TPA	299 ± 12	953 ± 175

Virus-infected or control cells were exposed to the test agent while in 0.5 mM Ca^{2+} medium. After 5 days, cultures were exposed to medium containing ^{3}H-thymidine. Values represent the mean ± s.e. of four samples for each exposure. DNA synthesis decreases in control cells exposed to TPA and increases in virus-infected cells.

Methods. Epidermal cells were isolated, cultured in 0.05 mM Ca^{2+} medium and infected with virus as described in Fig. 1 legend. Four days after infection, cultures were switched to 0.5 mM Ca^{2+} medium and continuously exposed to TPA or dimethyl sulphoxide (DMSO). After 5 days, the cultures were labelled with 1 μCi ml^{-1} [*Me*-^{3}H]thymidine (6.7 Ci $mmol^{-1}$, NEN) for 1 h, washed three times with phosphate-buffered saline (PBS) containing 1% unlabelled thymidine and frozen. Quantitation of label incorporated into DNA was performed as described previously[16].

differentiation programme, and this activity was not further influenced by TPA (Fig. 4), although initially TPA and Ca^{2+} acted synergistically to increase transglutaminase activity[17]. When virus-infected cells in high Ca^{2+} were exposed to TPA, there was a gradual decrease in transglutaminase activity; in some experiments, activity returned to that seen in low Ca^{2+}. Concurrent with the decrease in transglutaminase activity, TPA also caused a dose-dependent increase in ^{3}H-thymidine incorporation into DNA of virus-infected but not control cells in high Ca^{2+} (Table 1). These results suggest that maturing keratinocytes expressing an activated *ras* gene respond to phorbol ester tumour promoters by reverting to a less mature basal cell phenotype.

This new information on the biological state of keratinocytes infected with murine sarcoma viruses provides a biological

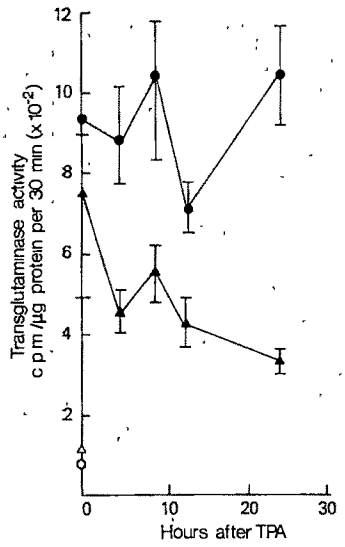

Fig. 4 TPA decreases epidermal transglutaminase in virus-infected cells. ●, Uninfected controls, 1.2 mM Ca^{2+}; ▲, Kirsten virus-infected, 1.2 mM Ca^{2+}; ○, uninfected control, 0.05 mM Ca^{2+}, △, Kirsten virus-infected, 0.05 mM Ca^{2+}. Values represent the mean ± range of duplicate determinations of duplicate samples. Identical results were obtained with Harvey sarcoma virus-infected cells

Methods. Keratinocytes were plated and infected with a 1:3 dilution of Kirsten sarcoma virus as in Fig. 1. After 72 h of virus exposure and 24 h of fresh 0.05 mM Ca^{2+} medium, dishes were switched to 1.2 mM Ca^{2+} medium for 48 h. Each group was treated with 0.1 μg ml^{-1} TPA and duplicate samples were washed and frozen on dry ice at 0, 4, 8, 12 and 24 h. Cells were lysed by 5 min incubation at 37 °C with PBS containing 1% Triton X-100 and 10 mM DTT. Transglutaminase was assayed on 50-μl aliquots of the lysate by adding 150 μl of the following freshly prepared mixture: 20 μl of 500 mM sodium borate, *p*H 9 5, 10 μl of 100 mM $CaCl_2$, 10 μl of 10 mM EDTA, 20 μl of casein (20 mg ml^{-1}, Sigma), 10 μl of [2,3-^{3}H]putrescine (NEN, 31.3 Ci $mmol^{-1}$) and 80 μl distilled water Samples and blanks (containing buffer used for scraping cells instead of cell lysate) were incubated for 30 min at 37 °C and 80-μl aliquots were spotted on Whatman 3MM disks for counting. Protein was measured by the method of Lowry after destroying DTT in 20-μl samples by addition of 250 μl of PBS containing 100 μg chloramine-T and incubation at room temperature for at least 30 min[28]

framework to explain how activation of a *ras* gene could yield a phenotype consistent with that hypothesized for initiated cells and required for epidermal tumorigenesis. Although these studies are confined to the effects of v-*ras*, both v-Ki-*ras* and v-Ha-*ras* produce similar effects. Thus, the results are probably relevant to other activated forms of the *ras* gene. We propose that an activated *ras* gene in keratinocytes provides the proliferative signal required to form a tumour, but that the cells are unable to maintain vertical growth above the basement membrane to produce a visible lesion. These cells may be indistinguishable from committed basal cells residing on the basement membrane, which lack proliferative potential[19]. Because virus-altered cells fail to complete their differentiation programme, they might be expected to accumulate within the epidermis and expand to a limited extent in the space available[19]. Exposure to tumour promoters would selectively reverse the quiescent growth state of those cells with an activated *ras* gene while normal committed basal cells would be unaffected or stimulated to differentiate further[14]. Repeated exposure to promoter, such as that required for tumour promotion, would maintain the permissive environment, allowing reactivated cells to grow in the suprabasal regions of the epidermis. Proliferation in the differentiating cell zone is a distinguishing feature of epidermal papillomas[3].

In many mouse strains, at least two classes of skin papillomas develop in protocols involving initiation and promotion[20]. Promoter-dependent tumours require repeated exposure to promoter for both expression and maintenance and regress on

withdrawal of the promoting stimulus[20]. Autonomous papillomas, once formed, do not require promoter exposure for maintenance and are more likely to progress to carcinomas[20,21]. The biological changes we have defined for keratinocytes expressing an activated *ras* gene are most consistent with *ras* activation being involved in the formation of promoter-dependent tumours. In contrast, the characteristics of chemically altered cells, selected by virtue of their resistance to differentiation, are most consistent with changes in autonomous papillomas. Whether the latter cell type requires more than one genetic change (of which *ras* activation could be a component and thus explain the isolation of an activated *ras* from 60% of papillomas) or an alteration in a different genetic element remains to be determined.

Both chemically altered and virus-altered cells fail to produce epidermal carcinomas in nude mice (ref. 22 and our unpublished data). Thus *ras* activation alone is not sufficient to complete the cancer process. We have shown previously that at least two genetic events are required to produce carcinomas in mouse skin[23]. Other studies have suggested that several viral oncogenes must work in concert to transform primary cultures of murine cells[24–26]. Weissman and Aaronson have shown that murine sarcoma viruses can elicit the transformed phenotype in aneuploid mouse epidermal cells[27]. Thus, the combination of an activated *ras* gene and aneuploidy may satisfy additional requirements for transformation.

We thank William Vass (National Cancer Institute) for supplying virus stocks and performing the virus titre assays, and Dr Edward Scolnick (Merck, Sharpe and Dohme) for supplying the producer cell lines and for advice on experimental methods.

Cigarette smoke induces DNA single-strand breaks in human cells

Tsutomu Nakayama, Motohisa Kaneko, Masahiko Kodama & Chikayoshi Nagata

Biophysics Division, National Cancer Center Research Institute, Tsukiji 5-1-1, Chuo-ku, Tokyo 104, Japan

Epidemiological evidence suggests that smoking is a major cause of human lung cancer[1,2]. However, the mechanism by which cigarette smoke induces the cancer remains obscure, although in tobacco carcinogenesis, promotion and/or co-carcinogenesis may have crucial roles. The epidemiological data show that if an individual stops smoking, the risk of his contracting lung cancer increases no further. Moreover, laboratory experiments show that cigarette smoke condensate (CSC) exhibits co-carcinogenic and promoting activities in tumour production and malignant transformation[3–5]. Clastogenic action is thought to be intimately involved in tumour promotion[6–8], and it is therefore interesting that visible chromosome changes such as chromosome aberrations and sister chromatid exchanges are known to be caused by cigarette smoke[9–11]. However, there has been no previous direct demonstration that cigarette smoke can cause single-strand breaks (SSB) in DNA. Here we report that cigarette smoke induces considerable numbers of DNA SSB in cultured human cells, and that such strand breaks may be ascribed to active oxygen generated from cigarette smoke.

Alkali-labile sites and SSB in DNA were analysed by an alkaline elution technique[12] Smoke from a commercial filter-tipped cigarette was passed through 6 ml of phosphate-buffered saline (PBS), *p*H 7.4, for 5 min and used immediately as 'smoke-PBS' (ref. 13). Human lung carcinoma (A549) cells prelabelled with ^{14}C-thymidine (50 nCi per nmol per Petri dish) were treated with smoke-PBS at 20 °C for 1 h.

Figure 1*a* shows the alkaline elution profile of human cell DNA after treatment with 1 ml of smoke-PBS. The cells showed ~50% plating efficiency after treatment with this volume of smoke-PBS and, according to dye exclusion tests, 100% of the cells excluded trypan blue immediately after smoke-PBS treatment. The number of SSB obtained using different amounts of smoke-PBS (Fig. 1*b*) was calculated by external standardization (4.05 SSB per 10^{10} daltons of DNA were produced in cells irradiated at 4 °C with 150 rad of γ rays of ^{60}Co at 37 5 rad min^{-1}). The number of SSB varied almost fivefold between experiments, probably because of the fluctuating conditions for trapping smoke and a subtle difference in the quality of individual cigarettes. However, when the same smoke-PBS was used, consistent results were obtained

Table 1 Effect of scavengers on DNA strand breaks caused by cigarette smoke or by H_2O_2 in a cell system

Treatment	SSB per 10^{10} daltons	%SSB relative to standard
Expt 1		
Smoke-PBS	55 1±3.2	100
Smoke-PBS+SOD (100 μg)	35 4±3.1	64
Expt 2		
Smoke-PBS	21.1±0 7	100
Smoke-PBS+catalase (2 μg)	3 4±0	16
Smoke-PBS+inactivated catalase (2 μg)	22.1±4.2	104
Expt 3		
H_2O_2 (32 μM)	9 5±0.8	100
H_2O_2 (32 μM)+catalase (2 μg)	1.6±0 2	17
H_2O_2 (32 μM)+inactivated catalase (2 μg)	8.3±2.2	87

The reaction mixture contained 3×10^5 cells and 1 0 ml of smoke-PBS The specific activities of catalase (Sigma) and SOD (Sigma) were 20,000 U mg^{-1} and 3,000 U mg^{-1}, respectively Inactivated catalase was prepared as follows Catalase (2 mg) was incubated in 1 ml of 0 1 M NaOH at 70 °C for 30 min and neutralized with 0 1 M HCl. Each experiment was performed in duplicate Other conditions were the same as in Fig. 1

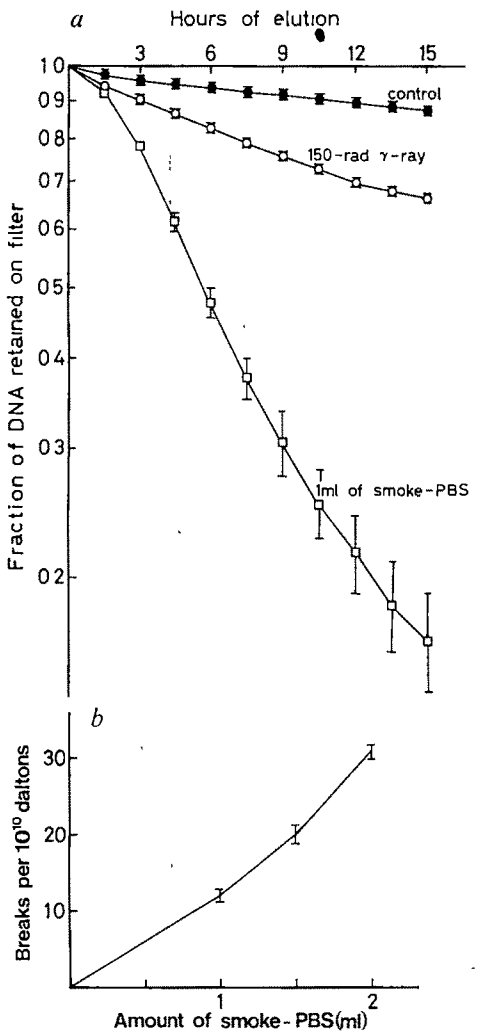

Fig. 1 *a*, Alkaline elution profiles of DNA from cells treated with 1 ml of PBS solution of cigarette smoke. *b*, Effects of different amounts of smoke-PBS on DNA strand breaks.
Methods. A549 cells (5×10^5 cells per dish) labelled with ^{14}C-thymidine were preincubated at 20 °C with 40 mM HEPES buffer (*p*H 7 2) containing heat-inactivated fetal calf serum at a final concentration of 7%. After 1 h incubation with (□) or without (●) smoke-PBS at 20 °C, the cells were washed twice with ice-cold PBS and collected with a rubber stripper in PBS on ice (As a standard for DNA strand breaks, cells were irradiated with 150 rad γ-rays from ^{60}Co and collected in the same way (○).) The cells were lysed on a polycarbonate filter (pore size 2.0 μm) with proteinase K (0.5 mg ml^{-1}) in the presence of 2% SDS, washed with 20 mM EDTA (*p*H 9.6) and eluted with 50 mM tetrapropylammonium hydroxide buffer containing 20 mM EDTA (*p*H 11 9) at a rate of 0.05 ml min^{-1}. Fractions were collected directly in scintillation vials at 90-min intervals. Radioactivity remaining on the filters was recovered by heating the filter at 70 °C for 1 h in 0.5 ml of 1 M HCl followed by the addition of 1 M NaOH All experiments were performed in duplicate and the bar shows two original points in each experiment

It was important to identify the component in cigarette smoke that is responsible for DNA SSB. Previously, we found that large amounts of active oxygen such as H_2O_2 and O_2^- were generated from cigarette smoke after trapping the smoke in PBS (~0 5 μg ml^{-1} of H_2O_2 was regularly detected in smoke-PBS)[13]. We also showed that SSB in DNA were produced by active oxygen radicals generated from active metabolites of carcinogenic aromatic amines[12]. These findings suggested that the active oxygen generated from cigarette smoke might be responsible for the observed SSB in DNA. To verify this, we checked the effect of catalase and superoxide dismutase (SOD) on the number of SSB produced, and found that both enzymes inhibited SSB, the inhibition with catalase being greater than with SOD (Table 1). Although the absolute number of SSB varied in several

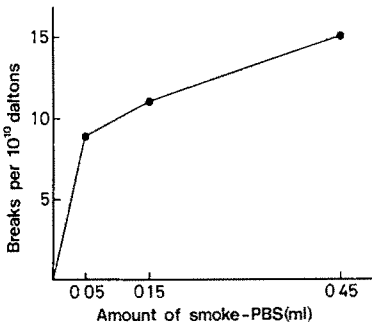

Fig. 2 Effect of different amounts of smoke-PBS on DNA strand breaks in a cell-free system. A549 cells (4×10^5 cells per dish) labelled with ^{14}C-thymidine were collected by trypsin treatment, put on polycarbonate filters and lysed with proteinase K (0.5 mg ml^{-1}) in the presence of 2% SDS The filters were washed twice with 20 mM EDTA (*p*H 9 6), then 5 ml PBS, 20 mM EDTA (*p*H 7 4) containing the indicated amount of smoke-PBS was added to the cell lysate on the filter with the outlet of the filter closed. The reaction mixture was kept in the dark at room temperature for 1 h, and the filters were then washed twice with 3 ml 20 mM EDTA (*p*H 9 8) and eluted with tetrapropylammonium hydroxide buffer (*p*H 11.9) containing 20 mM EDTA at a rate of 0.05 ml min^{-1} The subsequent treatment and calculation of SSB were the same as for the cell system (see Fig 1 legend)

Table 2 Effect of scavengers on DNA strand breaks caused by cigarette smoke in a cell-free system

Treatment	% SSB relative to standard
Standard	100
+SOD (10 μg)	11
+catalase (2 μg)	8
+inactivated catalase (2 μg)	100
+sodium benzoate (50 mM)	18
+DETAPAC (1 mM)	44

The standard system includes 5 ml of PBS (*p*H 7.4) containing 20 mM EDTA and 50 μl of smoke-PBS, and was incubated at room temperature for 1 h. Each value was obtained from four independent experiments performed in duplicate The average error was about 10% in each duplicated experiment. The SSB value of the standard was 6.2 ± 1.6 (mean ± s.d) SSB per 10^{10} daltons

independent experiments, the inhibition rates of the two enzymes showed a similar range (catalase, 85–95%; SOD, 30–45%). Inactivated catalase showed no effect in these inhibition experiments. Comparison of the activity of catalase and inactivated catalase in parallel, using authentic H_2O_2, showed clearly that the inhibitory effect of catalase was a result of its enzyme activity of quenching H_2O_2.

To exclude completely the contribution of DNA repair in SSB formation and to elucidate the mechanism of DNA scission more precisely, we looked for SSB in cell-free *in vitro* systems. Strand breaks were detected in protein-free DNA of high relative molecular mass which had been treated with smoke-PBS on polycarbonate filters, the number of SSB increasing dose dependently (Fig. 2). Table 2 shows the effect of several scavengers in a cell-free system. Catalase and SOD decreased the number of SSB, as did sodium benzoate, a hydroxyl radical (·OH) scavenger, while 1 mM diethylenetriamine-*N,N,N′,N″,N″*-pentaacetic acid (DETAPAC), a potent Fe^{3+} chelator, inhibited SSB in the presence of 20 mM EDTA. In cigarette smoke, ·OH could be formed through the Fenton-type Haber–Weiss reactions and/or the reaction of H_2O_2 with nitrogen oxides[13,14].

$$H_2O_2 + O_2^- \xrightarrow{Fe^{3+}} O_2 + OH^- + {\cdot}OH$$
$$H_2O_2 + NO_x \longrightarrow {\cdot}OH + HONO_x$$

Accordingly, it is probable that the SSB observed were caused by OH that had been formed by these reactions, which in their turn had been induced by cigarette smoke. From these results, we conclude that cigarette smoke has clastogenic activity on cellular DNA to produce SSB as detected by alkaline elution, and that such activity can be explained mainly by the action of active oxygen generated from cigarette smoke.

Although mutagenicity induced by CSC has been found in bacterial and mammalian cells[9], this does not necessarily mean that the mutagenic compounds are directly involved in tobacco carcinogenesis[15]. On the other hand, the frequency of benzo(*a*) pyrene-induced transformation of Syrian hamster embryo cells is enhanced by CSC as efficiently as by the tumour promoter phorbol myristate acetate[4,5] These facts and the recent findings that the clastogenic action of active oxygen is involved in the promoting process suggest an important role for DNA SSB induced by cigarette smoke[6-8]. The active oxygen is generated mostly from polyphenols, such as catechol, its methyl derivatives and hydroquinone, which occur in abundance in the smoke[13]. This is consistent with the previous finding that the co-carcinogenic fraction in CSC contains catechol and hydroquinone and that catechol shows potent co-carcinogenic action in benzo(*a*)pyrene carcinogenesis[16]

A good correlation has been found between free radical formation, generation of active oxygen and carcinogenicity by aromatic amine derivatives and other carcinogens[17-23]. This may imply a causal significance of SSB in carcinogenesis, because the SSB in DNA were generated by active oxygen from active metabolites of naphthylamines[12]. In the present experiments, one cigarette produced ~10^4 SSB per cell. Although in the body, most SSB caused by cigarette smoke are expected to be efficiently repaired, some would remain unrepaired and the accumulation of such SSB over a long period may have serious consequences, especially for heavy smokers.

This work is supported in part by a Grant-in-Aid for Cancer Research from the Ministry of Education, Science and Culture. We thank Miss Kimiko Saito for technical assistance.

Characterization of cDNA and genomic clones encoding the precursor to rat hypothalamic growth hormone-releasing factor

Kelly E. Mayo*, Gail M. Cerelli*, Michael G. Rosenfeld† & Ronald M. Evans*

* Molecular Biology and Virology Laboratory, Salk Institute for Biological Studies, Post Office Box 85800, San Diego, California 92138, USA
† Eukaryotic Regulatory Biology Program, School of Medicine, University of California, San Diego, California 92093, USA

Growth hormone-releasing factor (GHRF) is a hypothalamic peptide which positively regulates the synthesis and secretion of growth hormone in the anterior pituitary. The amino-acid sequence of a 43-residue GHRF peptide isolated from rat hypothalamus was recently determined[1]. Immunocytochemical techniques have been used to localize GHRF-containing cell bodies and nerve fibres largely to the medial-basal region of the rat hypothalamus[2]. The rat has also been used extensively as an animal model to study the effects of GHRF on growth hormone synthesis[3,4] and secretion[5,6] and on somatic growth[7]. To pursue questions concerning the biosynthesis of GHRF, the expression of the *ghrf* gene, and its regulation in the hypothalamus by neural and hormonal influences, we have now isolated and characterized both complementary DNA and genomic clones encoding rat hypothalamic GHRF. The rat *ghrf* gene spans nearly 10 kilobases (kb) of rat genomic DNA, contains 5 exons and encodes a 104-amino-acid precursor to the rat GHRF peptide. Comparison with previously characterized human *ghrf* cDNA[8,9] and genomic[10] clones has allowed patterns of conservation of amino-acid and nucleotide sequences between the human and rat GHRFs to be determined.

A 100,000-member cDNA library was constructed in the bacterial expression vector pUC8 (ref. 11) using as template poly(A)$^+$ RNA isolated from rat medial-basal hypothalamus, which was shown previously by immunohistochemical techniques to contain a concentration of GHRF-reactive cell bodies[2,12] This library was screened by hybridization using the insert from a human *ghrf* cDNA clone as probe[9], and two positive colonies were identified and isolated. Figure 1*a* shows the DNA sequence of the insert from one of these clones, prghrf-2 This cDNA includes a sequence encoding the complete 43-amino-acid rat GHRF peptide predicted from the amino-acid sequence data of Vale and co-workers[1] The structure of the entire rat *ghrf* cDNA insert is shown schematically in Fig 1*b* The GHRF peptide sequence is followed by a single arginine residue which presumably serves as a signal for proteolytic processing of GHRF from the precursor protein[13] This arginine is not preceded by a glycine residue, which is believed to serve as the amide donor in processed peptides that are C-terminally amidated[14]. This agrees with the published amino-acid sequence suggesting a free C-terminus[1], and makes rat GHRF different from human, bovine, ovine, porcine and caprine GHRFs, all of which are C-terminally amidated[15]. In cDNA clone prghrf-2, the GHRF peptide sequence is followed by a 30-amino-acid peptide of unknown function, a 105-nucleotide 3'-non-translated sequence and a poly(A) tract (Fig 1*b*) Comparison with previously characterized human *ghrf* cDNA clones[8,9] suggests that this rat *ghrf* cDNA clone lacks the N-terminal portion of the precursor, including the presumed signal peptide sequence and the 5'-non-translated sequences

The rat *ghrf* cDNA clone was used to screen a rat genomic library constructed in the λ vector Charon 4A (ref 16) Figure 2*a* shows the structures of two overlapping clones isolated from this library (rghrfλ101 and rghrfλ103) which predict the entire structure of the rat *ghrf* gene Hybridization identifies 5 exons which span more than 9 kb of rat genomic DNA, and reveals a structure very similar to that previously determined for the human *ghrf* gene[10]. Southern blot analysis of rat genomic DNA indicates that the rat *ghrf* gene is probably single-copy (data not shown). To define the structure of this gene more precisely, the DNA sequences of all exons, intron/exon boundaries and 5'- and 3'-flanking regions were determined by the strategy indicated (Fig 2*b*). Figure 3 gives the DNA sequence of the rat *ghrf* gene All four introns begin and end, respectively, with the consensus sequences GT and AG[17] Consensus TATA and CAT sequences, found in the 5'-flanking region of many eukaryotic genes[17,18], are located 31 and 76 nucleotides, respectively, 5' of the proposed messenger RNA cap site The location of the proposed mRNA cap site is based on its distance from the TATA

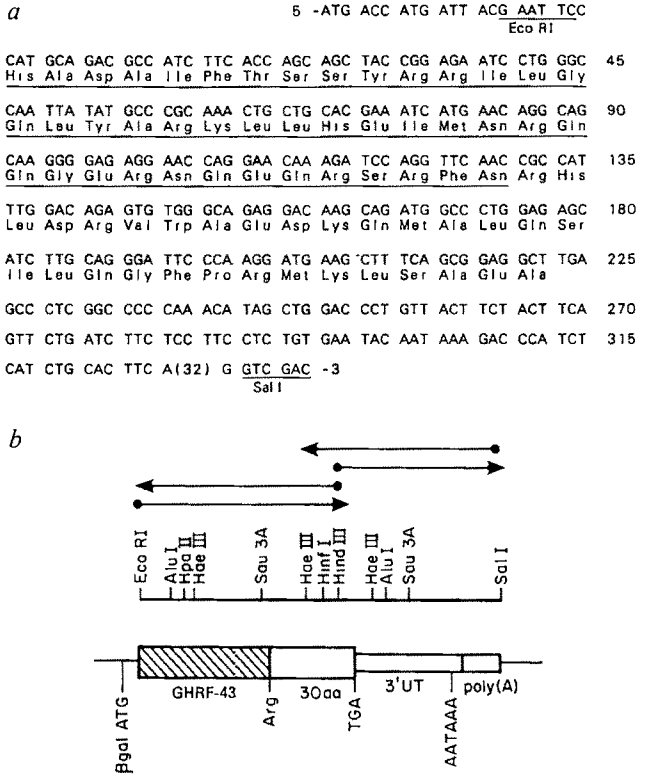

Fig. 1 Sequence and structure of a cDNA clone encoding rat hypothalamic growth hormone-releasing factor. *a*, DNA sequence of the insert from rat *ghrf* cDNA clone prghrf-2. The amino-acid sequence predicted from the open reading frame within the insert is shown beneath the DNA sequence. *Eco*RI and *Sal*I indicate the synthetic linkers ligated to the 5′ and 3′ ends of the cDNA insert, respectively. The sequence of the 43-amino-acid rat GHRF peptide is underlined *b*, Diagram of the structure of rat GHRF cDNA clone prghrf-2. The *ghrf*-coding region, the 30-amino-acid C-terminal peptide, the 3′-non-translated region and the poly(A) tract are indicated The positions of the *Escherichia coli* β-galactosidase initiation codon within the vector and the natural stop codon with the insert are also indicated. The restriction map indicates sites for common 4- and 6-bp cutters within the insert, and the arrows indicate the strategy used for DNA sequence analysis of the insert. **Methods.** Poly(A)$^+$ RNA was isolated using standard techniques from medial-basal hypothalamic fragments obtained from 150-g Zivic-Miller male rats that had been adrenalectomized for other purposes 3–4 days before they were killed. (These fragments were kindly provided by Dr Michael Browstein, NIH) This RNA was used as a template for oligo(dT)-primed first-strand cDNA synthesis with avian myeloblastosis virus reverse transcriptase. Second-strand cDNA synthesis was performed using the large fragment of DNA polymerase I, and *Sal*I and *Eco*RI linkers were added sequentially to the 3′ and 5′ ends of the double-stranded cDNA, respectively. Approximately 100 ng of cDNA were ligated into the bacterial expression vector pUC8 that had previously been digested with *Eco*RI and *Sal*I and the ligated mixture was used to transform $CaCl_2$-competent *E. coli* strain DH-1. Bacteria were plated at a density of 1,000 colonies per 82-mm plate onto L-broth agar with ampicillin, replica plated to nitrocellulose filters, and the filters screened by hybridization to the 350-bp *Eco*RI/*Bam*HI insert from human *ghrf* cDNA clone phghrf-54 (ref. 9), which had been labelled by nick-translation using [α-^{32}P]dCTP. Positive colonies from the high-density screen were re-screened at lower density until pure. Two positive colonies were isolated from 100,000 recombinants screened Because initial analysis indicated that both clones contained similarly sized inserts, only one was analysed in detail. Subsequent analysis indicated that the second cDNA clone contained a single additional G residue at the 5′ end of the insert. All cloning and screening procedures have been described in detail elsewhere[23]. DNA sequence analysis was by the chemical method of Maxam and Gilbert[24], using fragments that had been labelled using bacterial alkaline phosphatase, T4 polynucleotide kinase and [γ-^{32}P]ATP Enzymes were from either Bethesda Research Laboratories or New England Biolabs, and labelled nucleotides were from NEN

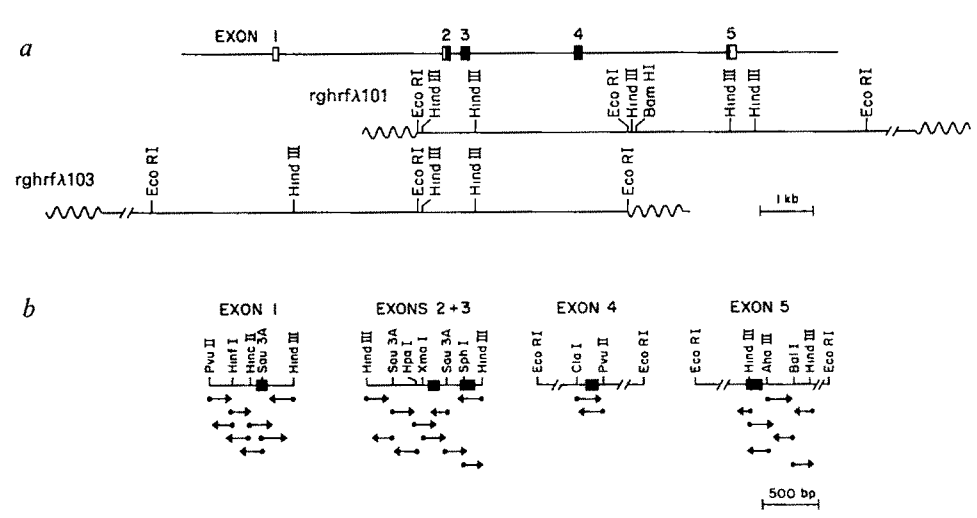

Fig. 2 Structure of rat growth hormone-releasing factor genomic clones and subclones. *a*, The top line indicates the deduced structure of the entire rat *ghrf* gene. Open boxes indicate non-coding exon regions and closed boxes indicate coding exon regions. Below this are indicated the structures of λ phage genomic clones rghrfλ101 and rghrfλ103. *Eco*RI, *Bam*HI and *Hin*dIII restriction enzyme sites used to establish overlap between the clones are indicated The wavy lines indicate the λ vector DNA, slashes indicate a break in the scale *b*, Regions of the above λ phage clones which were subcloned into plasmid vectors for further analysis are indicated, as is the strategy used to determine the DNA sequence of the rat *ghrf* gene Boxed regions are exons as indicated and selected restriction enzyme recognition sites used in the sequence analysis are shown Slashes represent a break in the scale. Dots represent sites that were labelled for DNA sequencing and the arrows indicate the direction and extent of derived sequence information **Methods.** Approximately 400,000 plaques from a rat genomic library consisting of partial *Eco*RI-digested rat DNA in the λ phage vector Charon 4A[16] were screened on nitrocellulose filters by hybridization to the 350-bp *Eco*RI/*Sal*I insert from rat *ghrf* cDNA clone prghrf-2 which had been labelled by nick-translation using [α-^{32}P]dCTP Two types of clones, represented by those shown in *a*, were isolated Exon regions were located by restriction mapping/DNA blotting techniques using appropriate probes. The rat cDNA clone was used as probe to identify exons 3, 4 and 5 Human *ghrf* cDNA clone phghrf-54 (ref. 9) was used to locate rat exon 2, and genomic probes isolated from the human *ghrf* gene[10] were used to localize rat exon 1 Regions from the genomic clones indicated in *a* were subcloned into plasmid pBR322 for DNA sequence analysis, which was by the chemical method of Maxam and Gilbert[24] Details of all cloning and mapping methods have been described previously[23]. Materials were from the sources indicated in Fig. 1 legend.

box[17,18], the fact that transcription generally begins at an A residue[19], and its homology to the cap site of the human *ghrf* gene, which has been determined by RNA mapping techniques[10]. The sequence AATAAA, thought to be important in polyadenylation[20], is located 21 nucleotides 5′ of the poly(A) addition site.

A combined analysis of the rat *ghrf* cDNA and genomic clones allows the entire amino-acid sequence of the rat GHRF precursor protein to be deduced. This sequence is compared with that of the human GHRF precursor protein in Fig. 4*a*. The GHRF peptides themselves are closely homologous, but differ substantially at their C-terminus (Fig. 4*a*) Because most of the

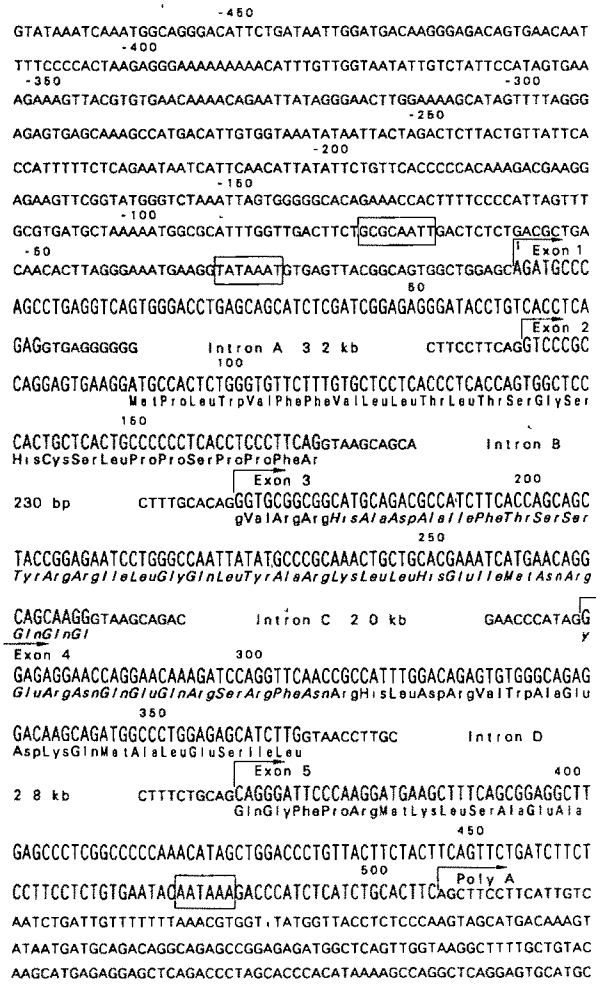

Fig. 3 DNA sequence of the rat growth hormone-releasing factor gene The DNA sequences of all exons, intron/exon boundaries and 5'- and 3'-flanking regions are shown. Numbering is from the proposed mRNA 5' cap site and the introns are not numbered. Arrows indicate the beginning of exons, or the poly(A) addition site (last arrow) The larger letters represent exons of the gene, exons were deduced either by identity with the rat *ghrf* cDNA or by homology with the exons of the human *ghrf* gene. The first and last 10 nucleotides of each intron are shown together with an approximate length of each intron The amino acids indicated in italic print are those of the 43-amino-acid GHRF peptide. The boxed nucleotides indicate consensus sequences as described in the text, they are the CAT box, TATA box and AATAAA sequence, in that order

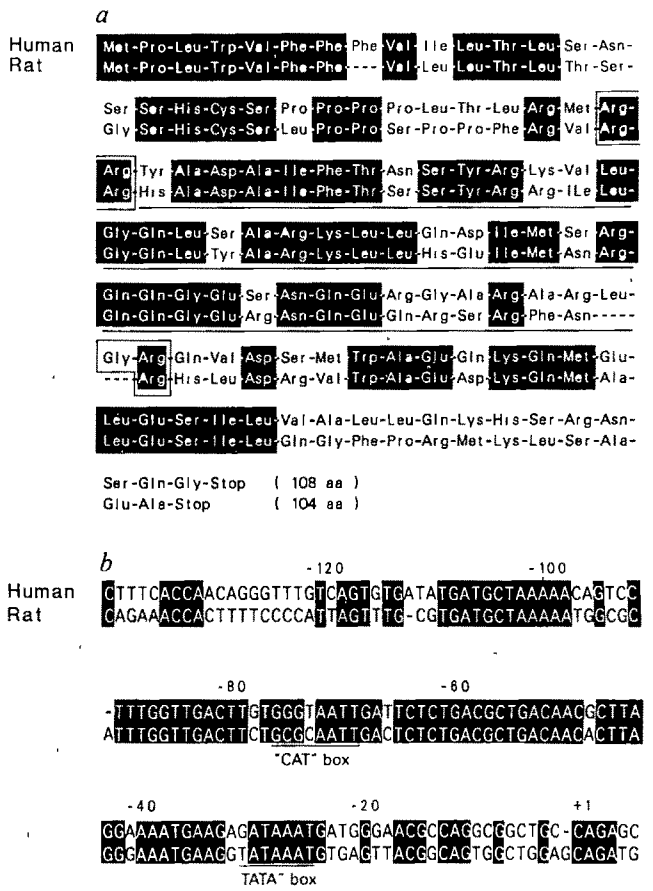

Fig. 4 Comparisons between the rat and human growth hormone-releasing factor precursor and gene sequences *a*, Comparison of the deduced amino-acid sequences of the complete rat and human GHRF precursor proteins. Identical residues are shaded; several gaps have been inserted to maximize the alignment. The GHRF peptide sequence is underlined and residues thought to be involved in the processing of this peptide from the precursor are boxed. *b*, Comparison of the nucleotide sequences in the 5'-flanking region of the human and rat *ghrf* genes Identical nucleotides are shaded, several gaps have been inserted to maximize the alignment. The positions of the consensus CAT and TATA box sequences are indicated.

biological activity of GHRF is localized to the N-terminal two-thirds of the peptide[21,22], changes in the C-terminal portion of the peptide can apparently be tolerated without loss of function. Proteolytic processing of GHRF from its precursor protein is expected to yield a C-terminal peptide of unknown function. Comparison of the human and rat precursor sequences (Fig. 4*a*) shows that the N-terminal half of this peptide is well conserved, whereas the C-terminal half diverges completely between rat and human. Analysis of the rat *ghrf* gene sequence (Fig. 3) reveals that this point of divergence corresponds precisely to a point where the precursor coding sequence is interrupted by intron D. Although the DNA sequence in this region is conserved between the human and rat *ghrf* genes, an apparent mutational event has resulted in a change in the 5' splice donor site used in the human versus the rat gene, shifting the translational reading frame (data not shown). Comparison of the human and rat *ghrf* gene DNA sequences indicates that although the two genes are homologous throughout, a particularly high degree of homology is found in their 5'-flanking regions (Fig. 4*b*). The sequence from −23 to −109 is 86% identical, compared with 76% identity between the *ghrf*-coding regions, 68% identity between the entire coding regions and ~58% identity between both the 5- and 3'-non-translated sequences. We presume that this high conservation of non-coding sequences in the 5'-flanking region reflects a functional importance, perhaps in the regulation of *ghrf* gene expression.

Because GHRF is believed to be an important physiological regulator of growth hormone synthesis and secretion[3-6], analysis of its synthesis and actions can be expected to lend insight into mechanisms by which the neural and hormonal control of somatic growth are integrated. The isolation of rat *ghrf* cDNA and genomic clones will enable us to use an animal model system to pursue questions concerning the expression of the *ghrf* gene in rat hypothalamus, to study its regulation by neural and hormonal influences, and to define the DNA sequences responsible for expression and regulation of this gene.

We thank Dr Michael Brownstein for providing the rat medial-basal hypothalamic fragments, and Marijke terHorst for secretarial assistance. This work was supported by grants from the NIH and NIAMDD to R M.E. and by Damon Runyon-Walter Winchell Cancer Fund Fellowship DRG-648 to K.E.M.

Clusters of CpG dinucleotides implicated by nuclease hypersensitivity as control elements of housekeeping genes

Stanley F. Wolf* & Barbara R. Migeon†

Department of Pediatrics, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205, USA

DNA sequences of the X-chromosome-linked hypoxanthine phosphoribosyltransferase (HPRT) and glucose 6-phosphate dehydrogenase (G6PD) genes have revealed the presence of clusters of CpG dinucleotides[1-3], raising the possibility that such clusters are involved in the control of expression of these genes, which are expressed in all tissues. Although CpG clusters are not exclusive features of the X chromosome[4-6], the analysis of X-linked genes provides the means to determine whether CpG clusters are control elements; one of the two homologous X loci in female mammals is not expressed[7], so that active and inactive versions of the gene can be compared. In fact, it has been shown that these CpG clusters are undermethylated when the gene is active and extensively methylated when the gene is inactive[2,8]. In addition to hypomethylation, chromatin hypersensitivity to endonuclease digestion is a known hallmark of regulatory sequences in eukaryotic genes[9]. We report here that the CpG clusters of the active *hprt* and *g6pd* genes are not only undermethylated, but also hypersensitive to *Msp*I, DNase I and S_1 nuclease, further supporting the suggestion that they are involved in the control of expression of these genes.

Figure 1*a* shows a restriction enzyme map of the 5′ region of the human *hprt* locus. A notable feature of the promoter region is a dense cluster of CpG dinucleotides (12 *Hpa*II and 15 *Hha*I sites within a 1.0-kilobase (kb) segment)[2]. As probe for studies of the *hprt* locus, we have used an intron sequence that hybridizes only to the *hprt* locus that is on the human X chromosome (pPB1.7)[1,2].

Figure 2*a* shows that the CpG cluster from the active *hprt* gene is extremely sensitive to digestion with *Msp*I, whereas the cluster from the inactive gene is not. When chromatin of male lymphoblasts (XY) is digested for 20 min with only 0.1 U of *Msp*I per μg DNA, the single active gene is completely cleaved, as shown by the presence of only the 9.5-kb sub-band in *Eco*RI digests of the purified DNA; this sub-band is also seen in chromatin digests from female lymphocytes. However, the 11.5-kb uncleaved fragment is also present, even if 10 times more *Msp*I is used. We infer that the uncleaved fragment comes from the inactive X because it is found exclusively in females and because the intensity of the band is proportional to the number of inactive X chromosomes (Fig. 2*a*, XX, XXX and XXXX lymphocytes). Further evidence that the inactive gene is resistant comes from studies of mouse/human hybrid cells, which contain the human inactive X homologue but not the active one. These hybrids are also a source of reactivants that have activated the *hprt* gene on the inactive X. Our observations of these reactivants indicate that acquisition of expression is accompanied by acquisition of nuclease hypersensitivity. When the gene is inactive (that is, on the isolated inactive X), the CpG cluster is resistant to *Msp*I digestion (Fig. 2*b*). However, when the *hprt* locus is re-expressed[2] as a result of reactivation of the locus on the inactive X, either spontaneously (X Rea-1) or induced by 5-azacytidine (X Rea-2), the cluster becomes as sensitive to *Msp*I as that on the active X (Fig. 2*b*).

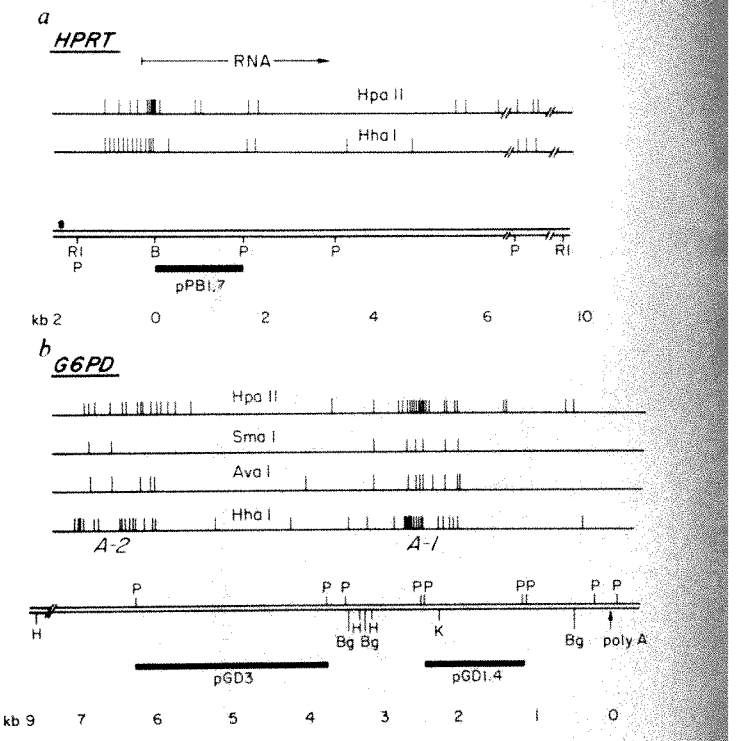

Fig. 1 Map showing relevant regions of *hprt* (*a*) and *g6pd* (*b*) loci and the cloned sequences used as probes. B, *Bam*HI; Bg, *Bgl*I; RI, *Eco*RI; H, *Hin*dIII; K, *Kpn*I; P, *Pst*I.

The 5′ *hprt* cluster is hypersensitive to digestion not only by *Msp*I, but also to DNase I and S_1 nuclease (Fig. 3). Moreover, the region of sensitivity not only coincides with the cluster, but corresponds to the region within the cluster which contains the greatest number of CpGs. The fragments resulting from cleavage of chromatin by DNase I and S_1 (and DNA by *Pst*I) are slightly larger than the *Bam*HI/*Pst*I fragment obtained by cleaving purified DNA (Fig. 3). Therefore, the hypersensitive site is immediately 5′ to the *Bam*HI site (see Fig. 1).

We have examined CpG clusters from *g6pd*, another X-linked housekeeping gene. It is not known if there are 5′ CpG clusters at this locus because clones from this region have not been isolated. However, there are two extensive clusters in the 3′ coding region. Figure 1*b* shows a map of the 3′ region and the two genomic probes[3] used for the analysis. In chromatin from the active gene, either in male cells (not shown) or in hybrids, both clusters are extremely sensitive to *Msp*I digestion. Sensitivity of the A-1 cluster in the active gene is shown in Fig. 4. In chromatin from female cells, not all clusters are cleaved by *Msp*I, as we observe the full-length *Bgl*I fragment in addition to the cleavage product obtained from active genes (Fig. 4). Studies of hybrid cells confirm that resistant clusters are from the inactive X; chromatin of hybrids with the inactive gene, but not the active one, is resistant to *Msp*I (Fig. 4).

The A-1 and A-2 clusters are also hypersensitive to DNase I and S_1 nuclease (Fig. 5). Moreover, as occurs with *hprt*, the

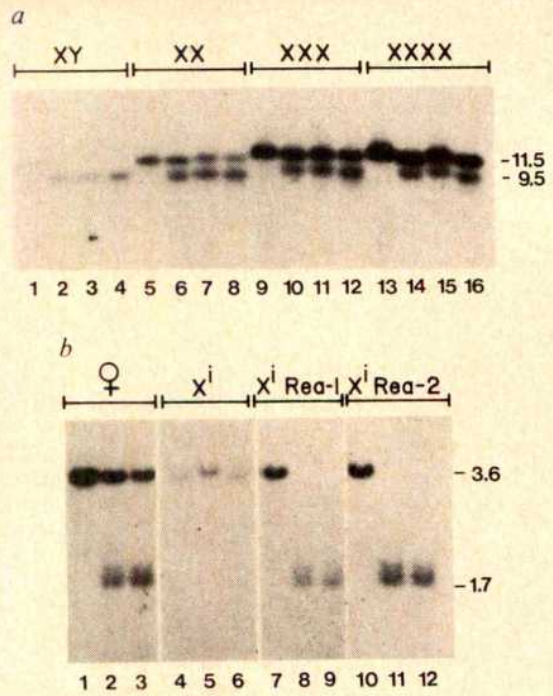

Fig. 2 *Msp*I digests of chromatin, showing sensitivity of the clusters in active *hprt* genes and resistance in inactive ones. *a*, Lymphoblasts. Lanes 1–4, 46 XY; lanes 5–8, 46 XX; lanes 9–12, 46 X/isodicentric X; lanes 13–16, 48 XXXX. Samples were treated with 0, 0.1, 0.3 or 1.0 U *Msp*I per μg DNA (from left to right in each group). Purified DNA was cut with *Eco*RI and probed with pPB1.7. *b*, Fibroblasts. Lanes 1–3, human 46 XX; lanes 4–6, hybrid G1×A9 with inactive human X; lanes 7–9, X Rea-1, spontaneous *hprt* reactivant of G1×A9; lanes 10–12, X Rea-2, 5-azacytidine-induced *hprt* reactivant of G1×A9. The hybrids and reactivants have been described elsewhere[2]. Samples were treated with 0, 0.5 or 1.5 U *Msp*I per μg DNA (from left to right in each group). DNA was cut with *Pst*I and probed with pPB1.7. Numbers on the right refer to molecular size markers in kb.

Methods. Chromatin was obtained from nuclei of lymphoblasts and fibroblasts. Lymphoblast cultures, collected at a density of 10^6 cells ml^{-1}, were washed in 0.9% saline and suspended (3×10^7 cells ml^{-1}) in RSB (10 mM NaCl, 3 mM $MgCl_2$, 10 mM Tris-HCl *p*H 7.5) supplemented with 1 mM phenylmethylsulphonyl fluoride (PMSF) and lysed by adding NP40 to a concentration of 0.2%. Nuclei from human dermal fibroblasts (or human/mouse hybrids) were purified as follows. The cells were trypsinized and resuspended in growth medium with 15% fetal calf serum, washed with 0.9% saline and treated with RSB for 10 min at 4 °C. Triton X-100 was added (to 0.2%) and the cells were lysed by Dounce homogenization to release the nuclei; then PMSF was added to a concentration of 1 mM. Nuclei were purified by washing in 50 ml RSB with 0.1 mM PMSF and resuspension in the same buffer so as to bring the concentration of nucleic acid to 250–500 μg ml^{-1}. Incubations with nuclease were carried out for 20 min at 37 °C. Reactions were stopped by quickly bringing the samples to 0 °C. The nuclei were pelleted and resuspended in 0.15 M NaCl, 0.01 M EDTA, 0.1 M Tris-HCl *p*H 7.5 and the DNA was purified by standard procedures[2].

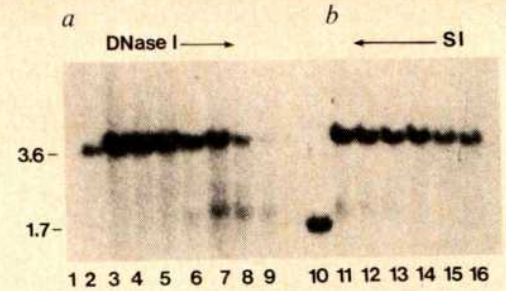

Fig. 3 DNase I and S_1 nuclease digests of chromatin showing hypersensitivity of the *hprt* 5′ CpG cluster in active genes. Lymphoblasts (46 XY) were prepared as described in Fig. 2 legend. For S_1 digests, nuclei were suspended in S_1 buffer (3 mM $ZnCl_2$, 30 mM NaCl, 0.2 mM EDTA, 30 mM sodium acetate *p*H 4.5) rather than RSB. Samples were incubated with increasing amounts of DNase I (0–0.02 U per μg DNA; lanes 1–9) or S_1 (0–20 U per μg DNA; lanes 16–11) for 20 min. DNA was cut with *Pst*I and probed with pPB1.7. A *Bam*HI/*Pst*I digest of placental DNA is included as an internal marker (lane 10).

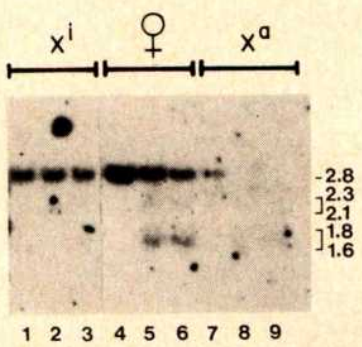

Fig. 4 *Msp*I digest of chromatin, showing sensitivity of the A-1 CpG cluster in active *g6pd* genes but resistance in inactive ones. Nuclei were prepared and digested with *Msp*I as described for Fig. 2. Lanes 1–3, human/mouse hybrid G1×A9 with inactive human X; lanes 4–6, 46 XX human fibroblast; lanes 7–9, human/mouse hybrid E×A9 with active X. Each sample was treated with 0, 0.5 or 1.5 U *Msp*I per μg DNA. DNA was cut with *Bgl*I and probed with pGD1.4.

hypersensitive regions correspond to regions having the greatest concentration of CpGs. For example, the A-2 cluster spans a 1.5-kb region, but the region of DNase I and S_1 hypersensitivity is less extensive, ~0.4 kb, deduced from the broad band (3.7–4.1 kb) representing the cleavage products (Fig. 5*c*, *d*). Furthermore, the absence of detectable DNase I or S_1 cleavage products in *Pst*I digests of the DNA probed with pGD3 (not shown) indicates that the sensitive region does not extend very far into the pGD3 sequence. That the hypersensitive region is confined to the densest part of the cluster is even more apparent in the A-1 cluster, for here there are two well-separated cleavage products (Fig. 5*a*); the hypersensitive sites map to the densest parts of the CpG cluster whereas the intervening region, which is relatively free of CpG dinucleotides, is insensitive.

Although both A-1 and A-2 clusters exhibit nuclease hypersensitivity, there are subtle differences between them. The relative intensity of the cleaved fragments indicates that the A-1 cluster is less sensitive than the A-2 cluster to either DNase I or S_1 (Fig. 5).

Our observations support the hypothesis that CpG clusters are involved in regulating the expression of *hprt* and *g6pd*. Like all regulatory regions identified[9], these clusters are hypersensitive to nuclease digestion and this sensitivity is concordant with expression of the relevant gene. Moreover, for both loci, the region of hypersensitivity maps to the clusters themselves rather than merely nearby, especially remarkable because DNase I usually prefers A+T-rich sequences[10].

The molecular determinants of nuclease hypersensitivity have been shown to be heterogeneous[9,11–13] and are likely to be complex. The ability to examine these CpG clusters in active and inactive homologues within the same cell provides insights into mechanisms responsible for hypersensitivity, at least at the loci examined. The differential nuclease sensitivity of homologous sites within the same cell indicates that neither *trans*-acting proteins[11] nor DNA sequences are sufficient determinants. Another component that seems to be required is hypomethylation of these clusters. We have never observed discordance between hypomethylation, nuclease sensitivity and expression of the relevant locus (refs 7, 8 and this paper).

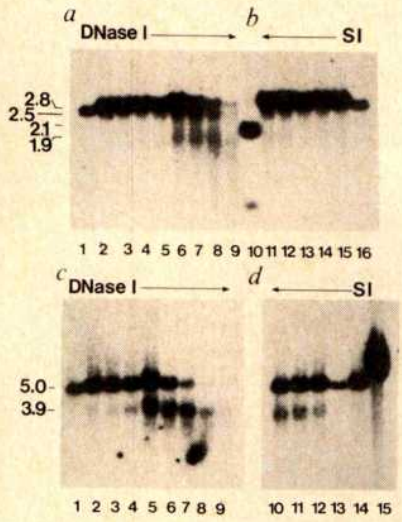

Fig. 5 DNase I (*a*, *c*) and S_1 nuclease (*b*, *d*) digests of chromatin showing sensitivity of both A-1 and A-2 CpG clusters in active *g6pd* genes. The nuclease digests of chromatin from 46 XY lymphoblasts were the same as used in Fig. 3. DNA was cut with *Bgl*I and probed with pGD1.4 (*a*, DNase I; *b*, S_1) or cut with *Hin*dIII and probed with pGD3 (*c*, DNase I; *d*, S_1). A *Bgl*I/*Kpn*I digest of placental DNA (lane 10 in *a*, *b*) is the internal marker. Lanes in *a* correspond exactly to those in Fig. 3; lanes 10–15 in *d* correspond to lanes 11–16 in Fig. 3.

The function of CpG clusters in these housekeeping genes is unknown. Although hypersensitivity of the 5′-promoter region in an active gene is not surprising, this region in *hprt* is atypical (ref. 14 and D. J. Jolly, personal communcation), lacking the characteristic regulatory signals (TATA and CAT). Thus, the 5′ cluster may provide a novel regulatory mechanism. The explanation for hypersensitivity in the 3′ region of *g6pd* is more enigmatic; however, the resemblance to the *hprt* 5′ cluster suggests that 3′ clusters may also be regulatory elements. The nuclease hypersensitivity of these CpG clusters provides the means to identify similar sequences elsewhere in the genome and the location of related clusters may provide insights into function. In any event, it is clear that CpG clusters are not unique features of X chromosomes, as they have been observed in autosomal genes[4,6]. On the other hand, these clustered CpG dinucleotides have been found most frequently in genes that are constitutively expressed, so that they may be special attributes of housekeeping genes. Such genes are unique because they are functional in all cells of the organism. The CpG-rich clusters might provide a cooperative means of minimizing the effects of chance *de novo* methylation in the regulatory regions, and/or by altering DNA structure. In conjunction with hypomethylation, these clusters could serve as irreversible switches to maintain the continuous activity of housekeeping genes.

The work was supported by NIH grant HD 05465.

Diacylglycerol in large α-actinin/actin complexes and in the cytoskeleton of activated platelets

Paul Burn, A. Rotman, R. K. Meyer & Max M. Burger

Department of Biochemistry, Biocenter of the University of Basel, Klingelbergstrasse 70, CH-4056 Basel, Switzerland

The interaction of the cytoskeleton with plasma membranes may be mediated by vinculin[1–4], α-actinin[5,6] and other proteins[7–11]; α-actinin can interact specifically with model membranes only if they contain diacylglycerol and palmitic acid[12]. On stimulation of platelets by thrombin, which leads to a reorganization of the cytoskeleton[13–15], diacylglycerol is produced rapidly[16], simultaneously with the disappearance of phosphatidylinositol[16–19]. One important function of the diacylglycerol produced in platelets may be the activation of the Ca^{2+}- and phospholipid-dependent protein kinase C[20–22]. We show here that, in the presence of diacylglycerol and palmitic acid, a supramolecular complex between α-actinin and actin is formed *in vitro*. In the electron microscope, this complex displays substructures similar to those of microfilament bundles *in vivo*. Furthermore, such α-actinin/lipid complexes can also be formed *in situ* during the stimulation of blood platelet aggregation. Thus, α-actinin may be one of the proteins directly involved in structures connecting the cytoskeleton to cell membranes.

The protein α-actinin is associated with the cytoskeleton in many cells[5,23–25], including platelets[26–29]. This association is particularly prominent on physiological activation of platelets

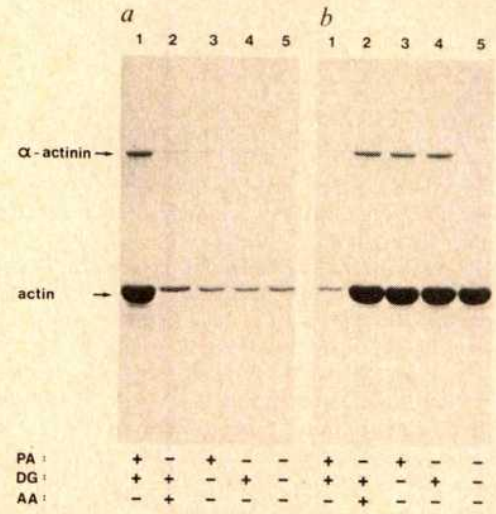

Fig. 1 SDS-polyacrylamide gel electrophoresis of α-actinin/ lipid complexes bound to filamentous actin. *a*, 10,000*g* pellets; *b*, 120,000*g* pellets. *a*, *b*, Lane 1, α-actinin and actin incubated with palmitic acid (PA) and diacylglycerol (DG); lane 2, with arachidonic acid (AA) and DG; lane 3, with fatty acid only; lane 4, with DG only; lane 5, actin incubated without lipids. *a*, Lane 1, >90% of the protein was in the 10,000*g* pellet; *b*, lane 1, <10% was in the 120,000*g* pellet. In all control experiments where the two specific lipids were absent the opposite result was observed, that is, <10% of the protein was in the 10,000*g* pellet and >90% in the 120,000*g* pellet.

Methods. 7 μg α-actinin (isolated from chicken gizzard) was preincubated with appropriate lipids for 45 min at room temperature. 55 μg G-actin (or F-actin) was then added and polymerization initiated by adding $MgCl_2$ (10 mM final concentration) and KCl (150 mM final concentration). After 30 min at room temperature, the samples were centrifuged for 5 min at 10,000 *g*. The 10,000*g* supernatants were removed and recentrifuged in a Beckman airfuge at 120,000*g*; <2% protein was left in this supernatant. Both pellets were washed and analysed on an 0.1% SDS/7.5% polyacrylamide gel[34].

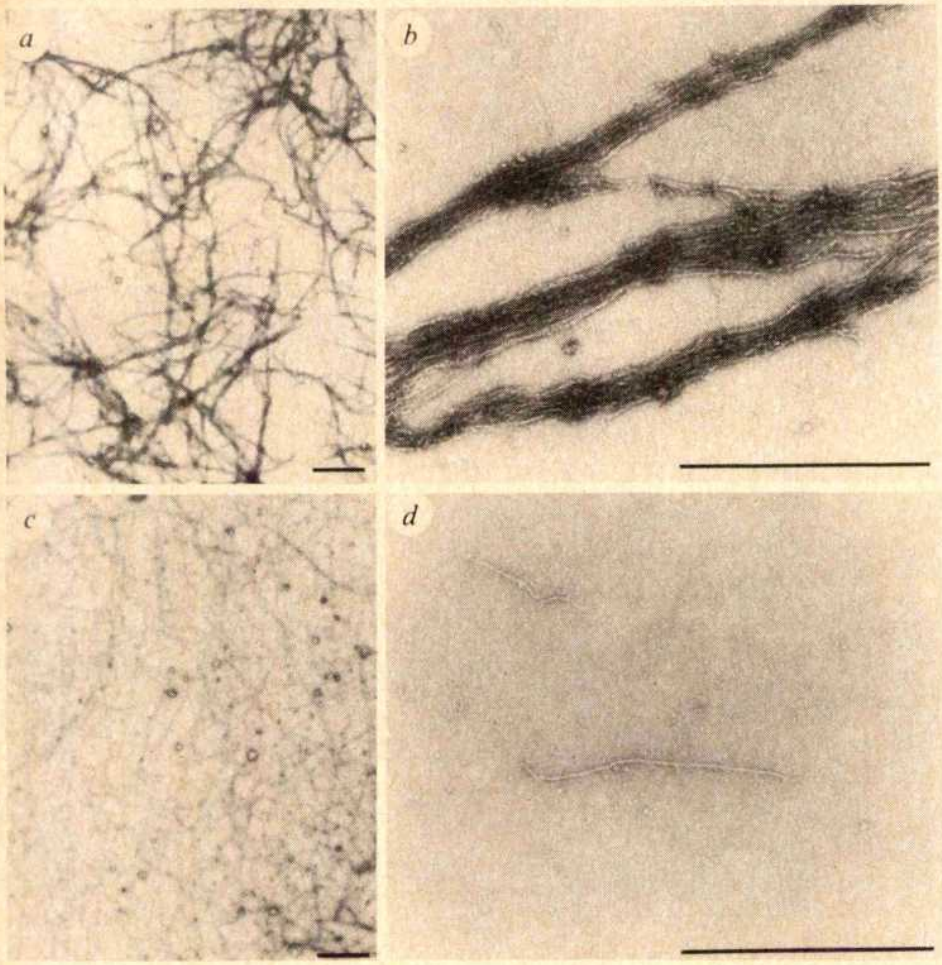

Fig. 2 Electron micrographs of negatively stained preparations of actin filaments *a*, *b*, with α-actinin, diacylglycerol and palmitic acid or *c*, *d*, with α-actinin alone. Scale bars, 0.5 μm.

Methods. Reaction mixtures containing actin, α-actinin, diacylglycerol and palmitic acid (*a*, *b*) or actin and α-actinin without lipids (*c*, *d*) were prepared and polymerized as described in Fig. 1 legend. Carbon-coated collodion grids were glow discharged and placed on a drop of particle suspension for adsorption. Samples *a* and *c* were diluted to 200 μg protein per ml immediately before being spread onto grids; samples *b* and *d* were centrifuged for 5 min at 10,000*g* as described in Fig. 1 legend. The 10,000*g* pellets were then washed twice with buffer before being spread onto grids. Adsorption of proteins was followed by post-treatment with the same buffer solution, rinsing with distilled water and staining with 2% uranyl acetate (*p*H 4.2). Specimens were examined in a Zeiss 109 electron microscope.

with thrombin[26], but the association of α-actinin with the cell membrane is less clearly understood. Some studies suggest that α-actinin is not in direct contact with the membrane[3,30,31], whereas other indicate that it is in close association with the cellular membranes of various nucleated cells[5,6] and the plasma membrane of platelets[26,32].

Recently, it has been shown that α-actinin forms a highly specific stoichiometric complex with two lipid components of the entire lipid extract of yeast cells[12]. These complexes always contain one molecule of diacylglycerol, one fatty acid of a certain type (for example, palmitic acid) and one α-actinin molecule. The need for these three components is absolute and has been demonstrated in monolayers lacking either of the two lipids[12].

Our results suggest that fatty acids, together with the diacylglycerol formed during thrombin activation of platelets, interact with α-actinin and may affect its location either in or at the plasma membrane, as well as its association with cytoskeletal actin filaments. Diacylglycerol may serve as a signal for the transmembrane control of protein phosphorylation via the activation of a novel protein kinase[21,22]. Similarly, diacylglycerol and fatty acids formed in the membrane during platelet activation may serve as a transmembrane signal for the redistribution of α-actinin in membrane regions of the cell and thereby the cytoskeleton.

A tight complex is formed between α-actinin, diacylglycerol and palmitic acid (but not between α-actinin diacylglycerol and arachidonic acid)[12]. Here we show, first, that this complex formation leads to large aggregates of α-actinin (from smooth muscle) and actin of the type observed in actin filament bundles, and second, that this complex is actually formed *in situ* during platelet activation.

The addition of α-actinin, diacylglycerol and palmitic acid to filamentous actin results in binding of the tri-component complex as well as aggregation of these actin/tri-component complexes. These large aggregates form a pellet when spun at 10,000*g* when the appropriate lipids, such as palmitic acid and 1,2-diolein, are present (Fig. 1, lane 1). Similar incubations of actin and α-actinin with other components (see Fig. 1) result in no such aggregation. This suggests that reorganization of the filamentous actin into larger complexes *in vitro* takes place only in the presence of the α-actinin/palmitic acid/diacylglycerol complex and is not just a general lipid effect. Similar results were obtained when the complex was first added to globular (G) actin followed by the induction of polymerization.

Electron micrographs (Fig. 2) confirmed these sedimentation results. A network of actin filament bundles was observed in the presence of diacylglycerol and palmitic acid (Fig. 2*a*)) whereas in the absence of lipids the network contained only single filaments (Fig. 2*c*). The 10,000*g* pellets of these preparations collected in the presence of lipids showed large actin filament bundles (10–40 filaments), whereas pellets formed in the absence of the appropriate lipids displayed an occasional single filament (Fig. 2*b*, *d*, respectively).

These results suggest that the formation of diacylglycerol and the appropriate fatty acid in membranes and their subsequent binding to a fraction of α-actinin affect the microfilaments in the cytoskeleton. To confirm whether such a complex is formed *in situ* and to demonstrate its biolgoical significance, we studied its formation in blood platelets.

Washed human platelets were labelled with ^{3}H-palmitic or ^{3}H-arachidonic acid, activated with thrombin and the cytoskeleton of resting and activated cells was isolated. The binding of lipid components to the cytoskeleton of activated platelets labelled with palmitic acid is six times higher than that of control platelets labelled with arachidonic acid. The relative binding of lipids to the cytoskeleton of activated palmitic acid labelled platelets is even more significant, considering the higher incorporation of arachidonic acid into resting platelets (74% of the total added, compared with 40% for palmitic acid), and also the higher incorporation of arachidonic acid into phospholipids

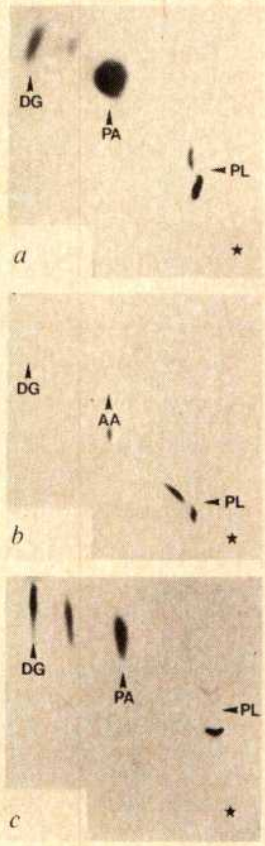

Fig. 3 Autoradiograms of lipids extracted from cytoskeletons or from immunoprecipitated α-actinin from cytoskeletons of thrombin-activated platelets analysed by two-dimensional TLC. *a*, Lipids extracted from cytoskeletons of ^{3}H-palmitic acid labelled and thrombin-activated platelets; *b*, lipids extracted from cytoskeletons of ^{3}H-arachidonic acid labelled and thrombin-activated platelets; *c*, lipids extracted from material immunoprecipitated by anti-α-actinin rabbit antiserum from dissolved cytoskeletons of ^{14}C-palmitic acid labelled and thrombin-activated platelets.

Methods. Platelets were prepared by a modified procedure of Schmidt and Rasmussen[27,33]. The washed platelets (3×10^{8} cells ml^{-1}) were incubated at 23 °C with ^{3}H-palmitic acid or ^{3}H-arachidonic acid (30 μCi ml^{-1}) in Ringer/citrate/dextrose buffer (RCD) (1.6 mM $CaCl_2$, 3.9 mM KCl, 107.8 mM NaCl, 0.5% glucose and 0.62% trisodium citrate, *p*H 7.4) for 2 h. The cells were centrifuged at 10,000*g* for 4 min and the pellet washed three times with RCD buffer. Cytoskeletons were isolated as described by Phillips *et al.*[28] and Rotman *et al.*[26]. Thrombin-activation was performed with 1 unit ml^{-1} (final concentration) at 37 °C. After 20 s, a solution containing Triton X-100 and EGTA was added to the platelet suspension until the concentrations of Triton X-100 and EGTA were 1% and 5 mM, respectively. The suspension was stirred for a further minute, kept on ice for 30 min, and then centrifuged for 4 min at 10,000*g*. The supernatants were removed and the pellets washed twice with RCD buffer containing 1% Triton X-100 and 5 mM EGTA and once with RCD buffer only. The lipids were extracted from the cytoskeletons or the immunoprecipitated α-actinin (as described in Fig. 4 legend) by the method of Bligh and Dyer[35] and separated by two-dimensional chromatography[12] on high performance TLC plates (Merck). The first dimension (upward) was in chloroform/methanol/H_2O (65:25:4). The second dimension (to the left) was in *n*-hexane/chloroform/methanol/diethylether (90:65:25:10). Radioactive profiles were obtained by exposing Kodak XS-5 X-ray film to the dried plates at −80 °C for 7 days (*a*, *b*) or 1 day (*c*). Similar results were obtained when the cytoskeletons were prepared without Triton X-100. Here, the platelets were sonicated and the pellet (1,000*g*) used for immunoprecipitation and lipid analysis. Arrowheads, phospholipids (PL), palmitic acid (PA), arachidonic acid (AA) and diacylglycerol (DG). Asterisk, origin of chromatography.

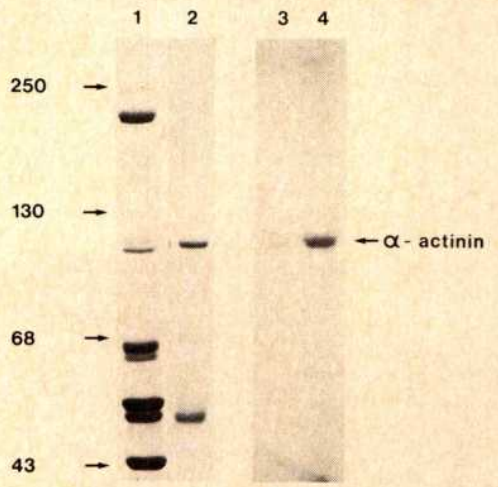

Fig. 4 Analysis of material immunoprecipitated by anti-α-actinin rabbit antiserum from cytoskeletons of thrombin-activated, ^{3}H-palmitic acid labelled platelets. (0.1% SDS/7.5% polyacrylamide gel electrophoresis). Lane 1, Coomassie brilliant blue staining of cytoskeletons (Triton X-100 residue) from thrombin-activated platelets. Lane 2, Coomassie brilliant blue staining of material immunoprecipitated by anti-α-actinin rabbit antiserum from cytoskeletons of thrombin-activated platelets. Lane 3, fluorogram of cytoskeletons (Triton X-100 residue) from ^{3}H-palmitic acid labelled and thrombin-activated platelets. Lane 4, fluorogram of material immunoprecipitated by anti-α-actinin rabbit antiserum from cytoskeletons of ^{3}H-palmitic acid labelled and thrombin-activated platelets. Numbers represent relative molecular mass, ×1,000.

Methods. Platelets and cytoskeletons were prepared as described in Fig. 3 legend. For immunoprecipitation, isolated cytoskeletons from ^{3}H-palmitic acid labelled platelets were dissolved in 1% SDS and then heated for 3 min at 95 °C. After dissociation in SDS, the sample was centrifuged for 4 min at 10,000*g*. The clear supernatant fraction was diluted with TNET-buffer (50 mM Tris-HCl, *p*H 7.4, 150 mM NaCl, 5 mM EDTA, 1% Triton X-100) to give final concentration of 0.1% SDS. The diluted suspension was pre-cleared with 100 μl of a 10% w/v suspension of glutaraldehyde-fixed *Staphylococcus aureus* cells for 45 min at room temperature. Then, 200 μl anti-α-actinin rabbit antiserum was added and the mixture gently shaken for 16 h at 4 °C. Immune complexes were adsorbed with a 10% w/v suspension of glutaraldehyde-fixed *S. aureus*[36] for 60 min at room temperature, washed, eluted and analysed[34]. For fluorography, the gel was soaked in 200 ml of 1 M sodium salicylate[37] for 20 min immediately after electrophoresis and exposed for 4 weeks. To minimize any loss of ^{3}H-palmitate label, SDS-polyacrylamide gels were not fixed and stained after electrophoresis[38].

for the same time interval (90% of the total uptake, compared with 3% for palmitic acid).

The relative increase of radioactive lipids in the cytoskeleton of activated platelets (labelled with ^{3}H-palmitic acid) compared with that of resting platelets was at least 30-fold, indicating that physiological activation leads to a sizeable and specific attachment of lipids to the cytoskeletal elements. The low binding of radioactive lipids to the cytoskeleton of resting platelets may result from a small population of activated platelets in the preparation.

Cytoskeletons from activated platelets pre-labelled by either ^{3}H (or ^{14}C) palmitic acid or ^{3}H-archidonic acid were isolated and the radioactively labelled lipids attached to the cytoskeletons analysed by high performance TLC (Fig. 3). Most of the radioactivity attached to the cytoskeleton of palmitic acid labelled platelets came from palmitic acid, diacylglycerol and phospholipids (Fig. 3*a*). The ratio of labelled palmitic acid to diacylglycerol was not 1:1, probably because some of the palmitic acid was attached to other cytoskeletal elements than α-actinin. In arachidonic acid labelled platelets, the radioactivity associated with the cytoskeleton was mainly in phospholipids, less in free diacylglycerol and practically none in free fatty acid (Fig. 3*b*). In this case, 90% of the total radioactivity

in the platelets were incorporated into phospholipids; however, the attachment of labelled lipids to the cytoskeleton was sixfold less than that of palmitic acid labelled platelets.

Further evidence that the lipids in the cytoskeleton are bound to α-actinin was obtained by the immunoprecipitation of α-actinin from solubilized cytoskeletons of ^{14}C-palmitic acid labelled cells by anti-α-actinin antibodies. Analysis of the lipids attached to this immunoprecipitate by two-dimensional high performance TLC shows that mainly diacylglycerol and palmitic acid are attached to the α-actinin (Fig. 3c), the ratio of these lipids being almost 1:1. Furthermore, this precipitate, when analysed by SDS-polyacrylamide gel electrophoresis and fluorography, shows a clear band of radioactivity in the position of α-actinin (Fig. 4). Gel filtration and chromatofocusing give further evidence of tight binding of radioactive lipid components to protein with relative molecular mass and isoelectric point values similar to α-actinin (data not shown).

Our results show that at least 30-fold more lipids (diacylglycerol and palmitic acid) are attached to the cytoskeleton during platelet activation and that diacylglycerol is associated tightly with α-actinin immunoprecipitated from cytoskeletons of activated platelets. Neither the molecular mechanism nor the significance of this process are yet understood. Thrombin, through interaction with its membrane receptor, may initiate the cleavage of phosphatidylinositol to diacylglycerol as well as of phospholipids to fatty acids via activation of phospholipases. The mechanism by which the phospholipases are activated is not yet known. If the appropriate fatty acid is available, a stable complex will be formed between it, diacylglycerol[16-19] and the α-actinin[12] that is already associated with the membrane[26], or may now be capable of association with the membrane. At the same time, the thrombin-induced activation leads to rapid actin polymerization and reorganization of the cytoskeleton[13,27]. Such a complex of diacylglycerol, fatty acid and α-actinin can increase the affinity and attachment of membrane-associated α-actinin with the cytoskeleton[26] and is therefore fundamental in the interaction between the cytoskeleton and the membrane. In addition, the interaction of α-actinin/lipid complexes among themselves, suggested by the monolayer complexes found[12], may initiate bundling of actin filaments in membranes. Provided that the appropriate lipids are available, a similar mechanism may be involved in restructuring microfilaments in the cytoplasm. As none of the components (diacylglycerol, fatty acids, α-actinin and actin) is unique to platelets but all are present in many other cell systems, this mechanism could be general in cytoskeleton/membrane interaction in cell-shape changes and migration.

We thank Erika Wenger-Marquardt for preparing the manuscript. This work was supported by grant 3.269.0.82 from the Swiss NSF and the Canton of Basel-Stadt.

Specific interaction between phosphatidylinositol 4,5-bisphosphate and profilactin

Ingrid Lassing & Uno Lindberg

Department of Zoological Cell Biology, The Wenner-Gren Institute, Stockholm University, Stockholm, Sweden

There is evidence that the polymerization of actin takes place at the plasma membrane[1], and that profilactin (profilin/actin complex), the unpolymerized form of actin found in extracts of many non-muscle cells, serves as the immediate precursor[2,3]. Both isolated profilin and profilactin interact with detergent when analysed by charge shift electrophoresis, indicating that they have amphipathic properties and may be able to interact directly with the plasma membrane[4]. We demonstrate here that isolated profilin, as well as the profilactin complex, interacts with anionic phospholipids. Phosphatidylinositol 4,5-bisphosphate (PtdIns(4,5)P_2) was found to be the most active phospholipid, causing a rapid and efficient dissociation of profilactin with a concomitant polymerization of the actin in appropriate conditions. These and other observations suggest the possibility of a relationship between the induction of actin filament formation and the increased activity in the phosphatidylinositol cycle seen as a result of ligand–receptor interactions in various systems.

Many eukaryotic cells have a dense weave of microfilaments (actin filaments plus associated proteins) in close association with the plasma membrane[5], apparently lying beneath the lipid bilayer all around the cell[6,7]. The dramatic changes in surface morphology and motile behaviour often seen in response to growth hormones and other cell stimulating agents seem to reflect changes in the organization and activity of this actin filament system[8], suggesting that regulated polymerization and crosslinking of actin and subsequent translocation (possibly myosin-linked) of filament assemblies formed are important steps in cell motility[6]. The detailed molecular mechanisms involved in these steps and their control, however, are unclear. Neither the site of polymerization of actin nor the nature of the transmembrane signal(s) inducing filament formation has been identified. The fact that actin polymerization occurs at the plasma membrane suggests that the precursor form of actin may be near, and possibly interacts with, the lipid bilayer. As profilin and profilactin behave like membrane proteins on charge shift electrophoresis[4], we have investigated the possibility that they interact directly with phospholipids using a viscosimetric assay that can detect effects on the stability of profilactin and on the kinetics and extent of actin polymerization.

Actin rapidly forms filaments when exposed to elevated salt concentrations (for example 50–100 mM KCl or millimolar concentrations of $MgCl_2$). However, mammalian profilin inhibits the polymerization of the homologous non-muscle actin (β- + γ-actin) quite efficiently in these conditions. Viscosimetric studies recently completed in our laboratory (H. Larsson, unpublished results) on the recombination of intact profilin and actin isolated from calf spleen[4] have shown that in 50 mM KCl, 0.1 mM $CaCl_2$, 0.5 mM ATP, 0.5 mM dithiothreitol (DTT) (25 °C), the dissoci-

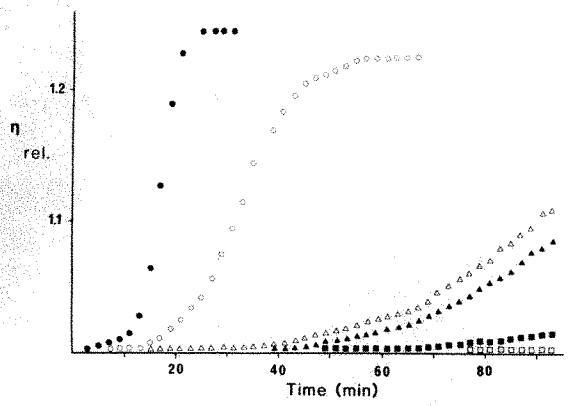

Fig. 1 Effect of various phospholipids on the stability of profilactin. Viscosity of profilactin was determined alone (□) and in the presence of PtdIns(4,5)P_2, bovine brain (●), PtdIns(4)P, bovine brain (○), PtdIns, pig liver (△), PhA, egg lecithin (▲) and PtdS, bovine (■) at various times of incubation. Phospholipid vesicles (100 μl, final concentration 0.4 mg ml^{-1}), prepared by sonication in G-buffer (5 mM potassium phosphate buffer *p*H 7.6, 0.1 mM $CaCl_2$, 0.5 mM ATP, 10 μM EDTA, 0.5 mM DTT) under nitrogen, were mixed with 429 μl of G-buffer, 8.4 μl of 1 mM EGTA, 14 μl of 4 M KCl (final concentration 80 mM) and 177 μl of profilactin-β in G-buffer (final concentration 0.4 mg ml^{-1}) in a Cannon-Manning viscometer at 35 °C (flow time 45 s). The viscosity of the incubation mixture was then measured at 2-min intervals for up to 2.5 h. In cases where polymerization had not occurred at the end of the incubation, the status of the actin was checked by adding $MgCl_2$ to 2 mM, which destabilizes profilactin. Filament formation then commences, with a lag phase of ~10 min (K_d of profilactin in 1 mM $MgCl_2$ is 4×10^{-7} M; H. Larsson, unpublished result). All phospholipids were purchased from Sigma except pig liver PtdIns, which was obtained from Serdary, London, Canada.

ation constant (K_d) of the complex is $\leq 4\times10^{-8}$ M, and that in 1:1 mixtures of the two proteins no filament formation occurs. These and previous studies on the behaviour of calf spleen profilactin[4,9,10] and on the kinetics of the polymerization of actin alone in various conditions formed the basis of our viscosimetric assay.

When profilactin-β (ref. 11) (0.4 mg ml^{-1}) was preincubated with phospholipid vesicles (0.8 mg ml^{-1}) for 15 min at low salt concentrations (5 mM potassium phosphate buffer *p*H 7.6, 0.5 mM ATP, 0.5 mM DTT) in the presence of 0.1 mM $CaCl_2$, then exposed to 80 mM KCl, all the anionic phospholipids tested destabilized the complex, causing variable amounts of the actin to polymerize. After preincubation with vesicles of phosphatidic acid (PhA) and PtdIns(4,5)P_2 the actin polymerized with a $t_{1/2}$ of 22 min. Phosphatidylserine (PtdS) was slightly less active, showing a $t_{1/2}$ of polymerization of 25 min, and PtdIns (soy bean) and phosphatidylglycerol (PtdG) were even less active ($t_{1/2}$ 35 and 37 min, respectively). The cationic phospholipids phosphatidylcholine (PtdC) and phosphatidylethanolamine (PtdE), and the diglyceride 1,2-diolein, on the other hand, were totally inactive in this respect. Very similar results were obtained with profilactin-γ prepared as described recently[11]. In controls with actin alone and with actin plus phosphatidylinositol bisphosphate (PtdInsP_2), the $t_{1/2}$ of polymerization was 21 and 17 min, respectively.

When profilactin was instead mixed with the phospholipid vesicles at an increased salt concentration, 80 mM KCl in the presence of 0.1 mM $CaCl_2$, 10 μM EDTA, 12 μM EGTA, 0.5 mM ATP, 0.5 mM DTT, 5 mM potassium phosphate buffer *p*H 7.6 (omitting the preincubation in low salt), both PtdIns(4,5)P_2 and phosphatidylinositol 4-monophosphate (PtdIns(4)P) exhibited high activities, with $t_{1/2}$ values of 16 and 35 min, respectively (Fig. 1), whereas PtdIns from pig liver and PhA gave respective $t_{1/2}$ values of 85 and 90 min; PtdS (and PtdIns from soy bean, not shown) was almost inactive ($t_{1/2}>$ 150 min). The finding that PtdIns(4,5)P_2 has no major effect on the polymerization of actin alone, and that the kinetics and extent of actin polymerization from profilactin in its presence

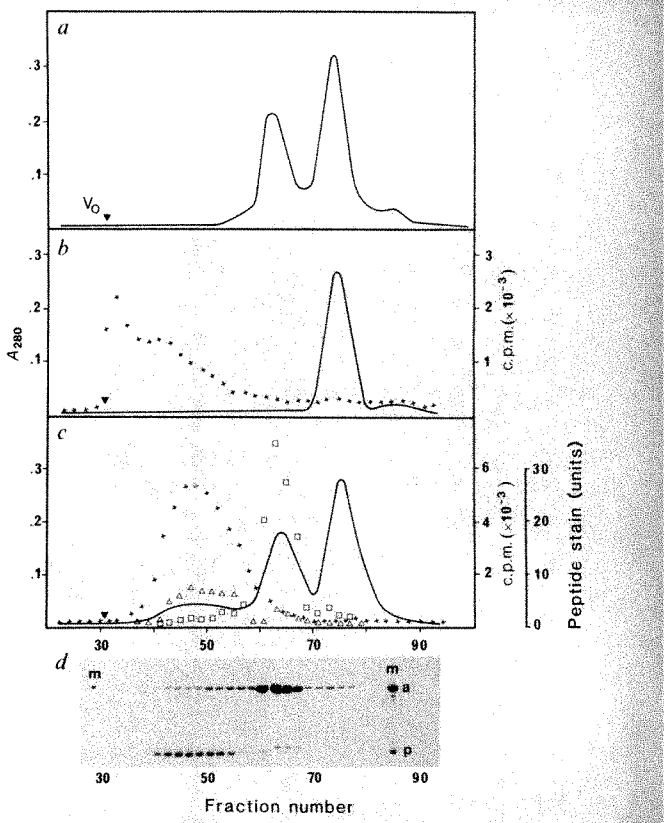

Fig. 2 The effect of PtdIns(4,5)P_2 on the chromatographic behaviour of profilactin. PtdIns(4,5)P_2 (0.8 mg; M_r 1,132)[13] was mixed with trace amounts of ^{14}C-labelled PtdIns in chloroform/methanol (4:1 and dried under vacuum. The phospholipids were then sonicated in 0.1 ml of G-buffer under nitrogen, immediately mixed with 0.4 ml of G-buffer containing 0.8 mg of profilactin-β and incubated for 10 min at room temperature, after which the incubation mixture was chromatographed at 4 °C on a column (1 × 56 cm) of Sephacryl 400 (Pharmacia) equilibrated with G-buffer (*c*). The fractions (0.5 ml per 2 min) were analysed for absorbane at 280 nm (—), radioactivity (×), profilin (△) and actin (□). To determine the relative amounts of profilin and actin, fractions of the chromatogram were analysed by electrophoresis on SDS-15% polyacrylamide gels[4] (*d*). The gels were scanned with an LKB 2202 Ultroscan after staining with Coomassie blue. Separate control runs of the same amounts of profilactin and PtdIn(4,5)P_2 are shown in *a* and *b*, respectively. In *d*, m represents marker profilactin, and a and p actin and profilin, respectively.

are closely similar to those of actin alone suggest that PtdIns(4,5)P_2 effectively eliminates the activity of profilin. (Preliminary experiments indicate that inositol trisphosphate has no effect on the stability of profilactin, but counteracts the effect of PtdIns(4,5)P_2. Furthermore, PtdIns(4,5)P_2 in mixed vesicles containing PtdIns(4,5)P_2, PtdC and PtdE in the proportions 10:45:45 is still highly active towards profilactin.)

Figure 2 illustrates the effect of PtdIns(4,5)P_2 on the chromatographic behaviour of profilactin at low salt concentrations and in the presence of 0.1 mM $CaCl_2$. In aqueous solutions, PtdIn(4,5)P_2 forms micelles of relative molecular mass (M_r) 93,000 (ref. 12). Chromatography on Sephacryl 400 alone produced low recovery of the phospholipid (20%). A large fraction of the eluted phospholipid appeared with the void volume (V_0), the rest being spread out over the first half of the chromatogram (Fig. 2*b*). When the PtdIns(4,5)P_2/profilactin mixture was analysed, however, a peak containing 50% of the phospholipid was eluted well behind the V_0. The absorbance profile obtained (Fig. 2*c*) had three major peaks, one coinciding with the phospholipid, one which was eluted at a position close to that of profilactin, and one which was eluted with the internal volume of the column. The last peak contained the ATP present in the incubation mixture. The distribution of profilin and actin over the chromatogram was determined by analysing selected fractions

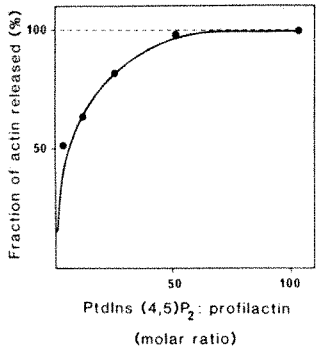

Fig. 3 Concentration dependence of the effect of PtdIns(4,5)P_2 on profilactin. Profilactin-β was mixed with PtdIns(4,5)P_2 at different molar ratios in the viscometer, and filament formation was followed as in Fig. 1. The fractions of the profilactin dissociated by the phospholipid were determined from the maximal viscosities reached, compared with that reached after addition of $MgCl_2$ (2 mM; see Fig. 1 legend).

by electrophoresis and scanning the gels (Fig. 2*d*). Gel scanning (Fig. 2*c*) indicated that the major part (88%) of the profilin co-chromatographed with the phospholipid and that 88% of the actin appeared as G-actin in the second peak. All the protein applied to the column was recovered. Thus, PtdIns(4,5)P_2 produced efficient dissociation of the profilactin complex, which apparently resulted from a relatively strong binding of profilin to the PtdIns(4,5)P_2 particles. The monomeric actin released, on the other hand, seemed unaffected by the phospholipid.

As PtdIns(4,5)P_2 clearly exerts its effect by binding to profilin, and as PtdIns(4,5)P_2 seems to have little effect on the polymerization of actin itself, it should be possible to estimate the stoichiometry of the PtdIns(4,5)P_2/profilin interaction indirectly by measuring the fraction of actin released using the viscosimetric assay at limiting amounts of PtdIns(4,5)P_2. For this, the fraction of actin released was determined by recording the maximum viscosity reached at varying concentrations of PtdIns(4,5)P_2. We found a direct relationship between the amount of PtdIns(4,5)P_2 added and the fraction of actin converted to filaments at low concentrations of phospholipid (Fig. 3), and from the initial part of the dose-response curve, calculated that dissociation of the protein complex required ~10 molecules of PtdIns(4,5)P_2 per molecule of profilactin. Considering the geometry of the PtdIns(4,5)P_2 micelles (spherical particles with a Stokes radius of 39 Å and a packing number of 82)[12] and of profilactin (Stokes radius 29 Å), this result indicates the possibility of a specific binding site for PtdIns(4,5)P_2 on profilin.

Clearly, binding of PtdIns(4,5)P_2 to profilactin causes the release of actin which is then available for polymerization in suitable conditions. Thus, the possibility should be considered that this phospholipid is involved in inducing actin filament formation in the cell. It has been realized for some time that ligand-induced turnover of phosphatidylinositol and mobilization of intracellular calcium may be causally related in many systems[13]. It was shown recently that a very early event following such receptor-mediated stimulation is the hydrolysis of PtdIns(4)P and PtdIns(4,5)P_2, resulting in the intracellular release of inositol 1,4-bisphosphate ($InsP_2$) and inositol 1,4,5-trisphosphate ($InsP_3$)[14-19]. The primary product, $InsP_3$, in turn seems to act as a second messenger for the induction of Ca^{2+} translocation[20-23]. Unstimulated cells contain a preponderance of PtdIns over the phosphorylated forms PtdIns(4)P and PtdIns(4,5)P_2, suggesting that the stimulated phosphorylation of PtdIns to PtdIns(4)P and PtdIns(4,5)P_2 through the action of membrane-associated kinase activities may be an equally early event (for review see ref. 24).

It is interesting that the increased activity in the phosphatidylinositol cycle induced by ligand-receptor interactions in turn seems to be closely correlated with an increased formation of microfilaments (polymerization of actin). Direct analysis of the G/F-actin ratio in cell extracts using the DNase I inhibition assay has shown that there is a rapid polymerization of actin following stimulation[25-30] of, for example, platelets with thrombin or ADP[25-27] and pancreatic β-cells with glucose[28-30]. In such cases, the ligand-receptor interaction has been shown to be linked to an increased turnover in the PtdIns cycle and Ca^{2+} mobilization[31-36]. Furthermore, ultrastructural studies suggest that one of the immediate events following stimulation of serum-starved glia-like cells and fibroblasts by platelet-derived growth factor (PDGF) and epidermal growth factor (EGF) is the polymerization of actin, causing an outgrowth of new membrane lamellae and microspikes[8]; this phase is followed by increased cell motility. Both PDGF and EGF cause increased PtdIns turnover[37,38]. Finally, similar morphological changes, although less well characterized, have been observed after activation of *src* gene in cells transformed by a temperature-sensitive mutant of Rous sarcoma virus[39]; it is now known that the *src* gene product can phosphorylate PtdIns(4)P to PtdIns(4,5)P_2, suggesting its involvement in the PtdIns cycle[40].

The results presented here provide biochemical evidence for a specific effect of PtdIns(4,5)P_2 on the putative precursor of microfilaments, profilactin. This may indicate that the formation of microfilaments and thus cell motility is regulated through the PtdIns cycle.

We thank Thomas Hult and Janusz Garbalinsky for technical assistance. This work was supported by a grant from the Swedish Cancer Society.

IMPOSSIBLE ANTIBODIES?

DESIGN OSCAR REUTERSVÄRD

Yes, impossible antibodies are for sale, antibodies that do not measure up to your requirements.

As scientists ourselves, we have suffered the agonies caused by such non-specific, impure, low-titer antibodies and therefore we decided to do something about it.

The result is MIAB—a new company on the antibody market — but with vast experience in high quality antibody production. So, now our know-how and experience can help you in your research as well. And nobody has ever regretted quality. A quality so superior that competitors will try to copy us.

Not only do we aim at supplying you with the best antibodies available. We also want to stimulate and enrich your environment by making available to you this fascinating picture of the impossible antibody in "perspective Japonaise".

Fill in the coupon and we will send you more information.

Sometimes things only seem impossible!

MIAB ANTIBODIES
THE TRACER QUALITY ANTIBODIES
FOR THE DEMANDING SCIENTIST.

miab

MIAB, BOX 97, S-741 00 KNIVSTA, UPPSALA, SWEDEN

Yes, please send me more information about the new, exciting MIAB ANTIBODIES of tracer quality.

PRINCIPLES AND PRACTICE OF INFECTIOUS DISEASES, 2nd Edition

edited by **G.L. Mandell,** *Division of Infectious Diseases, University of Virginia School of Medicine,*
R.G. Douglas, *Department of Medicine, Cornell University Medical College, New York and*
J.E. Bennett, *Laboratory of Clinical Investigation, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland*

Following on from the first edition of *Principles and Practice of Infectious Diseases*, which quickly became established as the "gold standard" of textbooks in infectious diseases, it is appropriate, after 5 years, that a completely revised and expanded new edition be published because of the rapid changes in the field of infectious diseases. The basic organization of the book remains unchanged, but this new edition has been converted from a two-volume to a one-volume format, containing more words and illustrations, therefore, making it more convenient to use.

Contents: PART I: BASIC PRINCIPLES IN THE DIAGNOSIS AND MANAGEMENT OF INFECTIOUS DISEASES: Microbial Virulence Factors; Host Defense Mechanisms; Epidemiology of Infectious Disease; The Clinician and the Microbiology Laboratory; Anti-Infective Therapy; PART II: MAJOR CLINICAL SYNDROMES: Fever, Upper Respiratory Infections; Pleuropulmonary and Bronchial Infections; Cardiovascular Infections; Central Nervous System Infections; Skin and Soft Tissue Infections; Infections Related to Trauma; Gastrointestinal Infections and Food Poisoning; Bone and Joint Infections; Diseases of the Reproductive Organs and Sexually Transmitted Diseases; Eye Infections; Hepatitis; PART III: INFECTIOUS DISEASES AND THEIR ETIOLOGIC AGENTS: Viral Diseases; Chlamydial Diseases; Mycoplasma Diseases; Rickettsiosis; Bacterial Diseases; Mycoses; Protozoal Diseases; Diseases Due to Helminths; Ectoparasites; Diseases of Unknown Etiology; PART IV: SPECIAL PROBLEMS: Nosocomial Infections; Infections in Special Hosts; Index.

HUMAN ANTIPARASITIC DRUGS:
Pharmacology and Usage

by **D.M. James** and **H.M. Gilles,** *Liverpool School of Tropical Medicine, Liverpool University*

Deals with the pharmacology of the drugs used clinically to cure and control those human diseases which are the outcome of parasitic invasion. Drugs are an integral factor in the study of parasitic disease, whether they are used for their curative effects or as tools to reveal the nature of the disease processes. A knowledge of their fundamental properties in this context is therefore essential for all embarking on studies of tropical and parasitic disease.

CONTROLLED DRUG BIOAVAILABILITY:
Volume 3: Bioavailability Control by Drug Delivery System Design

edited by **V.F. Smolen,** *PharmaControl Corporation,* and **L.A. Ball,** *University of Pittsburgh*

Series: Controlled Drug Bioavailability, Volume 3

Contents: Oral Drug Bioavailability; Variations, Limitations, and Control; Therapeutic Systems; The ALZA Concept; Automatic, Feedback Controlled, Drug Delivery Devices; Percutaneous Absorption; Bioavailability Properties of Osmotically Controlled Drug Delivery Systems; The Control of Drug Bioavailability from Ophthalmic Dosage Forms; Bioavailability of Macromolecular Drugs and Its Control; Molecular Entrapment and Release Properties of Drugs by Cyclodextrins; Index.

0471882011 454pp March'85 £102.75

THE ORGANIC CHEMISTRY OF DRUG SYNTHESIS, VOLUME 3

by **D. Lednicer,** *Mead Johnson and Company, Evansville, Indiana* and **L.A. Mitscher,** *The University of Kansas School of Pharmacy*

A single volume guide to virtually all syntheses used in the preparation of compounds given generic Names. This continuation of the successful earlier volumes covers the literature from 1976 through 1981.

Series: The Organic Chemistry of Drug Synthesis, Volume 3

0471092509 302pp March'85 £37.95

COENZYME Q:
Biochemistry, Bioenergetics and Clinical Applications of Ubiquinone

edited by **G. Lenaz,** *University of Bologna*

It is becoming increasingly apparent that Coenzyme Q (Ubiquinone) is a major component of the electron transfer chains within aerobic micro-organisms, photo-synthetic micro-organisms and mitochondria of eukaryotes.
This exhaustive, inter-disciplinary study presents our current knowledge of Ubiquinone's chemical and physical properties, its metabolism, its function in different organisms and its exciting possible applications in human medicine.

0471102865 528pp March'85 £53.00

PULMONARY AND ANTIALLERGIC DRUGS

edited by **J.P. Devlin,** *Boehringer Ingelheim Ltd, Ridgefield, Connecticut*

Outlines the current state-of-the-art in the development of pulmonary and antiallergic drugs and discusses practical applications. It reviews the advances made in our understanding of the pathophysiology and biochemical mechanisms of asthma and allergic rhinitis over the past 15 years. The book critically evaluates the *in vivo* pharmacological models of allergy, the significance of species variation, and the potentials they hold for future development.

Series: Chemistry and Pharmacology of Drugs, Volume 4

0471873950 400pp March'85 £90.70

BIOLOGICAL MACROMOLECULES AND ASSEMBLIES, VOLUME TWO:
Nucleic Acids and Interactive Proteins

edited by **F.A. Jurnak** and **A. McPherson,** *University of California, Riverside*

Comprehensively surveys the most current studies relating to the structural aspects of nucleic acids, and the proteins that interact with and regulate their function. The research is no more than two years old with much of it never before published. It will provide a firm basis for the design and evaluation of new experiments probing the properties of nucleic acid molecules. Projects potential future progress.

The duplex brain

John C. Marshall

Cerebral Dominance: The Biological Foundations.
Edited by Norman Geschwind and Albert M. Galaburda.
Harvard University Press: 1984. Pp.232. $27.50, £27.50.

CEREBRAL dominance, the specialization of the left and right sides of the brain for different functions, was *almost* discovered some two millennia ago. The physicians who compiled the Hippocratic Corpus observed that injury to one side of the head was frequently associated with paralysis of the opposite side of the body; they further noted that loss of language was usually associated with *right* hemiparesis. For us, the conclusion that the left hemisphere is dominant for language processing seems inescapable. Yet neither the Greek doctors nor the many later European neurologists who made similar observations did draw this conclusion. It was not until the 1860s that Paul Broca convinced the scientific community that "On parle avec l'hemisphère gauche". From La Salpetrière in Paris, Broca reported a series of autopsied cases of aphasia with relatively focal left-hemisphere lesions and argued that the dominance of the left half of the brain was expressed in its control of both language and handedness.

Two questions therefore arose. How are the brains of left-handed people organized? And what does the right (non-dominant) hemisphere do? Broca thought that the left-handed brain was simply the mirror image of the "normal" brain. We now know that this is not the case; most left-handers have left hemisphere dominance for language. Many nineteenth-century neurologists also seem to have believed that the right hemisphere of right-handers was merely a spare, functionless entity that only came into use by "taking over" the functions of the left, should that hemisphere be damaged. This claim likewise proved false when, in 1876, the English neurologist John Hughlings Jackson showed that the right hemisphere played the leading role in "visual ideation". Thus arose the modern notion of "complementary specialization".

Over the succeeding century a vast body of work has correlated particular functional deficits with damage to more or less precisely defined regions of the brain. Yet the question of *why*, for example, the left hemisphere is (usually) dominant for language was seldom broached. In the past 15 years, however, a small group of investigators has mounted a vigorous effort to discover the biological foundations of complementary specialization in the duplex brain. The volume under review presents a somewhat manic survey of this work, a survey in which eagerness sometimes outstrips the data, loose ends dangle precariously and counter-evidence quietly disappears. Yet if even half the ideas expressed are true, our understanding of cerebral dominance will have deepened very considerably. And if some of them can be translated into clinical practice the prospects for recovery from disabling brain damage will be immeasurably improved.

First, then, some facts. It is now beyond dispute that many adult human brains show gross anatomical asymmetries that

Wellcome Institute

The brain exposed — wood cut from De Humani Corporis Fabrica *by A. Vesalius (1543).*

reflect the size of specialized cytoarchitectonic areas (discussed in the book by Geschwind and Galaburda); some of these asymmetries can be observed *in vivo* by radiological techniques, some are present in infants and fetuses, and some have even left their mark in the fossil record as far back as Peking man (LeMay). More subtle asymmetries, the differential branching of dendritic trees, for example, may also exist (Scheibel). Many lateral asymmetries in the concentration of neurotransmitters and in susceptibility to pharmacological agents are likewise coming to light (Galaburda).

Do these asymmetries have any functional significance or are they simply random variation? That the typical direction of the asymmetry often corresponds with known behavioural specialization certainly predisposes one to the former view. Thus lesions to the left planum temporale are a common cause of Wernicke's aphasia, and this area is usually larger on the left. Direct evidence would, however, be more convincing. Sometimes that evidence is positive: Ratcliff *et al.* (*Brain and Language* **11**, 87-98; 1980) found lateral asymmetries of the posterior Sylvian branches of the middle cerebral artery that predicted language dominance as assessed by successive pharmacological inactivation of each hemisphere. Sometimes it is not: Henderson *et al.* (*Neurology* **34**, 1,086-1,089; 1984) failed to find a correlation between anatomical asymmetries of the language areas (as assessed by computed X-ray tomography) and known language dominance in two groups of patients who had, respectively, sustained aphasia after left-brain damage (the typical case) and after right-brain damage (the atypical case).

In one sense, current research suffers from an *embarras de richesses*. As more and more physical asymmetries are uncovered, the task of discovering which of them have genuine psychological significance becomes progressively harder. This issue is inadvertently highlighted in chapters by Kemper and by Duffy, MacAnulty and Schachter. Kemper and Galaburda have found multiple congenital lesions in the brains of patients with developmental dyslexia; Duffy *et al.* have found widespread electrophysiological abnormalities in the same population. The latter authors are thus led to propose that "Dyslexia pure may represent dysfunction within the entire widely distributed brain system devoted to language processing". But if this is so, we are left with the mystery of why the behavioural deficits are so specific to reading and spelling.

Animal models of cerebral dominance would no doubt help distinguish causal from merely correlational phenomena: controlled experiments with animals can supplement the study of fortuitous lesions in man. Although animals do not talk (with either hemisphere), convincing evidence of both functional and physical asymmetries is now accumulating in many non-human species.

In the rat, for example, not only are there hemispheric differences in cortical thickness (Diamond), but there is also lateralization of neuroendocrine control of grooming (Gerendai); lateralization of circling behaviour consequent upon differences in dopamine concentration in the two striata (Glick and Shapiro); and lateralization of the mechanisms involved in spatial choice, taste aversion and muricide (Denneberg). Denneberg's chapter is outstanding for the clarity with which it outlines how simple models of the logic of activation and inhibition within and between the hemispheres can be used to interpret the results of lesion experiments.

One area where animal models will play an important role concerns the effects of testosterone on the developing brain. Geschwind and Behan argue that excess

testosterone slows the rate of growth of the left hemisphere and suppresses the development of the thymus gland. They thereby attempt a unified explanation of the apparent over-representation of males and left-handers who present with developmental learning disorders and certain auto-immune diseases. This left hemisphere retardation may alter the brain's pattern of connectivity as competition for synaptic space takes place in the developing cortical plate, a process for which Goldman-Rakic and Rakic have provided an elegant experimental analysis in monkey. Nonetheless, one would like to see Geschwind and Behan's epidemiological observations replicated by independent investigators. In the past, left-handers have proved a notoriously unreliable group with respect to almost any measure of neuropsychological functioning one can think of. Curiously, Geschwind and Behan fail to mention the traditional story that left-handers are, on average, poor at visuo-spatial skills, for which right-hemisphere pathology would be implicated; they also ignore Kimura's recent evidence (*Human Neurobiology* **2**, 147-154; 1983) that left-handers, as a group, are just as left-dominant for speech representation as right-handers.

The best animal analogue of human vocal learning is to be found in bird-song. Song learning in canaries is, like human speech, "a left-sided affair" (Nottebohm). Lesion of the left hypoglossus nerve, which controls the left half of the syrinx, has a far more deleterious effect upon singing than does lesion of the right. More surprisingly, seasonal variation in the pattern of song appears to be determined by the growth of *new* neurones and synapses. Although there is currently no evidence for such synapto- and neuro-genesis in the adult human brain, Nottebohm speculates that:

> In the not-so-distant future it may be possible to treat local regions of the brain to activate genes that induce dendritic retraction and growth, that induce synaptic formation and shedding, that induce birth, migration, and differentiation of new neurons.

At present, Nottebohm's "hope for a new neurology" is science-fiction although the advances of the past decade do raise the serious possibility that the diagnosis of "irreversible" brain damage will eventually give way to a less horrendous prognosis. Such success would be a fitting tribute to Professor Geschwind, who died at a tragically early age last year. The emerging synthesis that this book displays can in large part be credited to the enthusiasm, dedication and insight with which Norman Geschwind always insisted that cerebral dominance does have demonstrable biological foundations. □

John C. Marshall is in the Neuropsychology Unit, part of the Neuroscience Group at the Radcliffe Infirmary, Oxford.

All keyed up in the laboratory

E.G. Richards

Computers in Biology: An Introduction.
By Robert Ransom and Raymond J. Matela.
Open University Press, Milton Keynes/ Taylor & Francis, Philadelphia: 1985. Pp.150. £9.95, $19.
Microcomputers in Biology: A Practical Approach.
Edited by C.R. Ireland and S.P. Long.
IRL: 1984. Pp.324. Pbk £15, $27.
Mathematics, Biology and Microcomputers.
By A.N. Barrett.
Elsevier-Biosoft: 1984. Pp.102. £24, $36.

THE day has not quite arrived when a biologist, unaccustomed to computers, can use one as he might use a centrifuge. He must go through the laborious and daunting process of coming to terms with whatever computer is available to him, its jargon, its hardware and its capabilities, its operating system and more besides. Having done that he then must either set about learning its language and write a program for the task he has in mind (and in the process more than likely reinvent the wheel) or, if he is lucky, use software written by somebody else.

Even then he is likely to encounter many pitfalls: the program may require modification before it will run on his computer (even if it is written in a language familiar to his machine); the documentation may be inadequate or even absent; it may lack robustness and die on him with an obscure error message as a result of a mis-key after he has been entering data for the last hour; he may be lulled into a false sense of security by a program which presents him with the unadorned slope of a straight line fitted to data points which are scattered at random.

Help in coming to terms with all this is provided by Ransom and Matela in *Computers in Biology*, a short but comprehensible account of some aspects of computer science. The book first explains how computers might be useful and what is involved in using them. It goes on to introduce data structures, lists and trees and the like, and then to discuss statistical analyses using computers, computer graphics, interfacing experimental apparatus with computers and finally the simulation of models for biological processes. One appendix is used to describe briefly computer hardware as we know it today, and discuss how to choose a computer (including a section on how to deal with computer salespeople), while another introduces operating systems and the facilities they might offer. A useful glossary is also provided.

In a book of such generality, no program listings are included but the text is illustrated with many examples of how computers might be applied in various branches of biology. Even if it does not cover your pet subject, it may give you seminal ideas.

Not every research worker has access to a mainframe or a mini, and may have to contemplate choosing a microcomputer. Assistance in this confusing task is at hand in *Microcomputers in Biology*, a multi-authored work edited by Ireland and Long. The first chapter goes some way to explain some of the jargon, also offering advice on choosing a microcomputer, and the book continues with chapters on the mysteries of interfaces, the problems involved in data-logging and the possibilities inherent in computer graphics. These are useful epitomes for workers with some experience in computing but may present problems to the complete beginner. The book includes summaries of some ways in which microcomputers can be used to control apparatus or analyse data obtained from several analytical techniques: spectrophotometry, chromatography and ultracentrifugation, among them. It ends with a chapter on controlling environmental factors. There is also a chapter on doing various things with nucleic acid sequences, which, it should be noted, does not attempt to come to terms with using sequence databases (such as is available from EMBL) with microcomputers.

The book should appeal to biologists who use such techniques and have some flair for instrumentation, and who are contemplating using a microcomputer. Most chapters end with listings of programs, usually in BASIC, which run on the author's microcomputer (discs containing versions of these programs are also to be available for four popular microcomputers). It is unclear how easy these will be to use, how robust they are or to what extent they protect the user from drawing false conclusions.

Barrett's *Mathematics, Biology and Microcomputers* also provides listings of simple programs (for instance to solve quadratic equations, though many of them would be better tackled on a hand calculator) but most of his book is taken up with an introduction to BASIC, solving quadratic and cubic equations (but stopping short of iterative methods for solving general equations), matrices, coordinate geometry, curve fitting, simple mensuration and so on. It is essentially an introduction to certain parts of mathematics and as such reflects, as do the biological examples, what are presumably the author's interests. It ends with a somewhat mysterious section on the manipulation of biological data by prime numbers. Unfortunately the reference to further details of this is still in press. □

Making good

Alan R. Lehmann

DNA Repair.
By Errol C. Friedberg.
W.H. Freeman: 1985. Pp.614. $39.95, £28.95.

WORK on oncogenes over the past three years has shown conclusively that a crucial step in the conversion of a normal cell to a cancer cell involves a specific alteration in the cellular DNA, whether this be a single base change or a chromosome rearrangement. In many (if not all) cancers, the initiating event is known to be the interaction of a carcinogenic agent with cellular DNA to produce some form of alteration or damage to the DNA. All cells have evolved a complex series of enzymatic repair pathways to protect themselves from the potentially devastating effects of such damage. The importance of these pathways is shown in a number of human genetic disorders (of which xeroderma pigmentosum is the best known example), in which a molecular defect in a DNA repair pathway may lead not only to an increased frequency of carcinogenesis, but also to disorders in the neurological, immune and vascular systems.

DNA Repair provides a comprehensive, detailed and up-to-date description of current knowledge of this subject. The format is similar to *DNA Replication* by Arthur Kornberg, and like that book Friedberg's account is likely to become a classic treatise for postgraduates and research workers.

The subject is covered in a logical manner, starting with the different types of damage produced in DNA by various carcinogens, and simple enzymatic reversal mechanisms. Early events in excision repair are covered with the emphasis on detailed enzymatic mechanisms. Following chapters deal with later steps in excision repair, and with the tolerance mechanisms whereby cells are able to cope with damage which is not removed from their DNA. In each section the relatively well characterized mechanisms elucidated in bacteria are described first, followed by the inevitably more poorly understood processes in eukaryotes. The discussions of the complicated and controversial topics dealt with in the later part of the book are clear and balanced, Friedberg taking especial care to distinguish between fact and speculation.

My only criticism of the book concerns a part of Chapter 1. Here the reader is thrown headlong into some rather subtle points to do with errors in DNA replication with insufficient introduction and definition of terms, and the section would have been better placed in a later chapter. This, however, is merely a niggle. One of the many virtues of *DNA Repair* is the depth and breadth of the literature citations, each of the nine chapters being accompanied by about 200 references; I was unable to find a single important reference which had been omitted. The diagrams are clear and uncluttered, the index is comprehensive and altogether it is difficult to see how the book could have been improved. □

A. Rupert Hall

The Classics of Science: A Study of Twelve Enduring Scientific Works.
By Derek Gjertsen.
Lilian Barber Press, New York and Gravesend: 1984. Pp.374. Hbk $24.95, £20; pbk $15.95, £12.95.

WHAT is a scientific classic? We may all recognize the type without agreeing upon the supreme examples of it; a classic is on a pedestal. No matter that it is rarely read, and never for pleasure, it is universally admired.

Most with any claim to an opinion would include among the great scientific writers Aristotle and Archimedes (both omitted from this selection), Harvey, Newton, Darwin . . . but there comes a point when the selection of Dalton to the exclusion of Lavoisier (as in the present volume) becomes a mere matter of taste. One could certainly publish a volume parallel to Mr Gjertsen's where a different selection would possess equal scientific merit and include areas (for example cytology and particle physics) completely neglected by him. Perhaps it is natural that a British author and an American publisher should combine to display five out of twelve scientific classics written by Englishmen; indeed, after Galileo all the "classic" scientists are English with the unique exception of Linnaeus!

The conception of a "classic", therefore, if restricted to twelve or twenty or even a hundred seems devoid of precise meaning. To say that is not to judge Mr Gjertsen's treatment of twelve familiar works from the *Corpus Hippocraticum* to the *Origin of Species* as without value or interest. He has done his work well and each short study is a useful introduction to a specialist literature as well as a review of modern interpretations and critical assessments. Not everyone knows that Lyell published roughly a volume for each year of his writing life, or that the *Origin* has been translated into Latvian (besides 28 other languages). Some "classics" are better and more elaborately treated than others: the last two of them — hardly poles apart in any sense — Lyell's *Principles* and Darwin's *Origin* together rate 66 pages; the first two (Hippocrates and Euclid) 59. There are a number of small factual slips for detection by the knowledgeable, and some questionable judgements: to hold that the Hippocratic corpus is "arguably the oldest western scientific text" is very much a matter of definition, for example. But preponderantly the book conveys sound information and sensible opinions about what are, by any standards, works of outstanding importance in the history of

Classic beginning — the title page of Newton's Principia.

science. The format is fairly regularly maintained: author's career, context of the book, its content, its reception and its publishing history.

One might describe these twelve vignettes as basic history, and recognize that taken together they give an odd and partial view of the development of science. Presumably it was not the author's intention that a reader should form such a distorted synoptic view by reading steadily through from page 1 to page 357, but rather that he would read particular sections according to his interests and needs. Treated as a mini-encyclopaedia this is a very useful book, capable of stimulating as well as informing. But there are of course other worlds in the history of science to which this method of approach and this choice of examples give no entrance: the danger of Mr Gjertsen's book might be in concealing the existence of such worlds and the merit of exploring them. Again, he probably did not intend to use the Kuhnian language of "scientific revolutions" to recommend a "great men" account of history since his short studies often draw attention to the force of parallelism and convergence (Darwin–Wallace, for example). But in the last resort the continuity of the past — continuity so obvious to us in our own present — is its feature that most resists historical reconstruction, and cannot be promoted by a Horner-like picking out of the plums, even dried plums.

A. Rupert Hall is Emeritus Professor of the History of Science, Imperial College, University of London.

How do enzymes work?

M.I. Page

The Bioorganic Chemistry of Enzymatic Catalysis.
By Myron L. Bender, Raymond J. Bergeron and Makoto Komiyama.
Wiley: 1984. Pp.312. £50.05, $39.50.

IT IS fashionable to justify the publication of work on some aspects of chemistry by invoking its relevance to the phenomena of life. Often this is unnecessary, because the chemistry is of interest in its own right (while sometimes the claim is exaggerated). In particular the no-man's-land between traditional disciplines is always exciting because this is where fresh understanding often emerges. The pioneering research of Myron Bender is a case in point; Bender helped to bridge the gap between chemistry and biochemistry and to define a new borderline area. Today the application of the techniques and phraseology of physical organic chemistry to enzyme catalysis is accepted practice and owes much to his work.

Our response to fundamental questions of life is usually to resort to models we think we understand. By definition, the model is a simpler system and only reflects a small part of the observed behaviour of the living system. Ill-defined separation of causes and effects *in vivo* may lead to only partial answers.

The fullness of an answer is of course determined by the question — in this case, how do enzymes work? In their book, Bender, Bergeron and Komiyama have aimed to show how an understanding of organic reaction mechanisms is relevant to an understanding of how enzymes work. They accept and propagate the view that the mechanisms — that is, the routes of bond making and breaking processes — of reactions are similar in non-enzyme and in enzyme-catalysed reactions. This is almost certainly correct. However, the number of amino acid residues of the enzyme directly involved in bond making and breaking is only a tiny percentage of the total number in the whole enzyme. What is the function of the rest of the enzyme's structure? Why can't the one or two amino acid residues involved in the "mechanism" catalyse the reaction as free amino acids? Besides enhancing the rate of reactions, enzymes are generally very discriminative in their choice of substrates. Why can't an enzyme catalyse the reaction of a compound which contains the necessary reactive function but is smaller than the normal substrate? Questions such as these are not addressed in the book.

It is not obvious that three authors have been involved in the writing, and the style throughout is uniform. This is an authoritatively written and well illustrated account of physical organic chemistry which should be useful to advanced undergraduate and graduate students wanting an understanding of the mechanism of reactions and an answer to why and how catalysis occurs. It is at its best when simple chemical reactions are discussed, but sadly fails to hint at the unsolved or controversial aspects of enzymatic catalysis. □

Viruses in disease

Clive Sweet

Concepts in Viral Pathogenesis.
Edited by Abner Louis Notkins and Michael B.A. Oldstone.
Springer-Verlag: 1984. Pp.409. $34.40, DM 94.
Viral Pathogenesis and Immunology.
By Cedric A. Mims and David O. White.
Blackwell Scientific: 1984. Pp.398. Pbk £14.80, $26.

UNTIL recently, most virologists have shied away from studies of pathogenesis, regarding them as too difficult, less interesting or less satisfactory than the more molecular aspects of virology. Much attention has been given to the structure and biochemistry of viruses, and mechanisms of replication in cell culture, but virus pathogenicity — that is, the ways in which they produce disease — has been relatively neglected. This emphasis is changing and there is now a keen interest in the mechanisms of disease production, possibly originating from a clearer understanding of host defence mechanisms but given impetus by the merging of interests of molecular virologists and those more concerned with the causation of disease. Pioneering work with segmented RNA viruses (reoviruses and orthomyxoviruses) has led to identification of virus genes and their products and has resulted in a better understanding of virus virulence at the genetic and molecular level. The new area of recombinant DNA technology has allowed these approaches to be extended to non-segmented RNA (polio) as well as DNA (herpes simplex, pseudorabies) viruses.

While studies on virus pathogenicity hold great promise, they demand a breadth of understanding across many specialized areas. Knowledge of virus structure, genetics and replication, together with broader aspects of cell and host biology, is required for a full appreciation of the subject. Consequently, the writing of a textbook on the subject is a daunting task. The two books reviewed here have tackled this problem in different ways.

The editors of *Concepts in Viral Pathogenesis* have chosen the multiauthor approach. No fewer than 75 authors have contributed a total of 53 articles under the headings of "Host Control of Viral Spread", "Host Range and Tissue Tropism", "Virus Maturation and Diversity", "Virus Persistence", "Virus-interaction with the Immune System", "Evolving Concepts in Viral Pathogenesis" and finally "Control of Viral Disease". The book is intended to be a series of mini-reviews and editorials, 1,000–2,000 words in length, each a "pithy distillation of the state-of-the-art".

Sadly, the book does not attain these objectives. Although all of the articles contain much information they often amount only to thumbnail sketches and are too short to be really useful. However, they are generally well referenced (with one notable exception where no references are given), allowing easy access to more detailed information. Inevitably, there is some duplication between chapters, (fortunately never contradictory), and some areas are ignored. For example, there is no chapter on virus-dependent damage (cytotoxicity) and the impression gained from reading the book is that viruses do not in themselves cause disease, this being almost entirely due to aberrations in host responses. A consideration in relevant chapters of how viruses avoid, counteract or fail to induce host responses would also have been useful. Nevertheless, the book is a helpful source of reference and concepts. Typographical errors are few but the occasional use of abbreviations without definition is annoying.

In contrast Mims and White have produced an excellent text with just two contributors. Their book is packed full of information in an easily digestible, interesting and entertaining style. It covers in considerable detail the various aspects of virus pathogenesis — basic characteristics of viruses, infection and spread of viruses through the body, the immune response to viral infection, mechanisms of disease production, determinants of viral virulence and host resistance, persistent infections and finally immunization against virus diseases — from the point of view of both the host and the pathogen.

The book is especially strong in its treatment of the immune response. Indeed, the depth of coverage of all topics makes it suitable not only for medical and science undergraduates and postgraduates but also for scientists in, or moving into, viral pathogenesis research, for whom the up-to-date and extensive reference section should prove especially valuable. Clear diagrams and tables illustrate many points throughout the book and each chapter concludes with a summary and selected readings. □

nature is keeping ahead. Are you being left behind?

New research results, the very latest international science news, key papers by the world's leading scientists and speed of publication ensure *Nature* remains one of the foremost weekly scientific journals in the world.

But if you're tied in to a circulation list at work, all this vital weekly information will undoubtedly reach you late, often incomplete and sometimes not at all.

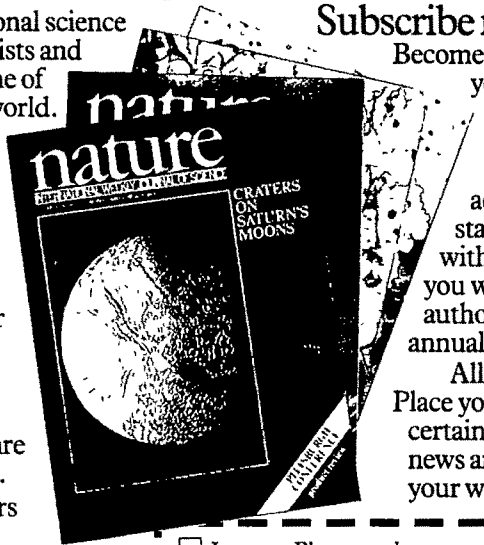
With your own personal copy, you solve the problem. Every week you'll have all the latest research results and science news in your hands within days of publication:

News reports from throughout the world of science and technology.

A **News and Views** section, where new ideas are analysed and discussed by leading researchers.

Articles and Letters in which key investigators disclose their work for the first time.

Book Reviews—Eminent figures offer expert judgments on a wide variety of recent publications.



Special Issues providing an in-depth treatment of topics of importance.

Product Reviews—Detailed descriptions of laboratory equipment newly available.

Classified Advertisements for a wide variety of positions all over the world.

You will no longer be dependent upon other people passing down the 'list' copy, and because you will automatically receive every issue, you won't risk missing a single copy through absence from work. Moreover, you keep all this key information for permanent reference.

Through your door every week

Subscribe now–and save!

Become a personal subscriber now and you will receive a discount of over 50% off the full rate.

All 51 weekly issues will be delivered to the address of your choice. You can start your annual subscription with any issue you choose. And you will receive six bi-monthly author indexes, together with the annual index of subject and author.

All this for just $2.12 a week.

Place your order now and make certain that you receive the scientific news and research results crucial to your work when *you* want them.

☐ I accept: Please send me a personal subscription to *Nature* for one year (51 issues) at the special rate of US$110.

☐ I enclose my personal check for US$110 made payable to Nature. (Note: Institutional checks cannot be accepted at this special rate. The instututional price is US$230.)

☐ Please charge to my credit card account.
Visa/Mastercharge/American Express.

CONVENIENT-INFORMATIVE-TIMELY-PROVOCATIVE

FOUR DYNAMITE REASONS WHY YOU SHOULD SUBSCRIBE TO BIO/TECHNOLOGY NOW . . .

1. You'll save time. Because you don't have time to read every journal in the field, BIO/TECHNOLOGY is written and edited to give you all the information you need in ONE convenient source. BIO/TECHNOLOGY is the only journal to give you news. Features. Original research. Product evaluations. Industrial applications. Job openings. Book and product reviews. And more. If it's important to your work, you'll find it between the covers of BIO/TECHNOLOGY.

2. You'll learn new ways to improve your on-the-job skills and run a more successful operation. Each month BIO/TECHNOLOGY gives you the scoop on invaluable start-up information . . . the latest instrumentation . . . marketing breakthroughs . . . funding sources . . . new technologies . . . patents and licences . . . profiles on how others are avoiding the pitfalls and reaping the rewards. In fact, just one practical tip from BIO/TECHNOLOGY can be worth many times the cost of your subscription.

3. You'll be up-to-date on all major industry developments. With correspondents all over the world, BIO/TECHNOLOGY delivers the inside story on who's doing what, where. You'll get the latest word on changing government regulations and tax law, and how they affect your work.

Plus you'll read original research papers by bench scientists, engineers, and biologists that will help keep you in the forefront of every new discovery worth knowing about.

4. You'll get new ideas you can put to use immediately. BIO/TECHNOLOGY lets you rub elbows with eminent scientists, tour new facilities and learn how new processes work in every field from genetic engineering to molecular biology. Each month, BIO/TECHNOLOGY helps spark ideas for your own research, for new industrial applications and for getting along in the increasingly competitive financial arena.

If you're not already subscribing to BIO/TECHNOLOGY, don't delay the moment any longer - return the coupon below and we will send you twelve issues. You risk nothing. If for any reason BIO/TECHNOLOGY doesn't live up to your highest expectations, just let us know and you'll receive a full refund on all unmailed copies. Remember too, that your subscription may be tax deductible.

TO START RECEIVING YOUR SUBSCRIPTION, FILL OUT THE COUPON BELOW AND RETURN WITH PAYMENT TO:

U.S.A.: BIO/TECHNOLOGY
Subscription Order Dept., P.O. Box 316
Martinsville, New Jersey 08836 U.S.A.

To speed up your subscription in the U.S.A., call toll free 1-800-524-0328.

ENGLAND: BIO/TECHNOLOGY
Subscription Order Dept., Macmillan Journals, Ltd.
Brunel Road, Houndmills, Basingstoke
Hampshire RG21 2XS, England

☐ YES! Please send me one year of BIO/TECHNOLOGY (12 issues). I understand that I may cancel my subscription at any time and receive a full refund on all unmailed issues.

☐ U.S.A.-$59.00* ☐ Australia-A$130**
☐ U.K.-£70** ☐ Elsewhere-U.S.$112**

In Japan, write Macmillan Shuppan, K.K., Eikow Bldg., 10-9 Hongo 1-chome, Bunkyo-ku Tokyo 113 Japan

Note *Represents 24% off Basic Subscription Price of U.S. $78.00
**All other prices quoted are "Air Speed"

☐ My payment is enclosed at the price checked.

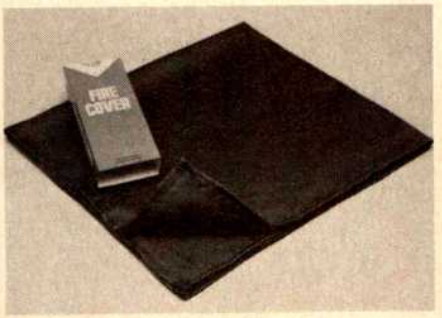
Blanket, mask and cream

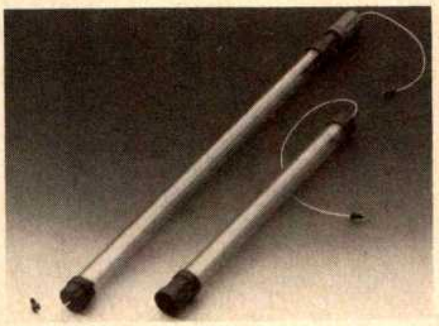
New this month are several items aimed at lab safety—including a fire-fighting blanket, a protective face mask and protective skin cream.



• For molecular cloning, Bio-Rad has introduced a T4 DNA ligase that can be used both to join double-stranded DNA molecules in recombinant applications and to repair single-stranded nicks in duplex DNA. Capable of ligating either cohesive-end or blunt-end DNA, the T4 DNA ligase is purified from an *Escherichia coli* strain and qualified for molecular cloning experiments by a number of quality assurance procedures. These include: monitoring ligation efficiency on both cohesive and blunt-end fragments; an endonuclease and an exonuclease activity assay and a ligation/recutting assay.
Reader Service No. 100.

• Celltech's range of reagents for the purification and assay of interferons now includes Beta Sepharose, a reagent based on monoclonal antibodies and intended for the purification of interferon beta. Beta Sepharose gives a single-step chromatographic process that can virtually eliminate all impurities and retain a high yield of active interferon beta.
Reader Service No. 101.

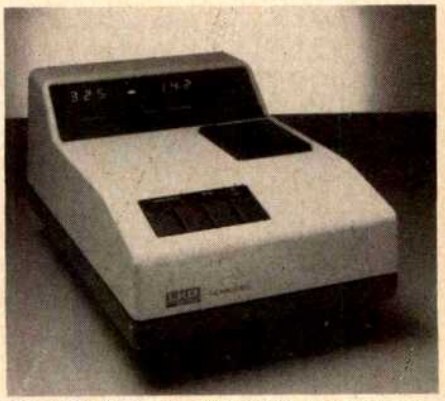
• A free newsletter available from Lab Safety Supply of Jamesville, Wisconsin, consists of abstracts of significant publications in the area of chemical health and safety. Subjects include personal protection, laboratory safety, safe handling, storage and disposal of toxic and hazardous chemicals, biosafety and radiation safety. For a complimentary copy of "Chemical Health & Safety Abstracts" use the Reader Service Card.
Reader Service No. 102.



• Three leading producers of dyes and stains for microscopy have collaborated to produce a range which microscopists can rely upon to give accurate results from batch to batch. Brand-named Certistain, the new range results from an agreement between BDH Chemicals Ltd, EM Diagnostic Systems Inc., and E. Merck, on individual stain specifications covering both chemical criteria and practical biological testing. The Certistain range initially contains 30 stains and this will be expanded over the next few years to a total of around 200. Supplies of Certistain dyes and stains can be obtained from any of the three companies, their associates, agents or distributors throughout the world. A comprehensive handbook on the new Certistain range can be obtained through the Reader Service Card.
Reader Service No. 103.

These notes are based on information provided by the manufacturers. For further details circle the appropriate numbers on the Reader Service Card bound inside the journal.

The graphite-impregnated Fire Cover.



• The Fire Cover fire blanket, a completely new fire fighting aid made of fibreglass cloth impregnated with graphite and Teflon, is now available from Bel-Art Products. The blanket is capable of extinguishing small laboratory and fume hood fires, as well as Class A, light oil and grease fires. The 39″ × 43″ Fire Cover fire blanket is packaged in a small instant-access container, which can be hung on walls or stored in any convenient place. The graphite impregnated in the cover rapidly absorbs heat generated by burning material and helps lower the flashpoint below a substance's re-ignition temperature. The close weave of the cover prevents atmospheric oxygen from getting into and feeding the burning materials.
Reader Service No. 104.

Pharmacia's new FPLC columns.

• Column HR 16/50, a new high-resolution chromatography column, and Packing Equipment HR 16, for efficient column packing, are specially designed for high performance preparative separations with the Pharmacia fast protein liquid chromatography (FPLC) system. The HR 16/50 column (for bed dimensions of 16 × 500mm) is particularly well suited for chromatography of biomolecules using the Pharmacia gels Superose 6B, Sepharose CL-6B and Sephacryl S-types. The HR 16/50 column and the Packing Equipment HR 16 are fully biocompatible and can be used at pressures up to 30 bar (3 MPa). The pressure specification allows efficient packing at higher flow rates.
Reader Service No. 105.

• Bio-Yeda now offers conjugated affinity purified goat antibodies directed against mouse Fab and mouse Fc fragments. These antibodies are particularly suited as secondary reagents in work with mouse monoclonal antibodies. They may be used in hybridoma screening with the ELISA technique and as instruments for detection of monoclonal antibodies on tissue or cell preparations using indirect immunoenzymatic or immunofluorescence methods. These affinity purified anti-mouse antibodies are exhaustively adsorbed with human serum proteins to assure minimal cross-reaction with human proteins on tissue or cell preparations. The anti-mouse Fab products offer sensitive and broad activity for all mouse immunoglobulins (IgG, IgA, IgM, IgE) where the anti-mouse Fc products react specifically with mouse IgG (all subclasses). Affinity purified antibodies to mouse Fab and mouse Fc are available unmodified or as fluorescein, peroxidase and alkaline phosphatase conjugates.
Reader Service No. 106.

The LKB Novaspec for visible spectroscopy.

• For applications where a highly sophisticated spectrophotometer is unnecessary, LKB has introduced the Novaspec, a simple inexpensive visible spectrophotometer made to modern optical standards. Simplicity of operation is ensured with only four keys controlling the instrument's operation. The Novaspec features automatic wavelength calibration at switch-on, and microprocessor controlled selection of correct filter combinations. The wavelength range is broad, and a universal cell holder adds to the instrument's versatility. For applications in the teaching laboratory, the LKB Novaspec is fully complemented by a range of educational accessories, including a textbook on the basic principles of spectrophotometry, and a wall chart summarizing these principles in a graphic way.
Reader Service No. 107.

• Tecator has developed a fully automated flow injection analysis system to bring the techniques to a larger number of applications than previously possible. FIAstar is intended primarily for the fast, simple analysis of water, soil, fertilizers and beverages. This use of the FIA technique also opens up the possibility of new applications in wet chemistry analyses.
Reader Service No. 108.

• Recent additions to the Sera-Lab range include four new monoclonal antibodies against mouse T-cells for use in *in vitro* and *in vivo* depletion of T-cells and T-cell subsets. Applications include the investigation of the role of different T-cells in models for infectious disease, autoimmunity, tolerance, neoplasia and transplantation, and also in cell sorting.
Reader Service No. 109.

Advertisements

Transfer of DNA/RNA to solid supports, Southern/Northern blots and filter hybridization

Our accurately temperature-controlled rotisserie oven gives **important advantages** as against bag: 2.4–3 ml hybridization solution. Lower background. Higher intensity of bands. Multiple hybridizations possible. Uniform distribution of solution.

The Gonotec automatic osmometer.

• A fully automatic osmometer using the depression of freezing point method for measurements of total osmolality in under one minute, is now available from Clandon Scientific Limited. The Gonotec Model 030 osmometer requires only 50 μl of sample (or 30 μl with lower precision) and displays results in osmol per kg. The instrument is very simple to use, being fully automatic after sample presentation. Measuring 210 × 360 × 240 mm, the 030 weighs approximately 9kg and can be connected to a recorder or printer.
Reader Service No. 110.

Locount cream protects the cleanroom environment from skin particles, and the skin from irritation.

• A new skin cream has been developed especially to solve problems with skin particulation and skin irritation in research and cleanroom environments. LoCount, from VWR Scientific absorbs right into the skin and has no particles in suspension to dry skin as oil-based creams do. The cream reduces skin particulation by as much as 90%. Its completely organic formulation means that standard cleaners easily take LoCount off any surface. LoCount is low in ionics and halogens, so if someone accidentally contaminates a device with the cream, LoCount presents minimal risk to the performance of an electrical circuit. Use of the cream reduces skin discomfort from wearing vinyl gloves for long periods, and the cream is hypoallergenic.
Reader Service No. 111.

Availability of frozen serum panels

A VARIETY of serum components have been reported to be useful in cancer diagnosis and/or in monitoring cancer treatment or recurrence. The US National Cancer Institute is interested in evaluating serum assays potentially useful in cancer diagnosis. Coded panels composed of 1 ml aliquots of pretreatment frozen sera from patients with various neoplasms, from benign disease patients, and from healthy controls are available to investigators to evaluate assays in which preliminary results indicate the ability to discriminate between cancer patients and controls. Promising results may form the basis for a subsequent grant application. Preliminary data documenting a useful test must be submitted and should include: a brief description of the assay, results in patients with cancer and in non-malignant disease, results in healthy controls and reprints of published work if available. Requests should be sent to: Diagnosis Serum Panels, Project Officer NCI-Serum Bank, Room 10A10, 5333 Westbard Avenue, National Cancer Institute, National Institutes of Health, Bethesda, MD, 20205.

• A new range of calibrated lattices has been developed by Rhône-Poulenc. These Estapor lattices make it easier to detect the complex formed by the immunological reaction between antigen and specific antibody. Calibrated lattices, because of their high uniformity, are increasingly used in diagnostic tests such as agglutination, ELISA, RIA and erythrocyte replacement. Other applications include electron microscopy, filtration and chromatography. Estapor lattices are supplied with or without functional group and are available in either coloured, fluorescent or magnetic forms.

• The Laboratory Facelet, produced by Charcoal Cloth Ltd, offers a high level of protection against toxic fumes, vapours, gases, odours and particles. The Laboratory Facelet is a derivative of the military facelet approved to NATO standards and currently in supply to the British armed forces for initial protection against chemical attack. Like the military version, the Laboratory Facelet incorporates activated Charcoal Cloth — a material composed entirely of 100% charcoal fibres which has a far higher rate of adsorption for gases and vapours than granular charcoal or charcoal-impregnated materials. In addition, other filtration materials have been included to provide a high level of protection against a particulate threat. The facelet features a low breathing resistance, a high level of speech transmission, and is light and comfortable. The mask is reuseable and much cheaper than conventional respirators.

A new digital thermometer from Automatic Systems.

• Automatic Systems Laboratories, of Milton Keynes, has introduced a new digital thermometer which is capable of absolute and differential temperature measurements with a resolution of 0.001 °C between minus 270 °C and plus 630 °C. The digital readout, even at high resolution, is completely stable. The new microprocessor-controlled instrument gets its extreme stability from the use of low frequency a.c. techniques, which eliminate the thermally induced voltages and drifts associated with d.c. systems.

AMF Cuno's new polypropylene pleated filter.

• The AMF Cuno Polypro is a high-surface-area, all-polypropylene pleated filter designed for critical filtration applications. Polypro cartridges are produced by pleating multiple layers of a non-fibre releasing polypropylene matrix. The 100% polypropylene construction assures compatibility with a wide range of solvents. Five absolute micrometre ratings are available from 0.6 to 10.0 μm. Applications include pharmaceutical solvents, high-purity water and photographic emulsions.

• Available from Medical Systems Corporation of Green Neck, New York, The Model MF-83 Microforge is specifically designed by the Narishige Instrument Laboratory of Japan for polishing glass micropipettes used for patch clamping. The MF-83 has a magnification of 600×, and the 40× objective features a long working distance. Incorporated in the Microforge are: an adjustable lamp and heat control; an external foot switch, which controls the heating of the glass micropipettes; full manipulation of both the glass pipette and the heating element.

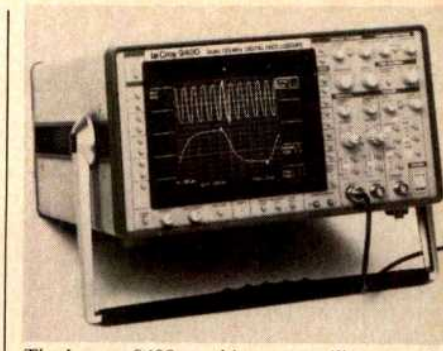
Government Chemist opens the doors



THE Laboratory of the Government Chemist, under the auspices of the UK Department of Trade and Industry, is now offering its range of materials testing facilities for contract use by the private sector. The LGC has been actively involved with materials research and development for over 20 years. Work began in the field of dentistry but has now moved into other industrial areas such as coatings technology and controlled-release. Among the facilities available at LGC are techniques for measuring:

- **Mechanical properties — including strength, hardness, roughness, abrasion resistance and fatigue.**
- **Rheological properties.**
- **Chemical and microstructural analysis.**
- **Colour measurement and translucency.**
- **Thermal properties.**
- **Environmental weathering properties.**

These facilities can be used on a regular or *ad hoc* basis for investigating the properties of polymers, ceramics, glasses, metals, coatings, rubbers, cements and dental materials and also for solving problems associated with materials in industry.
Reader Service No. 118.

• A comprehensive range of monoclonal antibodies for tissue typing is now available from Amersham International. Seven monoclonals make up Amersham's range for identifying a cell's intermediate filament protein structure. The new products are anti-cytokeratin, anti-desmin, anti-vimentin, three anti-neurofilaments and anti-glial fibrillary acidic protein. For those wishing to classify unknown tissue, Amersham offers a composite pack of basic antibodies necessary for tissue typing, while for those studying particular types of cell all the products are available separately. In addition to this new intermediate filament range, Amersham already has an established line of monoclonal antibodies for typing other intracellular structures.
Reader Service No. 119.

• The Metachem Diagnostics Cell-ect is a cost-effective system for separating cell populations without the need for expensive instrumentation. Cell-ect kits provide the reagents and instructions necessary to perform 10 separations. The principle of the system is to prepare polystyrene dishes with a specific ligand. A cell suspension is poured onto the plate and incubated. The non-adherent cells are removed by decanting the supernatant, while the adherent cells are recovered by pipetting. The kits currently available are: total histamine (TH), for the separation of all histamine receptor bearing cells; histamine receptor 2 (H_2), for the separation of Type 2 receptor bearing (H_2R^+) cells; and human Ig, murine Ig, for the separation of Ig-bearing cells from non-Ig bearing cells.

The Lecroy 9400 combines an oscilloscope with the function of a transient recorder.

• The LeCroy 9400 Dual 125-MHz digital storage oscilloscope combines the advantages of an oscilloscope and a transient recorder in an easy-to-use and portable (14-kg) instrument. The 9400 features complete programmability and extensive interfacing options for remote control and computer archiving, with a wide 125-MHz analog bandwidth. Both input channels are identical, with accurate 100 megasample per second, 8-bit analog-to-digital converters and very large 32K work acquisition memories.
Reader Service No. 121.

• To facilitate studies in the field of oncogene research, Triton Biosciences Inc. is now marketing affinity-purified antibody to Ha-*ras* p21 protein. Antisera are generated in sheep against a variety of synthetic peptides corresponding to potential antigenic sites on the native protein molecule. Antibodies are purified by peptide affinity column chromatography and are characterized by Western blot and immunoprecipitation analyses.
Reader Service No. 122.

Orion's portable meter.

• Orion Research Incorporated has introduced two new meters for *p*H, DO/BOD, and redox potential measurements in the lab or field. The meters, SA 210 and SA 230, have measuring ranges of 0–14 *p*H and + 1,999 mV. The SA 210 is a *p*H/mV meter. The SA 230 is a *p*H/temperature/mV meter with ATC probe for automatic temperature compensation. Both meters come with a rugged carrying case, all the essentials needed for measuring *p*H, and a special electrode holder that attaches to the carrying case, allowing the meter to remain in the case during measurements. Battery life is approximately 100–150 hours, continuous use, and an a.c. line adapter is available.

The Cambridge phenomenon

from Richard Pearson

As science parks continue to proliferate throughout the United Kingdom, it remains difficult to define the ingredients for success

HIGH technology and small businesses are seen as two essential routes to job creation in both Europe and North America. As a result, policy makers are looking for the key to unlock such job creation potential by stimulating the development and utilization of high technology, and by aiding and encouraging the would-be entrepreneur. For some, science parks are the magic catalyst which draws the two phenomena together. By observing the success of Silicon Valley in the United States, which itself was spawned by Stanford University via its science park, and now has 200,000 jobs, every higher education institution and local authority in the United Kingdom now has plans or ideas for developing its own version of a science park. For those thinking on a grander scale, then the replication of Silicon Valley itself, for example as in Silicon Glen in Scotland, which has developed as a result of public policy initiatives and now has 40,000 jobs, or the M4 sunbelt in England where growth has been more spontaneous, is the ideal translation from high technology to job creation. In the United Kingdom the concept of the science park is taking many different forms, ranging from, at one extreme, the re-labelling of a high quality industrial estate in pleasant surroundings, to the park located adjacent to and on land owned by a higher education institution. There are now over 40 such initiatives under way.

The Cambridge Science Park, formed in 1973, and owned and developed by the University of Cambridge, has been one of the UK pioneers. In addition, the area has also spawned the 'Cambridge phenomenon', the apparently spontaneous emergence of a cluster of high technology companies along the lines of Silicon Valley. As well as being the home for Sinclair and Acorn, two of the biggest microcomputer companies in the world, the area contains over 300 other high technology companies, employing nearly 14,000 people between them and accounting for one in six local jobs. Their total turnover in 1984 has been estimated at £890 million[1]. While the first high technology company to come out of Cambridge University can be traced back to 1881, when Cambridge Scientific Instrument Company was formed by Charles Darwin's son to manufacture scientific equipment for the university, the Cambridge phenonemon can be said to have really taken off some 100 years later. Over the past 20 years one new company has been established in the area every month, with peak rates of establishment occurring in 1978, 1981 and 1983 when over 2 per month were being established (Fig.1).

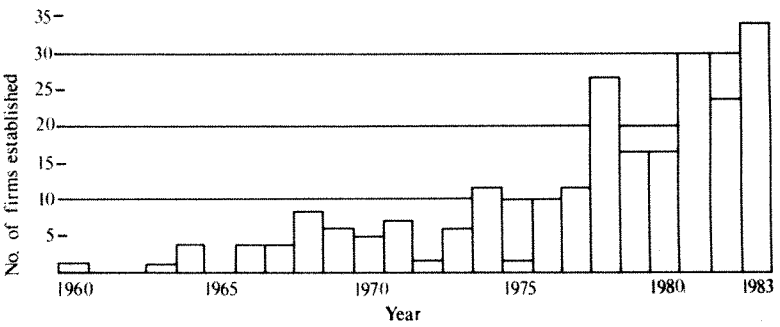

Fig.1 Dates of establishment of companies in the Cambridge area, as surveyed in ref.1.

Three quarters of these companies are new independent enterprises with the balance being made up of new branches of existing UK or overseas firms, or companies moving into the area. There is a high preponderance of very small companies in the total, one in three having five or fewer employees or an annual turnover of under £400,000. Electronics and computer hardware are the dominant business activities, but there is also a strong representation in biotechnology. A significant proportion of the companies' activities centre on research, design and development and consultancy.

The origins of the vast majority of these companies can be linked to the university, but only in a few cases, one in six, have they been formed by people coming straight from the university. For the majority it is because key staff have left one local company to start their own business in the area. This interconnection between companies, together with associated mobility of professional staff between companies, is seen as one of the great strengths and ingredients for success in both the formal settings of science parks, where the flows are expected to be between the educational establishment and industry, and in the 'Silicon Valleys', where it is between the companies involved. An additional asset of an area like Cambridge is the social network.

A distinguishing feature of high technology companies is the high qualification profiles of their workforces, a factor reinforced by the separation of manufacturing facilities to distant, and often offshore locations. In the Cambridge case, one in three of the staff in the companies were either managers or professional scientists and engineers, with the most recently formed companies having over half their staff in these categories. While shortages of such people are operating as a constraint in many locations, Cambridge does not seem to be suffering too badly. In part this is a result of the large supply of professionally trained graduates being produced by the university, but also the attractive location is an attraction to would-be migrants.

For many, the whole idea of a science park is that of the interplay of ideas between higher education institutions and local companies. In the Cambridge case, a study in 1983[2] showed that there were surprisingly few formal linkages between the companies on the park, and that companies located elsewhere in the area were just as likely to have research contracts, consultancies and teaching commitments with the university. Such linkages would seem to find more expression through informal social contacts, ease of recruitment, and a 'halo' effect which stimulates action and change by example, rather than simply as a result of close physical proximity.

What, then, are the implications for other locations seeking to encourage new high technology firms? The first is that Cambridge has many special features which are unlikely to be repeated in many other areas. The second is that such developments take time, the Cambridge phenomenon had its beginnings many decades ago, with the science park having taken over 10 years to come to full fruition, and the park itself is only one small part of the process. Finally, if US experience is anything to go by, for every success, there will be a series of still-born or struggling parks. Science parks and high technology 'clusters' may have emerged quickly in the fashion stakes; the rewards for the successful will, however, come over a much longer time span, and while initiatives by public agencies can aid this process, 'natural' advantages will be just as important, and many of these are still not well understood □

Richard Pearson is at the Institute of Manpower Studies, Mantell Buildings, University of Sussex, Brighton BN1 9RF, UK.

nature

NATURE VOL 314 11 APRIL 1985

Towards a new world trade war?

The huge US trade deficit can be reduced in two ways—by fiscal rectitude or protectionism. There is a risk that Congress will seek the second path, which could spell disaster.

THE most remarkable modern economic phenomenon is the financial mess into which the United States has stumbled. For the past six years, since before the beginning of the Reagan administration, the federal government has been running a fiscal deficit which has increased over the years to something like $220,000 million per annum. Part of the explanation is all too familiar—the unwillingness of the government to cut public spending to match income. More recently, for the past four years, the deficit has been sustained by the Reagan administration's conviction that taxes should be cut in the interests of economic revival, and its determination that they should not even now be increased. The consequence of the deficit has been that the US government has had to borrow money in the international money markets, which has been possible only by making investment in dollar securities attractive, by high interest rates and by the promise that the domestic recovery would be strong and sustained. The consequence of that state of affairs is that the dollar itself has been "strong", which is another way of saying that the dollar has been over-valued relative to most other currencies. And the consequence of that, in turn, is that US manufacturers and farmers have been at a disadvantage compared with those elsewhere in the export markets of the world, whence the large and growing trade deficit, estimated at $137,000 million in 1984.

This state of affairs has now begun to hurt large sections of the US economy. The plight of the farmers has been clear for the past eighteen months (see *Nature* 14 March, p. 119) but is only partly attributable to the difficulties of selling US agricultural products on the international markets. Steel manufacturers have for longer been under pressure from competitors elsewhere, Europe, Japan and even some developing countries. Now the competition is beginning to hurt the traditionally strong sectors of the US economy, the general run of manufactured goods, and also those in which the United States is technically among the most advanced, electronic and telecommunications equipment for example. The glitter of the economic recovery is being dimmed by the difficulties into which some pockets of the economy have been plunged. The sharp fall in the value of the dollar (by an average of 8 per cent) against other currencies since the middle of last month will help, but only after some time and to a small extent. The fall has not yet been sufficient to correct the whole imbalance of US external trade. So, inevitably and even understandably, the US Congress is under pressure from its constituents to shield them from the unpleasant consequences of the imbalance. Last month's wild talk of a general protective duty on all imports from outside has mercifully been stilled, at least for the time being. Now, the emphasis is on correcting the trade imbalance with Japan, estimated at $35,000 million in 1984.

Reprisals

The consequences of that are odd, to say the least. On 2 April, a committee of the US Senate passed a bill that would require the federal government to take reprisals against Japan if the trade imbalance does now somehow correct itself. (The bill is not yet a law and, even if it were, its influence would be merely hortatory, but it is a sign of the way the tide of sentiment is flowing in the United States.) There has also been a flurry of bizarre diplomatic activity, with secret exchanges of special envoys between Tokyo and Washington, ostensibly seeking assurances that the newly deregulated Japanese telecommunications system will be open to equipment made in the United States, but whose political objective has been to demonstrate to the Congress that the administration is not sitting on its hands. (Even if Japan gave up the manufacture of telecommunications equipment and imported everything from the United States, the effect on the US trade deficit would be that of a drop in a bucket; the value of Japanese production in this field last year was a mere $2,300 million, less than 10 per cent of the total deficit.)

Imbalance

The issue of the trade imbalance with Japan is a red herring, but no less dangerous on that account. By any reasonable test, nobody should be surprised that if the United States has a trade imbalance on the present scale, the largest share of that should accrue to Japan, far and away the industrial economy that is the most successful at producing manufactured goods, from motor cars to electronic consumer products, which are cheap, of high quality and suited to what the international markets need. President Reagan, who is fond of telling European governments that they would be economically more successful if they were more like the United States (which may be true), should spare some time to remind US manufacturers that they should emulate their Japanese competitors.

But is not the competition from Japan unfair? This is the recurring cry, not only in the United States but also in Western Europe. And it is true that some sectors of the Japanese economy are closed to competition from elsewhere. Japanese consumers must pay more for beef than if it were imported from Texas (or Australia), for example, which has been a fierce bone of contention with the United States during the past year. But is the United States saying that the time has come when all governments, itself included, must abandon agricultural protectionism? That would be in the general interest, but no more acceptable politically in Washington than in Tokyo. For the rest, it is far from clear whether the difficulties that US manufacturers report in exporting to Japan are consequences of the supposed conspiracy of the Japanese bureaucracy against imports of any kind. But there would be serious dangers in any sustained campaign by the United States to single out Japan as the target for its chagrin over the size of the trade imbalance, not least of all the risk that the industrial community of the West, established painfully since the Second World War, may be undermined.

Whether or not competition with Japan is unfair is in any case irrelevant to the present difficulty of the United States. And everybody knows what the remedy must be. So long as the federal government's deficit is running at its present level, and while policy remains to bridge the gap by borrowing from overseas rather than by printing money (which would be inflationary), the trade imbalance will persist. So the urgent task for Congress and the administration is to cut the deficit. That is one of the issues with which the present Congress has been faced. Last week, the administration and its party's

leadership were hoping to cut $52,000 million from next year's deficit. The first thing to be said about even this ambition is that it is far too modest. The second is that it will eventually be for the Congress to decide whether the administration will get the cuts it seeks. The present preoccupation with protectionism, and with the Japanese phenomenon, is a way of hiding from the real need to cut spending or to raise taxes. Painful though these questions are, they will have to be answered at some point down the road on which the United States is travelling dangerously. □

Professional research

How to stimulate research when application is of the essence?

ENGINEERS insist that, while their professional skill is based in science (no longer exclusively physical science), that is only half the story. And similarly, physicians insist that there is more to their craft than applied biology. So much is easily accepted. But in the past several years and especially recently, there has grown up a great sense of confusion about the character and the role of research in both engineering and clinical medicine. In most places, there is a belief that suitably designed research programmes would improve the practice of engineering and medicine, and in some countries there are glowing demonstrations of what these benefits may be. But there is no general understanding of how these few successes may be replicated elsewhere, or how the universities should be most fruitfully involved.

Britain just now has encountered problems on both fronts. Thus the Medical Research Council (MRC) appears to be embarking on yet another reappraisal of its Clinical Research Centre, founded in the 1960s at least partly out of admiration for and envy of the hospital-based research carried out by the US National Institutes of Health at Bethesda (see p. 487). The British experience, unfortunately, has not been nearly as encouraging as people hoped, but for reasons that should have been anticipated.

In one sense, it is bad luck that most of the interest in the past two decades has been in the research by means of which the biological basis of medicine has been so dramatically enlarged, but MRC's clinical centre has also been frustrated in another of its original objectives, that the development of new clinical techniques and therapies should be put on a sounder basis, both by example and by the training of a new generation of research-minded clinicians. In the event, the pace of development in clinical medicine has been determined by people of the kind who have traditionally made the running, usually members of the staffs of teaching hospitals. Most often, in Britain, the costs of these developments have been borne unselfconsciously by the health services. The practical question MRC will soon have to ask is whether its influence on the direction and pace of change in medicine would be greater if more of its resources were spent on research grants, and less on in-house research. The dangers in spending money on research grants, sometimes apparent in the United States, is that the techniques of assessment by peer-review that work reasonably well in basic science are a poor guide to the selection of projects and people in the field of applications. The paper-chasing that sullies much of clinical research in the United States should be a warning of the dangers.

Similar difficulties arise in engineering research. Everybody agrees about the need that basic research should prosper (and in fields such as materials science, British support for the foundation of engineering is sadly deficient). There is also a general conviction that what is called engineering research should also prosper. In the United States, one result has been (see p. 488) that the National Science Foundation has now set up the first six of what is intended as a network of engineering research centres closely linked with universities. The hope is that these will become the well-springs of technological change in the decades ahead, but that they will also train the executors of innovation. The goal is sensible enough (and the centres closely resemble the network established in Britain over the past decade by the private charity called the Wolfson Foundation, many of whose centres have well served their purpose). But the question remains of what engineering research is like.

The point is nicely illustrated by the dilemma in which the British Science and Engineering Research Council now finds itself. For well over a decade, the council (which is the chief source in Britain of support for academic research) has been under pressure to do more to turn ideas into wealth. Its response has been to spend money on a variety of schemes for inducing collaboration between industry and universities (most of them successful and cost-effective), but also to spend more money on engineering research, whatever that may be. Direct spending in universities and polytechnics in the United Kingdom under the heading of engineering is now more than 40 per cent of the total (which is one reason why spending on, say, basic physics is being skimped). Yet a committee report, on which the research council is now seeking general opinions, would have the scale of spending further increased, with the objective of turning British higher education into one of the principal sources of technological innovation. An important part of the argument is that the acknowledged differences between science and the practice of engineering require that engineering projects should be directed not at the discovery of new knowledge as such but at the conception and design (not necessarily the development) of new products and machines. The research council is believed to be in two minds about the proposal, and even for the first time to be prepared to contemplate a separate research council for engineering.

This may be the only way to go in a country such as Britain, but everybody should be aware what is entailed. Higher education is for training students, and research (whose first product is scholarship) is also an extension of that process. Most engineering education (like most medical education, especially in Britain) neglects the basic science of the field (which may be part of the reason why British industry has been slow to exploit scientific innovation). There are several conceptual fields, such as the development of techniques for telling complicated computer systems what to do, or in definition of the relationship between the chemical and physical microstructure of a semiconductor and its properties, where it is easy to see armies of talented people providing future engineers with grist for important mills. But if it is to be the role of engineering research within a university environment to take on the precompetitive development of new products, the question must naturally arise of what the role of industrial companies' research and development departments should be. And will it be possible for universities to use their existing techniques of peer-review and the like to decide who should do what, with what resources?

Exploitation

The six new centres established by NSF should yield some first-hand experience of the problems to be solved, although there are already whole institutions such as the Massachusetts Institute of Technology which are partly organised along these lines already. In Britain, the case for following the path that seems now mapped out is that there is a need, unmet by industry, for the more deliberate exploitation of new ideas, that such a development would also lend engineering some of the distinction engineers say it lacks and that there is a need for a stronger relationship between industry and higher education on more general grounds. The arguments against are that universities may turn out to be poor managers of such novel institutions (and worse, that they might persuade academic engineers to follow inappropriate norms of academic attainment). But the essential criterion is that more support for these engineering initiatives in universities should not rob basic research of funds. □

US fusion research

Hope now depends on overseas collaboration

Washington

THWARTED by a probable 17 per cent cut in the US fusion research budget in two years, US scientists are pinning their hopes for further progress on increased collaboration with Europe and Japan. Plans have been abandoned for a US device that would both achieve plasma ignition, the point at which fusion becomes self-sustaining, and simultaneously allow the testing of high-performance technology needed for a commercial fusion reactor.

The US Department of Energy's latest magnetic fusion programme, now before Congress, makes clear that the next US machine will instead concentrate primarily on the physics of plasma ignition; no timetable is specified. Details of how the programme should be implemented are being worked on at Argonne National Laboratory. The best hope now is that, through international agreements now in the final stages of negotiation, US scientists might participate in research on high performance technology on a machine outside the United States.

Waning interest in fusion research in the United States is, according to the Department of Energy, due to the oil glut. The new plan says simply that there is no longer a premium on the early development of fusion power. Instead, the goal now should be to further scientific understanding of different options for plasma confinement. The US fusion research budget fell from $470 million in 1984 to $436 million in 1985 and the administration's proposal for the 1986 budget is $390 million. There seems to be no chance that Congress will increase this amount and, indeed, a further decrease cannot be ruled out despite lobbying efforts by the research community.

The impact of the reduction so far has been felt both in the five national laboratories where fusion research is carried out and in universities. Some job losses now seem inevitable. At the Princeton Tokamak Fusion Test Reactor, plans to introduce tritium (which would be used, along with deuterium, as fuel in a fusion reactor) have been delayed by two years, until 1988, and construction of the MFTF-B tandem mirror device at Lawrence Livermore Laboratory has been indefinitely postponed. The 1970s goal of achieving a commercially feasible fusion reactor by the year 2000 is now acknowledged to have receded by at least 25 years.

The Department of Energy's programme suggests four major areas of research for special attention. These have been agreed in principle with international partners and will be discussed at the next economic summit meeting at Bonn later in the year. The objectives are the choice of confinement system, the properties of burning plasmas (not now being investigated), the development of suitable construction materials for a future commercial reactor and the development of a blanket for extracting the energy emitted from a fusion reactor in the form of energetic neutrons.

Two international agreements are being negotiated by the Department of Energy under the auspices of the International Energy Agency. These would cover US work on the ASDEX device and the Wendelstein stellarator in West Germany. A further agreement being negotiated with the European Community would formalize US collaboration in the TORE-SUPRA device under construction in France (a steady-state tokamak). Although there have been significant scientific exchanges in the past, legal difficulties—especially over patent rights—have limited extended stays, according to John Clarke, director of the Department of Energy's fusion programme; separate bilateral agreements with Japan are already in operation.

Fusion researchers are sensitive to the suggestion that they have failed to deliver the goods to their sponsoring agencies: there are encouraging results shortly to be reported from the Princeton tokamak which put the US "well on the way" to achieving the goal of scientific break-even, according to Harold Furth, director of the Princeton Plasma Physics Laboratory. A break-even demonstration is scheduled for 1988. Furth hopes that a small US ignition device could be started in 1988, for completion five years later; experience with low-duty cycle experiments would then start in the mid-1990s. Design work is well advanced on a larger technology-testing device that could be constructed in collaboration with international partners starting in 1990 or 1991. This device, known as INTOR, has been planned by the International Atomic Energy Agency since 1978. If built, experience with high-duty cycle operations could start at the turn of the century. Whether governments will provide the necessary funds remains to be seen.

Tim Beardsley

Clinical research

UK centre under scrutiny again

AFTER one rather futile attempt to help the UK Medical Research Council (MRC) to decide the future of its Clinical Research Centre (CRC), a committee under the chairmanship of Sir Michael Stoker is to try again. The outcome should be an assessment of the first 15 years of the centre's work and is likely to include recommendations as to how CRC should be changed to meet both the changed circumstances in which it finds itself and widespread scepticism of its value.

At a cost of £10.4 million in 1983–84, CRC is the most expensive MRC research establishment. Despite a 20 per cent cut in its running expenses and no money for new equipment last year, CRC consumed nearly nine per cent of the total MRC budget. The cost per unit head is not excessive. The question now is not so much whether there are too many heads—although many would like that to be asked—as whether the centre fulfills its role.

That question can be answered only if the role is clear, but Stoker's first committee seems to have drawn a blank on this point. Nevertheless, it seems agreed that CRC was set up to be a focus and centre of excellence in clinical research in the context of commonplace diseases. That is why it shares a site and facilities with Northwick Park Hospital, an otherwise ordinary district hospital of the National Health Service. This arrangement has certain advantages but, according to Sir Christopher Booth, director of CRC for the past seven years and four years from retirement, it also has disadvantages.

One is that there has been little room for medical specialization within the hospital, although the regional health authority now seems willing to change that. A second is that the CRC director has little influence over hospital appointments although, unless those appointed have an interest in research, CRC cannot thrive. Sir Christopher also believes that CRC suffers from not being a recognized centre for postgraduate training.

To some outsiders, including many MRC scientists, the problems of CRC are greater. In 15 years, it has not made its mark as a centre of excellence and has not been quick enough to take aboard new approaches and technology. Why, in particular, is it only now that the application of molecular biology to medicine is beginning to find a place at CRC?

Stoker's second committee has the task of trying again to establish the original aims of CRC but also, and much more importantly, to advise MRC whether the objectives should now be changed and, if so, how to go about it. The committee's report is expected to reach MRC by the end of the year.

Peter Newmark

US engineering research

Six special centres founded

Washington

THE National Science Foundation (NSF) has now designated the first six of its engineering research centres, planned to operate in close association with university departments. They were proposed in 1983 by NSF's engineering directorate in response to widespread concern about the quality of engineering research in US universities. The six centres will be at: the University of California at Santa Barbara; Columbia University, New York; the University of Delaware, with Rutgers University; the University of Maryland, with Harvard University; Massachusetts Institute of Technology; and Purdue University.

NSF's proposal to designate special engineering research centres was endorsed heartily last year by the National Academy of Engineering, which urged NSF to aim for no fewer than 25 centres. NSF's director, Erich Bloch, said last week that progress towards that goal would depend on the continuing support of Congress. The administration's budget proposal for fiscal year 1986 includes $25 million for engineering centres, which should allow a further five or six centres to be designated next year.

The subject area to be covered at each centre was proposed by the host institution. NSF did not attempt to identify in advance the particular specializations it wanted to support, but merely sought to avoid duplication. The purpose of the centres, according to Bloch, is to "enhance the future competitiveness of US industry in international markets" by furnishing industry with a "solid knowledge base".

Location	Funds (over five years)	Subject
University of California, Santa Barbara	$14 million	Robotic systems in microelectronics
Columbia University	$20 million	Telecommunications
University of Delaware (with Rutgers University)	$7.5 million	Composites manufacturing
University of Maryland, College Park (with Harvard University)	$16 million	Systems research
Massachusetts Institute of Technology	$20 million	Biotechnology process engineering
Purdue University	$17 million	Intelligent manufacturing systems

The centres will together receive $94.5 million from NSF over five years, but funds will also be contributed by the host institutions. NSF hopes that its contribution will be matched by state governments and industry. The emphasis is on fostering interdisciplinary research in such areas as robotics, materials science, telecommunications, biotechnology engineering and artificial intelligence; each centre will concentrate on a particular area. Extensive collaboration with industry is expected. The centres will also be used for training, both of graduates and undergraduates; new courses

At least one US senator had lobbied NSF to locate an engineering research centre in his state, apparently successfully. But Bloch insists that siting decisions had been made exclusively on the basis of peer review of the 142 proposals from 106 institutions. **Tim Beardsley**

NASA budget freeze in prospect?

Washington

THE House of Representatives last week sent a message that it may be in no mood to go along with the Reagan Administration's programme of selective budget increases for science while other non-military portions of the budget are slashed. By a surprisingly large 369–36 vote, the House refused to approve the 5 per cent increase for the National Aeronautics and Space Administration (NASA) that the administration had requested for fiscal year 1986. Instead, if the House gets its way—the Senate has yet to act—NASA's overall budget will be frozen at its present level.

The House offered no prescription for allocating the cut among NASA's many programmes, except to say that $45 million of the $375 million reduction should come out of salaries and administrative costs.

The details could be worked out in a House–Senate conference or conceivably left to the NASA administrator.

The President's budget proposal for NASA—which had been approved largely unaltered by the House Science and Technology Committee—specified major increases for the space station (up to $220 million from the current $140 million) and for space applications and commercialization (up to $580 million from $440 million). The scientific research programmes were due for much more modest rises.

By a much closer margin, the House took a token step towards demanding that the shuttle should pay for itself. NASA had wanted to hold the maximum price for a full shuttle payload to $71 million, rather than raising prices in 1988. The House ordered the maximum price to increase in 1988 to $105 million.

Stephen Budiansky

Soviet research

Aleksandrov on self-reliance

SOVIET science must try harder to be self-sufficient, Dr Anatolii P. Aleksandrov, president of the Soviet Academy of Sciences, told the academy's general assembly last month. In some fields in which the Soviets had originally been in the lead, he said, projects had been held up for so long that, in the end, foreign equipment had to be purchased under licence and Soviet work in the field had been terminated. The very scale of Soviet industry seems to be a large part of the difficulty.

Aleksandrov is well known as an advocate of Soviet self-sufficiency. On many occasions, he has somewhat grudgingly referred to international cooperation as necessary in the interests of detente and the elimination of duplicated effort, while emphasizing that the Soviet Union needs no outside help.

Nevertheless, Aleksandrov's new criticisms of Soviet industrial performance are more than his habitual harping on self-sufficiency. His special targets have in common their concern with short-run production.

Thus, said Aleksandrov, the Soviet chemical industry, in spite of its "tremendous" scale, cannot produce the relatively small quantities of reagents needed for high-accuracy analysis. Similarly, in spite of the scale of the nuclear industry, which is capable in theory of supplying the economy with all necessary isotopes and isotope-labelled compounds, many institutes still have to purchase such products from abroad.

Similarly with precision research instruments, although the Soviet instrument-making industry produces a vast quantity of general-purpose equipment each year (to the value of some 30–40 million rubles, including 8 million rubles on systems for the automation of routine analysis), it is not geared to small runs where fewer than 50 items are needed at a time. Moreover, many of the instruments produced are, Aleksandrov said, "frankly speaking, completely useless".

Aleksandrov drew particular attention to the failure, so far, of the Ministry of the Radio Industry to produce the special radar sets needed to monitor soil moisture and salinity. These devices, originally a spin-off from the Venus programme, have an important role to play in the union-wide Food Programme, Leonid Brezhnev's final bequest in 1982 to the Soviet Union. In spite of the efforts of the academy's Institute of Radio Engineering and Electronics in adapting the Venus radars to agricultural use, Soviet industry, Aleksandrov said, has not yet managed to produce the devices so urgently needed. **Vera Rich**

Italian research

Renewed discontent of staff

THE underpaid researchers at the Italian national research council (CNR), the largest state research organization in Italy, are getting impatient. Five months after the hopeful appointment as president of the Milan physiologist, Professor Luigi Rossi Bernardi, they are still awaiting action.

So at least says the Comitato Ricercatori, the researchers' committee which now claims 700 of the 2,500 CNR scientists as members. The Comitato appears to be pushing Rossi Bernardi faster than he wishes, or is able, to go. A Comitato spokesman complained last month of Rossi Bernardi's "refusal to make contact with us", and outlined old sores between the CNR staff and the universities, among which pay predominates. Even a top CNR researcher receives the equivalent of only a little over £9,000 a year, net of tax, compared with a top professor's £20,000. The most junior jobs in CNR and among university lecturers are paid about £6,500 and £9,000 respectively.

In Rome last week, Rossi Bernardi said he had now met the Comitato and "we agree on many points". Moreover, he said, "everything they say is obvious—what remains to be done is to do it". But some things are plainly easier to achieve than others.

According to the Comitato, one of the main CNR complaints apart from pay is the relative status of university and CNR staff. This will not be easy to change. The CNR advisory committees which plan the research programmes are dominated by 130 university professors against just 10 CNR researchers. Officially, CNR scientists are described as "collaborators", suggesting a role subservient to the universities. The Comitato also complains that the management of the 270 CNR research institutes and centres falls to university professors so that CNR scientists must "obey decisions without their being consulted". Yet according to statistics prepared by Rossi Bernardi himself, and published in the 1984 CNR report, CNR scientists published six times as many papers per head in 1983 as the average Italian scientist, who published only once in four years.

Thus Comitato members are pressing for at least a career structure comparable with that of the universities. The powerful trades unions, on the other hand, insist on a research "contract" structure for CNR under which researchers would be paid for work done.

The real problem, according to Rossi Bernardi, is to produce a new legal structure for CNR, in which promotion on merit is now virtually impossible. Salaries, taking a quarter of CNR's present £500 million annual budget, could hardly be increased without such a structure. So will a new law be possible? Rossi Bernardi says he is doing what he can, but that it is "a political problem".

Meanwhile, some reforms are under way. Thus Rossi Bernardi has proposed that CNR researchers should supplement their incomes by contracts and consultancies with industry. Then, acknowledging that CNR "cannot do everything", he says it should concentrate on areas of "strategic" importance.

Rossi Bernardi is also planning to concentrate CNR funds next year on CNR institutes whose performance after assessment is found creditable. He will pay out half the 1986 CNR research funds "on merit" he says, which will be a big change for CNR but one of which the Comitato Ricercatori should approve. Indeed, the Comitato says it will agree provided that merit is assessed "by the scientific community rather than by bureaucrats and union representatives", Comitato members "are ready to submit themselves to international competition" said a spokesman. **Robert Walgate**

Planetary missions

Soviet frankness cheers US

Washington

WHAT appears to be the first detailed account of the Soviet planetary exploration programme, including plans for an ambitious mission to Mars and its moons in 1988, has been provided by a delegation of Soviet space scientists in the United States last month. The delegation, led by Dr Valery Barsukov of the Vernadsky Institute, described a plan for soft-landing a small probe on the surface of Phobos, the larger of the two martian moons, and then making it "hop" to other points on the surface by the remote firing of small rockets.

Under the plan, two spacecraft will be launched in 1988, carrying solar-physics packages to study particles and fields in the ecliptic. After entering Mars orbit, one of the craft will assume a circular orbit matching that of Phobos, and manoeuvre to within 50 metres or so of its surface. In collaboration with French scientists, the Soviets are developing a 1-Joule laser that will vapourize and ionize surface material from Phobos, which will then be drawn through an on-board mass spectrometer for analysis.

The second craft will primarily be a back-up that may rendezvous with Demos, Mars's second moon, if the first attempt to land on Phobos is successful.

The delegation also described plans for a lunar polar orbiter to be launched in 1989 or 1990 so as to produce a detailed map of the Moon's geochemistry as well as for the possible mission to Venus in 1991 that would include dropping a lander on to an asteroid, possibly Vesta, on the way.

US scientists who heard the delegation's presentation, given at the Lunar and Planetary Science Conference at Johnson Space Center in Houston, say they were both surprised by the Soviets' frankness and impressed by the ambition of their plans.

Although Soviet scientists had previously outlined their planetary programme (most recently at a meeting arranged by the Planetary Society during last year's conference of COSPAR, the Committee on Space Research of the International Council of Scientific Unions, in Graz, Austria), last month's presentation filled in many gaps. It was welcomed as what seemed part of a move away from the secrecy and deliberate vagueness of previous Soviet announcements of future space missions.

Official contacts between the National Aeronautics and Space Administration (NASA) and Soviet space officials were ended in 1982, when the Reagan administration declined to renew a ten-year-old space cooperation agreement, citing the imposition of martial law in Poland. But in recent weeks, different administration officials have revived talk of cooperative space ventures, including a joint rescue training mission involving the US shuttle and the Soviet Salyut spacecraft and coordination of Mars exploration.

Last autumn, President Reagan signed a non-binding Senate resolution sponsored by Senator Spark Matsunaga (Democrat, Hawaii) calling for renewal of the cooperation agreement. Matsunaga has now filed another bill that would set up an "East–West" working group on Mars exploration.

During this hiatus, informal contacts between Soviet and US scientists have continued, typified by the arrangement by which US scientists built an instrument with NASA funds which is being carried on the Soviet Vega mission to Halley's comet (see *Nature* **312**, 3; 1985). There have been other informal approaches to US scientists qualified to supply instruments for the Soviet Venus-asteroid and other missions.

A more likely form of low-level cooperation, according to US specialists, is, however, data-sharing and join calibration of instruments on the Soviet Mars probe and the US Mars Geoscience Climatology Orbiter, due for launch in 1990. The Planetary Society is hoping that concrete plans to these ends will be agreed at the 1986 COSPAR meeting in Toulouse. **Stephen Budiansky**

Soviet espionage

Furore over French allegations

Le Monde, the Paris daily, has caused a furore by publishing what is alleged to be a secret report from the Soviet Ministry of the Aviation Industry on the "utilization of positive foreign experience"—in other words, industrial espionage. The disclosure, which coincided with the opening of high-level Franco-Soviet economic talks, caused the Soviet embassy in Paris to issue denials of this "flagrant disinformation" in even more vigorous terms than usual.

Le Monde claims that the disclosures were leaked to it by French intelligence and were the evidence on which President François Mitterrand expelled 47 Soviet diplomats two years ago. They include a description of the alleged inner workings of VPK, the Commission on Military Industries, which is said to issue "shopping lists" to Soviet representatives abroad, specifying what high-technology information the military establishment needs most urgently.

Claims that such lists exist have surfaced regularly in West Germany, and a recent Swedish survey of alleged Soviet industrial espionage by Charlie Nordblom (*Industri Spionage*, Timbor Förlag, 1984) specifically alleged that the State Committee for Science and Technology and the Academy of Sciences of the USSR are involved in compiling them.

The euphemistic Soviet description of the undertaking is not to be wondered at. At one time, the United States ran a Soviet-watching project, operating from the Weisbaden air force base in West Germany, known as STEP, the Science and Technology Exploitation Program.

The Soviet Union may have had advance warning of the impending disclosures in *Le Monde*. The president of the Academy of Sciences, Dr Anatolii P. Aleksandrov stressed to the general assembly of the academy last month that the Soviet Union intended to rely even less in future on imported know-how, while a few days before *Le Monde* published the documents, Radio Moscow broadcast an extensive interview with an "expert of the Soviet State Planning Committee", Dr Aleksei Petrov.

Petrov complained that the West had long suggested that Soviet technical progress depended on Western know-how, but "facts are facts and they show something quite different". During the past 20 years, Petrov said, the Soviet Union sold to the United States twice as many licenses as it had purchased, and almost two-thirds of Soviet imports consisted of raw materials.

Petrov's data, of course, referred to the civilian sector, while the *Le Monde* documents refer primarily to military aviation. To a Soviet planner, however, the distinction would probably seem artificial. The extremely low figures for military expenditure published in the Soviet budget (around 18,600 million rubles annually) make sense only if they refer to the replacement of existing military hardware, with military research and development absorbed by the civilian sector.

Vera Rich

Australian veterinary science

Lab. at last

Canberra

AFTER several years of to-ing and fro-ing about its value and safety, the $A160 million Australian National Animal Health Laboratory (ANAHL) was officially opened early this month. The ultra-secure laboratory at Geelong, 70 km south-west of Melbourne, was designed by the Commonwealth Scientific and Industrial Research Organization (CSIRO) for rapid diagnosis of and research into exotic livestock diseases, especially foot and mouth disease virus (FMDV), not detected in Australia since 1872.

Over the years, the unfinished laboratory has been a repeated source of political contention. Two issues have arisen—the high cost of the facility, and the objections of many in Australia to the notion that FMDV might be imported, even if for research only, into a virus-free continent.

The laboratory is designed on the "box within a box" principle, in which the work area of highest security is at the centre of the building and is surrounded by a series of "boxes" of decreasing security classification.

For the present, ANAHL scientists are conducting investigations into endemic local diseases such as bovine leukosis and rhinotracheitis, and are attempting to clone the gene for the two outer protein coats of the local bluetongue virus, a serotype of which was isolated from insects collected in Northern Australia in 1977. In a few months, however, it is likely that work will begin on several exotic diseases including rabies, swine fever virus, Aujeszky's disease (pigs), exotic bluetongue, Newcastle disease (poultry) and vesicular diseases which could be mistaken for FMDV. Ultimately, permission may be granted for work on virulent exotics such as rinderpest or rift valley fever, but the importation of live FMDV has been shelved until 1987 at the earliest.

The laboratory will cost $A8 million a year to operate, but an outbreak of foot and mouth disease would result in the loss of an estimated $A3,000 million in export earnings.

Jeffrey Sellar

European research

Curien wants more

Strasbourg

PLANS for using science and technology to improve Europe's competitiveness with the United States were put forward in a speech to a gathering of geologists on 1 April by M. Herbert Curien, minister of research in the government of France. Curien's proposals, which have been hammered out over the past few months by groups of scientists and politicians, are to be presented to the Council of Europe early in May, at a meeting called for by M. François Mitterrand, the French president.

One of Curien's themes was European collaboration in space research and development, chiefly through the European Space Agency (ESA). The past twelve years of ESA's work, Curien said, had been creditable, but he urged last week that by the end of the century, Europe should be in a position not merely to build and launch satellites but to put men and women into space and to provide a full "customer service".

More generally, Curien said, Europe could respond to the apparent superiority of the United States in science and technology only if it were "united, ambitious and autonomous". Specifically, Curien lent his weight to proposals of the European Communities and the European Science Foundation (ESF) for research "networks". Since last September, some 50 proposals have been put forward and have now been whittled down to about a dozen.

The network plan is to involve groups of European research laboratories on common projects, much as several different groups of European geophysicists are now involved in the European Geotraverse project of deep seismic sounding (begun in 1983 by ESF). Last week, Curien referred to neurosciences and polar studies as potentially fruitful areas for collaboration on the same pattern.

Curien also wrung his hands last week over one of Europe's longstanding problems, the difficulty of encouraging mobility within the research community. He said that there were signs, in France, that mobility had recently declined. The difficulty, now as previously, is to devise appropriate incentives for the encouragement of mobility. There remain, said Curien, delays in arranging for the exchange of people, financial assistance to people on the move is lacking while there are even difficulties in transferring equipment across national frontiers. He urged that the impetus for the better coordination of the European research community should come from scientists themselves rather than from rule-bound institutions.

Peter Gambles

Brazilian energy

Physicists seek new nuclear policy

BRAZIL should limit its nuclear power programme to the one US (Westinghouse) reactor now operating, "study" the two West German (Kraftwerk-Union) reactors under construction and take more account of the environmental and social consequences of its grandiose hydroelectric schemes, according to a report prepared by Brazilian physicists and delivered to both houses of the Brazilian parliament late last month.

The physicists are still smarting from their anger at not being consulted when, in 1977, the previous military regime drew up plans with Kraftwerk-Union and others for an eight-reactor grid and a complete nuclear fuel cycle. They now say that the West German deal should effectively be cancelled.

The physicists are thus seizing the opportunity to shift the directions of Brazilian energy policy, now that Brazil has its first civilian elected president for some years, Señor Tancredo Neves. Neves made a cut-back in the nuclear programme part of his election platform—and the idea may have appealed to the electorate partly because the principal nuclear power construction site is at Angra dos Reis, on a beach between São Paolo and Rio de Janeiro in the middle of a popular resort region.

A response to the physicists' proposals has, however, been complicated by Neves's illness (he has had four intestinal operations in the past three weeks) which overtook the 75-year-old president-elect before he or his government could be sworn in. It is likely to be six months before Neves is fit to govern, and in the meanwhile few major policy changes are expected in Brazil.

Nevertheless, Neves has unofficially nominated to the new post of energy minister Dr José Israel Vargas, a physicist who specializes in energy matters and was prominent in Brazil's alcohol fuel (gasohol) programme. Vargas was involved in most of the previous military government's energy projects and is said to understand the economic pressures that led the military to commit Brazil to hydroelectric and nuclear power.

In the mid-1970s, the Brazilian economy in the south-east was growing at up to 12 per cent a year, and the national utility FURNAS sought an 11 per cent annual growth in production. Plans were made for 60 nuclear power plants to produce 75 GW by the year 2000, and construction began of one of the world's largest hydropower complexes on the border with Paraguay.

Brazilian physicists complain that the military's energy plans were made without any democratic consultation, and imply also that there was a hidden defence objective in the agreement with West Germany.

More sanguinely, a Brazilian government official said that "there was then great euphoria and trust in the future". Now the economy has slumped and atomic energy "doesn't make much sense".

The physicists' report, prepared at a meeting chaired by Dr Luigi Pinguelli Rosa of the University of Rio de Janeiro and attended by the president of the Brazilian physical society, Professor Fernando Souza Barros, and the chairman of São Paolo Electric Power Stations Limited, Professor José Goldenberg, recommends that the new government should:

- Cancel the agreement between the Brazilian nuclear power agency, Nuclearbras, and West Germany for "joint enterprises".
- Stop the construction of nuclear reactors outside Angra dos Reis, and "study" the continuation of construction of the two German reactors at that site.
- Question the effectiveness of the jet nozzle uranium enrichment supplied by West Germany.
- Restructure the Brazilian nuclear sector to make it more accountable and "civilian".
- Re-examine Brazil's nuclear future by open debate.
- "Give priority" to social and environmental considerations in the planning of future energy projects, particularly nuclear and hydroelectric stations.
- Take dam construction out of the exclusive hands of the electric utilities.
- And take account, in a democratic way, of the effects of dams on local populations and the local environment.

Robert Walgate

Gifts to universities

Threat from US tax reforms?

Washington

PRIVATE universities in the United States, which each year receive close to $3,000 million in charitable contributions from individuals, have been among the loudest to complain about US Treasury proposals for tax simplification that would reduce the allowable charitable deduction.

Congress has yet to take up tax reform seriously; but already an academic squall has broken out over the extent to which donors are truly influenced by tax considerations.

Under the Treasury proposal, charitable contributions would be deductible against income only to the extent that they exceed 2 per cent of the taxpayer's gross income. In addition, donations of non-cash items, such as real estate, art works and stocks, would receive far less favourable tax treatment. At present, the full appreciated value of such property can be claimed as a tax deduction, but under the proposal, the donor could deduct only the purchase price plus an allowance for inflation or the fair market value—whichever is lower.

According to a study made by Professor Charles Clotfelter of Duke University at the request of the Association of American Universities, overall contributions to universities by individuals would fall to 72 per cent of the present level if the Treasury proposal became law. Yet both the universities and those who challenge predictions such as Clotfelter's agree that the most damaging effect of the Treasury proposal would stem from the proposed lowering of the highest marginal tax rate from the current 50 per cent to 35 per cent. Instead of receiving 50 cents off of his tax bill for each dollar given, the wealthy taxpayer would receive only 35 cents off. This has placed the universities in an awkward spot: they can hardly be seen to lobby for higher tax rates.

The universities are thus taking the line that the damage inevitably done by lowering rates should at least not be made worse by further restricting charitable deductions. And they are especially concerned about the treatment of non-cash gifts, which account for 40 per cent of their contributions (and a proportionately higher share of contributions from the wealthiest donors). The universities estimate that the Treasury proposals would effectively double the "cost" to donors of such gifts.

A more fundamental question is whether the "cost" of giving matters to donors—particularly wealthy donors. Bruce Davie, chief tax economist of the House Ways and Means Committee, has recently identified an increase of donations by high-income taxpayers over the period 1975 to 1983, despite the reduction of the highest marginal rate from 70 per cent to 50 per cent in 1982.

Clotfelter, in an article to be published shortly, responds that the taxpayers in question had an 86 per cent increase in after-tax income, in constant dollars, during the same period but that their contributions went up by only 23 per cent in constant dollars. The universities are also attempting to prove their case by pointing to a sharp drop in contributions by taxpayers with gross incomes in excess of $1 million after the lower marginal rate went into effect in 1982; average contributions among this group fell from $205,000 to $145,000 in that one year.

Stephen Budiansky

When does life begin?

SIR — The widespread notion "that human life begins at conception" is not based on scientific evidence as J.R. Ling (*Nature* 24 January, p. 262) implied. It results from misleading oversimplifications and misconceptions about the biological basis of human individuality.

That our personal individuality develops after conception is conclusively shown by the natural occurrence of identical twins, triplets and so on. A fertilized egg is not yet "a potential human being" as J.R. Baker (*Nature*, 14 February, p. 524) puts it; left undisturbed, it may instead develop into several human beings, or even more commonly spontaneously abort without producing any. Because the timing of the split of the cell mass that produces identical twins is quite variable, no exact time can be given for the "start" of their individual human bodies — but it is always many days after conception.

If what we are interested in is not the start of individual body form, but the personality of individual humans (surely more important), this develops much later — only after the formation of the nervous system. Consciousness and a sense of self seem to develop only after birth and growing experience of the outside world.

If the vague term "human life" refers not to any of these features of the life of the individual but to human life in general, then this had no clear starting point at all in our gradual evolution from apes.

The notion of giving protection to all *potential* humans is an argument against contraception that would condemn us to gross overpopulation and misery. What we should protect vigorously are *actual* individuals possessing human feelings. The consequent legal and ethical necessity to choose a sensible dividing line at which such protection should be given must inevitably be somewhat arbitrary because of the gradualness of development. It is a fallacy to suppose that biology provides an easy answer to the problem.

TOM CAVALIER-SMITH
School of Biological Sciences,
University of London,
King's College,
26-29 Drury Lane,
London WC2B 5RL, UK

SIR — The leading article of 21 February (p. 612) asks ". . . who can object to the proposition that there can be no such thing as a human being without implantation?"

Let us examine how such a conclusion can be reached, beginning with some default assumptions about the meanings of the words used. Human life begins at conception (conception = the beginning of life), commonly taken as occurring at the moment of fertilization, the adjective "human" denoting the fact that both sperm and ovum are of human origin. Human life, in order to proceed, requires implantation; this also is not disputed. Having proceeded by means of this process, the life in question develops to a greater degree of complexity and, in due course, is (normally) born. At this point we are running into trouble because the same words ("human life") are used both before and after implantation. We must therefore define our terms carefully, as follows; the words "human being" must refer only to human life which has at some stage been carried in its "mother's" womb; from this your conclusion follows easily. But perhaps this is not good enough, for as is well known, a baby cannot become a living person unless cared for by adults (if we define our terms carefully), on whom he/she also depends for "emotional and physical security".

On the other hand, perhaps all this playing around with words is idle sophistry. One could as well say that human embryos are not persons because a person is a human being with full rights under law which a human embryo plainly does not possess. Obviously, it follows that not all human beings are persons.

What is to be gained by all this? The following; the public will become confused, Parliament will produce legislation riddled with loopholes, research will thereby go on and human embryos will continue to be subject to experiment and destruction.

Sir, you do science a disservice.

Sequence data

SIR — A national service for the retrieval and analysis of nucleic acid and protein sequences is being supported by the Medical Research Council (MRC) and is available to academic workers in the United Kingdom. The service is based on 4 databases which are regularly updated : the EMBL Nucleic Acid Sequence Library (currently 2.1 million bases); the GenBank Nucleic Acid Sequence database (currently 3.3 million bases); the Protein Information Resource (0.5 million amino-acid residues) and the NEWAT Library of Doolittle[1]. Computer programs are available for database searches[2] and for the analysis of individual nucleic acid and protein sequences[3,4]. The Staden programs[5,6] for the experimental determination of DNA sequence have also been implemented. The service provides documentation of the databases and programs, help-files and facilities for communication within the user community[7]. There are currently some 50 scientists located at 15 sites throughout the United Kindom accessing the databases.

The service was established in collaboration with scientists from a number of departments at the University of Cambridge, particularly Dr M. Ashburner and Dr M. Bishop, and with the MRC Laboratory for Molecular Biology. The databases and programs are mounted on the IBM 3081 computer, maintained by the University of Cambridge Computer Service, and there are plans to mount them also on a VAX computer. The databases can be readily accessed through the Joint Academic Network (JANET) or through PSS from any location in the United Kingdom. Those interested should contact me or Dr Geoff Kneale at the address below (telephone: 0223 66499) for further information.

Rings of light

SIR — Readers of *Nature* who look for intriguing optical phenomena in the world around them will have enjoyed Professor Thomas Gold's observation of puzzling relections in water[1]. He will, I am sure,regard it as a shared enthusiasm, and not a criticism, if I point out that others have observed and recorded these twists and loops too.

Minnaert's book[2] contains at section 14 ("Irregular reflection on slightly rippling water") a general bibliography stretching back to 1840, and he says of his own Fig. 17 "Remarkable is the appearance of closed coils of light . . ."

The most comprehensive discussion is perhaps in a book by Sir Montagu Pollock[3] published in 1903. His chapter on "Reflections in rippled water" outlines the geometry, though more particularly of the reflection of horizontal spars rather than of vertical masts. His book is illustrated with many plates by the Yorkshire marine photographers F.M. Sutcliffe and C.E. Wanless, who were fascinated by just such reflections of ships seen in the waters of Whitby and Scarborough harbours: Sutcliffe's Plate XXV is remarkably similar to Professor Gold's, and his Plate XXXV is appropriately titled by the artist "Rings".

Monitoring quantum jumps

A neat theoretical calculation shows how to monitor the state of a simple model atom without interfering with its quantum state. But Heisenberg's principle remains intact.

IF Heisenberg's uncertainty principle means anything at all, it must surely mean that it is impossible to keep a continuous record of the transition of a quantum system, say an atom, between two distinct quantum states. That is the general expectation. Suppose, for the sake of argument, that a particular atom may be found in one of only two states, a ground state and an excited state, and that some measurement is carried out to establish which state is occupied. The result is certain to be that the measurement will interfere with the system. Ordinarily the atom will be left in the condition that the measurement reveals, at least until something happens to shift it into the other state. So an ambition to monitor the state of the atom continuously would seem to conflict with these familiar expectations.

But, it seems the outlook may not be that unpromising. Richarch J. Cook of the United States Air Force Institute of Technology at Dayton, Ohio, and H.J. Kimble of the University of Texas at Austin, have devised what seems to be a neat way around the difficulty (*Phys. Rev. Lett.* **54**, 1023; 1985). Their proposal hangs on the techniques by means of which it has now become possible to confine single atoms (strictly, ions) in a small region of space by means of electromagnetic traps of various kinds (of which the Penning trap is the prototype). Spectroscopists nurse ambitions to use such traps as ways of carrying out spectroscopy with single atoms. Cook and Kimble's proposal for the direct observation of quantum jumps is one such application. To be fair, the authors do cautiously use the word "possibility" in the title of their paper. They go on to add that the effect which they predict has not yet been observed, "but probably will be in the near future".

This is how the proposed Cook/Kimble experiments would work. The first need is for an atom with two excited states which are connected to the ground state by transitions that are respectively strong and weak. Put one such atom into a Penning-like trap (which is naturally easier said than done) and illuminate it with a laser with a frequency which corresponds to the excitation energy between the ground state and the strongly coupled excited state, and measure the intensity of the fluorescence radiation of the same frequency which is given off by the single atom. What happens is merely that the atom is repeatedly excited (by the laser beam) and de-excited (by spontaneous radiation emission). If the ground and excited states are indeed strongly coupled, the rate of emission of fluorescence radiation can be as much as 100 million photons a second, well within the capacity of radiation detectors. And while, as Cook and Kimble say, the fluorescent signal will in reality be a succession of quantum events, there will be no difficulty in recording this as steady current in, say, a photomultiplier system. That is the first step.

Next, take a laser whose frequency corresponds to the energy difference between the ground state and the other excited state, that to which the ground state is only weakly coupled, and simultaneously illuminate the single atom with that as well. The predominant process will be the repeated excitation and de-excitation of the strongly coupled state, but occasionally the weak excitation will be excited instead. And when that happens, the electron whose oscillation into and out of the strongly coupled state is responsible for the main fluorescence signal will be out of action, marooned in the weakly coupled state instead. And since the coupling is weak, the main fluorescence signal will be turned off for the length of time the electron stays in the weakly coupled state. So the output from the photomultiplier circuit will consist of a series of signals corresponding to the full value of the strong fluorescence punctuated by gaps when the signal vanishes, and which correspond to the times when the weakly excited state is occupied. That, then, is the running record of when the weakly excited state is occupied. The signal from the photomultipliers will be, for all practical purposes, like telegraph signals in which the dots and dashes have random length. There will be no difficuly in interpreting the record with macroscopic measuring devices — the output signal can be drawn on a moving paper chart and interpreted by eye, if need be.

Cook and Kimble attribute the origin of their neat proposal to H. Dehmelt, who is said to have suggested a scheme rather like this in the context of the detection and measurement of weakly coupled optical transitions. Their own chief purpose is to provide a theoretical calculation of the details of the effects of competitive excitation within their three-level model atom on the fluorescent signal eventually produced, and in particular to calculate the statistical properties of the gaps in the fluorescence signal in terms of the parameters describing the two transitions.

The argument follows a now familiar line. The rate of excitation of each state is determined by the Einstein parameters from each transition, that which determines the rate of spontaneous emission (conventionally labelled A) and that which determines (with the intensity of the exciting radiation) the rate of excitation (labelled B). Cook and Kimble simplify the algebra somewhat by supposing that the light exciting the strongly coupled transition is intense enough to saturate the single atom (so that, if the weakly coupled excitation did not exist, the atom would spend exactly half of its time in the ground state and the excited states). The practical problem is merely to calculate the probability that the fluorescence signal due to the strong transition will persist for a length of time, say T. Inevitably, the results all depend on the Einstein parameters for each transition, but their practical value is that they involve the Einstein A parameter representing the rate of spontaneous de-excitation of the weakly-coupled state, a quantity that is not easily determined by conventional measurements.

This neat recipe for an experiment not yet carried out will obviously spur on the single-atom spectroscopists. On the assumption that the result is that which has now been predicted, the question obviously arises of the sense in which Heisenberg's uncertainty principle must be qualified. Fortunately, a little reflection will show that the question is a red herring. The underlying assumption in what Cook and Kimble have done is that the rate of transition between the ground state and the strongly coupled excited state is very much greater than the rate of transition to the weakly-coupled state. Moreover, there is no way in which this system could be used for arranging that the atom is excited one way or the other to order, for the state of the atom at any time is determined by strictly random processes.

So despite this apparent assault, the uncertainty principle remains intact. What does, however, emerge from this neat piece of experimental design is a vivid illustration of the interesting things that will be possible when single-atom spectroscopy moves into the laboratory, which should not be much delayed.

John Maddox

Cellular immunology

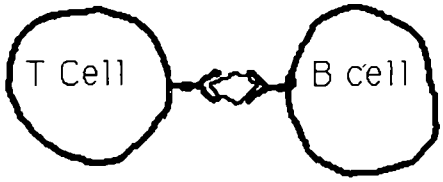
Immunological help at last

from Jonathan C. Howard

AN opportunity to celebrate the end of nearly twenty years of ignorance about an essential immunological relationship is provided by the paper of Lanzavecchicia on page 537 of this issue[1]. The relationship is that which forms between T cells, B cells and antigen molecules when T cells provide help to B cells during the induction of antibody formation. The conceptual significance for cellular immunology of what has now been accomplished is difficult to overstate since T-cell help provides the paradigm for all specific regulation of the immune response. Perhaps the best evidence that something important has happened recently is that the two best up-to-date textbooks[2,3] contain no hint of the elegant and, I will risk saying, certainly correct model that I am about to describe.

In Burnet's clonal selection theory, each clone of lymphocytes was autonomous, distinguished from others by the specificity of its cell-surface receptor for antigen. In theory, the selecting power of antigen alone was sufficient to define lymphocyte clones destined for antibody synthesis. However, the 'autonomous' model of antibody induction had to be abandoned as a result of pressure from two directions. First, Burnet's 'lymphocytes' were shown to consist of two developmentally independent and functionally distinct lineages of cells. In particular, thymus-derived (T) lymphocytes never turned into antibody-producing cells, whereas marrow-derived (B) lymphocytes did so, but only if T lymphocytes were also present. T-helper cells therefore somehow helped B cells to make antibody. Second, it became clear that T cells made an antigen-specific contribution to B-cell induction from studies on the structural properties required for antigens to be immunogenic. For an antibody to be raised in animals against any defined small determinant or hapten it had to be attached to a carrier molecule that was an immunogen in its own right. In a series of influential experiments, Mitchison[4] showed that the requirement for T-helper cell in the induction of antibody responses against hapten-carrier conjugates resulted from the obligatory recognition by T cells of antigenic determinants on the carrier. In addition, hapten and carrier had to be linked on the same molecule. To accomodate these facts, Mitchison proposed the antigen-bridge model for T-cell help (Fig. 1), in which the antigen is bound through a haptenic determinant to the B-cell receptor, which is immunoglobulin (Ig) and is simultaneously bound through a carrier determinant to the T-cell receptor. For over a decade this model has provided the only accessible mental image of antigen-specific T-B collaboration.

It was 'MHC restriction' that ultimately destroyed the antigen-bridge model. It is an operating principle of the immune system that T cells can recognize and be activated by antigen only when the antigen is associated with a molecule of the major histocompatibility complex (MHC) on a cell surface. It was shown first by Katz *et al.*[5] (in a remarkable experiment that anticipated by quite some time the conceptual advances needed to explain it fully), and subsequently by others, that antigen-specific T-B interactions are MHC restricted in just this sense. To visualize the structural basis of such interactions, it was supposed that the antigen specific T-cell receptor forms an antigen bridge with the B cell, as in the Mitchison model, while a hypothetical second T-cell receptor binds independently to MHC molecules expressed



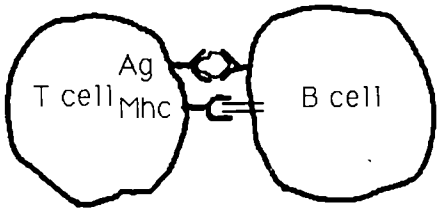


Fig. 1 Antigen-bridge model. The T cell binds to a carrier determinant on the antigen, the B cell binds to a distinct haptenic determinant.

Fig. 2 Modified antigen-bridge model, incorporating MHC restriction. The T cell is given a second receptor (Mhc) with which to bind B-cell Ia molecules. The T-cell receptor for the antigen (Ag) is the same as in Fig. 1. Sometimes the two independent binding sites for Ia and antigen are shown as attached to the T cell via a single stem.

on the B-cell surface. It is an interesting commentary on the importance of the visual imagination that this dual-receptor image (Fig.2) should have persisted at a time of general acceptance that MHC-restricted T-cell recognition of antigen is mediated by a single receptor with a single combining site[6]. It has, however, been difficult to see how, with a single receptor, a T-helper cell could first be activated by antigen associated with an MHC molecule on a presenting cell, and then deliver help in an MHC-restricted manner to a B cell bearing the antigen in its Ig receptor. For a single receptor, how could the structure antigen + MHC be equivalent to the structure antigen + Ig + MHC?

The resolution of this paradox began when Benacerraf[7] pointed to strong circumstantial evidence that protein carriers were not normally in their native configuration when they were recognized in an MHC-restricted manner by T-helper cells. Both he and Unanue[8] suggested — and it was later demonstrated[9] — that native antigen is taken up by phagocytic cells, partially degraded and then returned to the cell surface as peptide fragments in association with MHC class II molecules (H-2 Ia in the mouse, HLA-DR in the human). This complex then stimulates specific T-helper cells. Similar peptide/Ia associations could exist on B cells and be recognized by active T-helper cells. Furthermore, the Ig receptor of B cells should concentrate specific antigen on some B cells rather than others.

The clearest early formulation of the new model that I know is from Uhr and his colleagues[10]. If T-helper cells recognize Ia-associated fragments of carrier antigens presented on macrophage surfaces, they wrote in 1980, "this presumption implies that the B cell can only be specifically helped by a T-helper cell if a similar antigenic fragment is presented by the B cell. Thus, we could hypothesize that the B cell can pinocytose and degrade antigen like the macrophage. The only difference would be that Ig receptors for specific native antigen equip the corresponding B-cell clone with a means for capturing antigen which is then processed and presented by the B-cells' Ia antigens to the T-helper cell."

This new model of antigen-specific help, represented in Fig.3, has been substantiated by some particularly striking and elegant experiments, of which Lanzavecchia's, on page 537, represent the culmination. It has been crucial to show that the B-cell Ig receptor functions as an antigen-concentrating device, rather than an antigen-presenting device, for specific B cells. Grey and colleagues were the first to show that molecules captured by B-cell Ig receptors can be efficiently presented to T cells[11]. They went on to show that B-cell lymphomas can internalize and process non-specifically-bound antigen, and re-present it in the form of peptide fragments to MHC-restricted T-helper cells[12].

These important experiments fell short of demonstrating that specific antigens captured by the B-cell Ig receptor normally are processed and re-presented in that way. Last year, Rock *et al.*[13] found that TNP-specific B cells, purified from an immune spleen, could present a TNP-carrier conjugate to carrier-specific helper T cells; a strikingly low concentration of conjugate was required compared with that required for presentation by unselected normal B cells. These results showed, for the first time, that specific antigens captured by the Ig receptor are ultimately presented very efficiently to T cells: what they did not prove is that antigens thus captured are processed before presentation.

Lanzavecchia has finally settled the issue using antigen-specific T-cell and B-cell clones from the same individual and prepared against the same antigen, tetanus

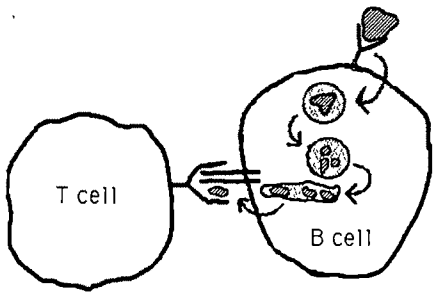

Fig. 3 The new model. The T cell only has one receptor, which recognizes a complex of processed antigen and Ia molecule on the B-cell surface. Antigen processing is initiated by attachment of native antigen to the Ig receptor.

toxoid (TT). The B-cell clones, transformed by Epstein-Barr virus, possess Ig receptors with affinity for TT and present TT in an MHC-restricted manner to TT-specific T-cell clones. In terms of free antigen concentration, TT capture by the B-cell Ig receptor is approximately four orders of magnitude more efficient than non-specific uptake of TT. Lanzavecchia shows that the Ig receptor is involved only with antigen capture, and not directly with antigen presentation, by separating the two events in time. B cells are pulsed briefly with antigen, washed and then allowed to present the antigen to T cells: while the uptake of antigen during pulsing can be prevented by an antibody to Ig, the same reagent has no effect on the ability of pulsed B cells to present antigen to T cells.

As the new model requires, uptake of the TT is not enough for its presentation to T-helper cells; the antigen must also be internalized and processed. Thus, uptake is followed by a stage which is sensitive to the lysosomotropic agent, chloroquine, already known to prevent antigen processing[14]. After this stage, antigen-pulsed B cells can be fixed with gluteraldehyde and still present antigen to T cells. By analogy with other work[12], the fixative-resistant state occurs when processed derivatives of the antigen have been returned to the cell surface and have become associated with class II MHC molecules.

Although the haptenic determinant plays no necessary role at the time when help is delivered to the B cell, and although antigens are digested into peptides before presentation, the requirement of hapten-carrier linkage is satisfied by the new model. Only B cells with a receptor for determinants on the native molecule can present carrier determinants efficiently to T cells.

As long as antigen-bridge models were current it was assumed that if the B cell recognized one part of the molecule, then the T cell must recognize another, so that both could bind together to form the antigen bridge. In the new model this condition disappears completely. B cells of any specificity that can bind and internalize an antigen can presumably receive help from any T cell that can recognize the processed form of the molecule.

Like Grey and Rock, Lanzavecchia assays the response of T cells to antigen presented by B cells. For help, it is clearly the response of the B cells to T-cell recognition that counts. Lanzavecchia has recently shown (personal communication) that EBV-transformed B-cell clones respond to antigen-specific interaction with T cells. In the same antigen dose range that stimulates T cells, specific T-cell clones induce what seems to be terminal differentiation in the EBV clones; cell division is arrested and immunoglobulin release increases.

The quantitative implications of the new findings give as much pleasure as the qualitative. Both Rock *et al.* and Lanzavecchia show that B cells can accumulate and present immunologically significant antigen with an external concentration in the range of 10^{-12} M, which is low enough to be physiologically meaningful. In Lanzavecchia's case, the affinity of the B-cell receptor for TT is about 10^{-8} 1 mol^{-1}. At an external concentration of 10^{-12} M, the mean occupancy of the B-cell receptor by a univalent ligand such as TT would be about 0.01 per cent, or about 10 molecules per B cell with 10^5 Ig receptors. Surely this is not enough to process and present to T cells. An attractive solution to this paradox is that continuous receptor recycling allows specific B cells to accumulate processed material. Clearly, this option, which I call 'pumping', is not available to B cells in an antigen-bridge model. In confirmation of the pumping hypothesis, Lanzavecchia has now shown (personal communication) that it takes longer for B cells to acquire the ability to stimulate T cells, the lower the external concentration of antigen.

Lanzavecchia's experiments are a considerable achievement. The clarity and elegance that come from studying the interaction between two antigen-specific clones are bought at a high price in technical skill. Nor are there many experiments in cellular immunology of such great pedagogic value as these, which display so accurately the formalism that they are intended to represent. It is a special bonus that these experiments are with human, not rodent, cells.

I do not doubt that the new model is essentially correct. There are however, unresolved problems of considerable interest. Does the binding of antigen to the B-cell receptor deliver a necessary differentiative signal to the B cell, or does the B-cell receptor function only to capture antigen? How is the recognition of processed antigen-MHC complexes transduced into a differentiative signal for the B cell (or, indeed, for the T cell) and what is the causal relationship between this signal and isotype-switching? To what extent does B-cell proliferation and differentiation depend on the availability of non-specific (in an immunological sense) growth factors of either T-cell or B-cell origin? These are important questions but none, surely, so central to immunology as the one that has finally been settled. □

Gamma-ray astronomy

How much H_2 in the Milky Way?

from Leo Blitz

ON PAGE 511 of this issue Bhat *et al.* deliver a new salvo in a battle that has been raging among astrophysicists since 1980 over how much molecular hydrogen there is in the Milky Way. The crux of the issue is how to convert observed line strengths of the CO molecule into absolute quantities of molecular hydrogen; Bhat *et al.* argue for a lower quantity than any yet published.

The debate has been fierce, emotional and at times has degenerated into *ad hominem* attacks. But why so much bile over such a seemingly esoteric quantity? The reason is that the real issues are much larger astrophysical questions such as: how, when and why do stars form in a spiral galaxy; why do spirals look different from one another; and how do these spiral galaxies evolve?

The source of the controversy dates to the years around 1970 when millimetre-wavelength radio astronomy was in its infancy. A plethora of molecules was discovered in the interstellar medium, including water, ammonia, formaldehyde, carbon monoxide, ethyl alcohol and a number of molecules not observed terrestrially. It was quickly demonstrated that excitation of the key species implied collisions by neutral hydrogen molecules at high density (by interstellar standards) and at a temperature as low as about 10 K. The problem is that when the gas is cold, molecular hydrogen does not emit an observable quantity of radiation and therefore cannot be directly observed. In-

stead, its presence has to be inferred from trace constituents with abundances at most 10^{-4} that of H_2. The most widely used tracer is CO because it is the easiest to observe, but estimating H_2 masses from CO observations is like estimating the weight of a dog from the number of hairs on its tail. To make matters worse, CO is an optically thick molecule; the strength of its radio-spectral lines is more closely related to the temperature of the gas cloud than to how many molecules are radiating.

Two significant discoveries in the mid-1970s emphasize the importance of obtaining accurate H_2 masses from the CO observations. The first is the ubiquity of CO in the plane of the Milky Way, implying that a significant fraction, perhaps most, of the interstellar gas is H_2 and not atomic hydrogen (H I), which previously had been thought to be the reservoir of the star-forming gas. The second is that essentially all present-day star formation takes place in giant molecular clouds, which have masses of about 10^5 solar mases and are composed almost entirely of H_2 (but detected by radio observations of CO). Therefore, the question of star formation on a galactic scale was reduced to the question of how giant molecular clouds form. Do they, for example, condense from the atomic gas, or do they form from the collisional accretion of small molecular clouds without the mediation of an atomic phase? Important clues were to be found in the relative amounts of H_2 and H I. (Ultimately the answers can be applied to studies of other spiral galaxies. The evolution of the disk of a galaxy is essentially its star-formation history, which in turn is largely the history of the giant molecular clouds.) The results of the first CO surveys of the galactic plane implied that between the galactic centre and the position of the Sun, which is about half-way out, the interstellar gas is overwhelmingly molecular. One study suggested it contained ten times as much H_2 as H I, which in turn implied that atomic gas is largely irrelevant to the formation of giant molecular clouds, but these conclusions were quickly challenged by several groups who argued that the molecular phases are about equal in abundance inside the solar distance. In that case, instabilities in the atomic component are likely to play an important role in the formation of the giant molecular clouds.

The different estimations have been largely the result of using different ratios to convert CO line strengths to H_2 column densities, and also to the importance of temperature and heavy-element abundance variations in the Milky Way. New light has been shed on this subject by gamma-ray astronomy. It was established in the 1970s that diffuse high-energy gamma-rays (> 50 MeV) come primarily from the interaction of cosmic rays with the interstellar gas. If the gamma-ray emissivity of the gas can be determined, the number of hydrogen nuclei in a column along a given line of sight can be obtained from measurments of the gamma-ray intensity. The contribution to this intensity from atomic hydrogen is known from 21-cm line observations; the remaining contribution must therefore be from molecular hydrogen (corrections due to helium and other trace constituents are straightforward). In principle, this approach is the most accurate way to determine the H_2 from CO, because the gammas rays directly trace the dominant component of the gas — hydrogen — independently of excitation and abundance variations in the CO.

Interpretation of the gamma-ray results has not been without its problems, however. Initially, the results from the US SAS-2 satellite and the European COS-B satellite were not in agreement — a large and difficult to determine instrumental background for COS-B seems to have been the culprit — and other technical problems with the data analysis have only recently been solved. Nevertheless, the quantity of molecular hydrogen in the Milky Way reported by the Durham group on page 511 of this issue is still half that derived by the Caravane collaboration, which launched COS-B. The groups agree, however, that the gamma-ray data unequivocally imply that the H_2 does not dominate the H I inside the solar distance.

More H_2 would simply produce more gamma rays than are observed. The work of the Durham group implies that nowhere in the Milky Way does the H_2 surface density dominate that of the H I. In the published work of the Caravane collaboration, H_2 may dominate weakly within a small range of distance from the galactic centre. The residual difference between the two groups probably results from systematic uncertainties that increase the formal erros assigned to the data by Bhat *et al.* A new sophisticated analysis by the Caravane collaboration using the most extensive available data sets is forthcoming and should shed additional light on this nagging astrophysical controversy. □

100 years ago

THE way in which a bird builds its nest, seemingly without instruction, has been brought forward as a proof of blind instinct governing it in its task. A remarkable instance, however, of a changed mode of nest-building has been brought to my notice by Mr W. Burton. His brother took to New Zealand some young chaffinches. Some of the birds have built a nest, and the structure shows very little of that neatness of fabrication for which the bird is noted in England. The cup of the nest is small, loosely put together, and the walls of the structure are prolonged for about eighteen inches, and hang loosely down the side of the supporting branch. Clearly these New Zealand chaffinches were at a loss for design when fabricating their nest.

From *Nature* 31 533, 9 April 1885.

Evolution

Interpretations of mass extinction

from Michael J. Benton

IT IS becoming clear that the history of life has been punctuated by a series of events during which, typically, an apparently random selection of organisms died out. These mass extinction events can be seen to have 're-set' the evolutionary clock: they wiped out whole families or orders of plants and animals, irrespective of the darwinian fitness of the individual organisms or of the species involved, and created opportunities for the survivors to radiate out into the 'empty' ecospace that was left. The recent suggestion that mass extinctions might be cyclical in occurrence is important because it raises the possibility of identifying one kind of explanation for all mass extinctions through time, whether or not the events have a regular periodicity and whether the ultimate causes are terrestrial or extra-terrestrial. These ideas have important implications for evolutionary biology and for historical geology.

The most important recent impetus to the discussion of the causes of mass extinctions has been the suggestion of Raup and Sepkoski[1], from their analysis of the fossil record of marine animals, of a regular periodicity of about 26 Myr to mass extinctions over the past 250 Myr. Hallam[2] has pointed out how uncertainties in dating of mass extinctions, especially before the late Cretaceous, weaken the claim of regular periodicity, but the suggestion remains a very important one and is having a considerable influence on the ways in which we may interpret a cyclical pattern of mass extinctions.

Four interpretations of the cyclicity are possible and worth considering. The first two are deterministic and the other two stochastic viewpoints: (1) each extinction event was triggered by the same external impulse, acting directly; (2) the cyclical pattern of extinction events correlates with some physical phenomenon that follows the same cycles (for example, fluctuations in temperature or sea level), and these are controlled by a third external variable; (3) the events are caused by a variety of factors that relate to the internal dynamics of the biological system; (4) the apparent cyclicity is an artefact of the patchiness of the fossil record.

The first interpretation is favoured by Raup and Sepkoski and their followers, who suggest an extraterrestrial cause for the periodic mass extinctions. Three main schools of thought have sprung up. The

first is that a hypothetical companion star of the Sun (called Nemesis) disturbs the Oort cloud and sends a shower of comets hurtling towards Earth every 30 Myr[3,4]. The second is that the whole of the Solar System oscillates through the galactic plane with a semi-period of 30 Myr and periodically scatters Oort cloud comets into the terrestrial zone[5-7]. The third idea is that the unknown Planet X, located beyond the orbit of Pluto, follows an eccentric path which causes it to disturb a comet belt beyond Neptune and precipitate a shower of comets, some of which would eventually reach the Earth, every 28 Myr[8]. These astronomical theories are still highly speculative and controversial (see *News and Views* 7 March p.17).

The second interpretation, that cycles of mass extinction correlate with cycles in terrestrial phenomena, has been the generally held view for some time. Fischer suggested that the Earth has passed through cycles of different orders of magnitude[9,10], the largest of which each lasted about 300 Myr and began with rapid convection in the mantle. This led to the break-up of Pangaea-like supercontinents, elevated sea levels and marine transgressions, intense vulcanism, release of CO_2 to the atmosphere and the development of a greenhouse climate, resulting in worldwide warm conditions and warm seas. Such episodes occurred from late Cambrian to late Devonian and early Jurassic to late Eocene.

The second phase of each 300-Myr supercycle was characterized by low mantle convection, continental accretion, low sea level and regression, reduced atmospheric CO_2 and the development of an icehouse state. This gave high latitudinal climatic gradients, cold dry polar regions and cold oxygenated ocean waters. These conditions characterized the latest Precambrian to early Cambrian, the late Palaeozoic to Triassic and the latter half of the Cenozoic, in which we still live. The crossovers from greenhouse to icehouse correspond to mass extinctions in the late Cambrian (500 Myr), the late Devonian (355 Myr), the late Triassic (192 Myr) and the late Eocene (40 Myr). These crossovers are about 150-Myr apart, giving a span of 300 Myr for the full cycle. This model does not explain the terminal Permian and the terminal Cretaceous extinction events.

Fischer also described two classes of shorter-range cycles in tectonic activity and world climate[9,11], one set occuring every 30 Myr and the other consisting of smaller climatic cycles in the range 20,000-400,000 years, which are induced by orbital pertubations. The 30-Myr cycles are reflected in temperature fluctuations, variations in carbon isotope ratios and in the fossil record of planktonic and nektonic taxa.

Newell[12,13] and Hallam[14,15] have argued that sea-level changes are the most important prime cause of mass extinctions, thus laying the main emphasis on one segment of the Fischer theory. Sea-level changes have exhibited a cyclicity on several scales through the Phanerozoic and many of the well-known mass extinctions correlate well with worldwide episodes of regression. In general terms this usually coincides with a reduction in the area of diversity of continental shelf habitats, and in some cases (for example, the end-Pliensbachian, end-Cenomanian and possibly the end-Triassic, late Devonian and end-Ordovician events) with periods of oceanic anoxia, as recorded by extensive black shale deposits.

The other-kind of terrestrial explanation, which modifies part of Fischer's thesis and relegates sea-level changes to a minor role, emphasizes changes in temperature. This has been championed recently by Stanley[16-18]. He notes evidence of global episodes of cooling that coincide with mass extinctions in the late Eocene and the Plio-Pleistocene and hints at evidence for temperature changes linked to earlier mass extinction events (it becomes harder to pin down temperature changes the further back in time one goes). Stanley supports this thesis with the fact that mass extinctions have frequently been concentrated in the tropics, which became a refrigerated trap into which high-altitude forms migrated and were then wiped out. He also argues that the long periods of time that characterize most mass extinctions accord more with a gradual change in temperature than with a catastrophic change brought about by an exterrestrial agent.

If, however, cyclicities in geological processes should turn out to have regular periodicities, an extraterrestrial cause will have to be considered. Has the time come with the discovery by Rampino and Stothers[19] of two dominant periodicities, of about 33 and 260 Myr, in a time-series analysis of various geological phenomena (sea-level fluctuations, sea-floor spreading discontinuities, tectonic activity, geomagnetic reversals)? These correspond to the two major orders of cyclicity identified by Fischer, Rampino and Stothers suggest they were caused by periodic comet impacts. The issue at stake is clearly the evidence for regular periodicity in geological processes, which has been questioned (see *News and Views*, 7 March p.17).

There are important philosophical consequences if we accept some or all of these aspects of regular cyclicity in mantle, plate-tectonic, eustatic, atmospheric and climatic processes and their concomitant effects on the history of life. Periodicities of these kinds would form a part of Charles Lyell's interpretation of Uniformitarianism which has generally been abandoned[20]. Lyell believed that there were constant changes on the Earth, but that these cycled endlessly and with no direction. He would not accept the idea of progressionism in the history of life, believing instead that any life form could exist at any time if the conditions were right: thus he expected to find Silurian mammals, or dinosaurs, at some future time. This anti-progressionist stance was ignored or abandoned by most other scientists during Lyell's lifetime, and the idea of uniformity of conditions has also not found favour. Now it must be reconsidered if we accept that most major processes on the Earth have followed, and continue to follow, long-term cyclical patterns.

The third interpretation of cyclical mass extinctions — that they arise from the internal dynamics of the biological system — has recently received support from Kitchell and Pena[21]. Attempting to fit different time-series models to the extinction curve of Raup and Sepkoski, they find that the best statistical fit is a stochastic time-series model that shows 'pseudocycles' every 31 Myr. This model takes account of the observed spacing and the relative magnitude of each peak of mass extinction. Kitchell and Pena conclude that each extinction event should be investigated on its merits; it may be incorrect to seek an overall controlling pattern or an ultimate cause that explains all mass extinctions.

The fourth explanation, which is that the apparent regular pattern is an artefact, has also received support. Re-analysing Raup and Sepkoski's data, Hoffman and Ghiold find that they correspond just as well to a neutral model, in which origination and extinction rates vary independently and randomly through time, as they do to the deterministic periodic model[22]. Episodes of high origination and high extinction rates usually correspond with highly fossilferous geological units. The apparent periodicity of 26 Myr in mass extinctions could be an artefact of the average length of stratigraphic stages, the basic time units used in the calculations.

We are left with all four explanations for mass extinction cycles. Arguments for and against each view will continue. But more detailed analyses of the fossil data, and refinements in dating events in the geological past, will be necessary before we can decide which view is correct. □

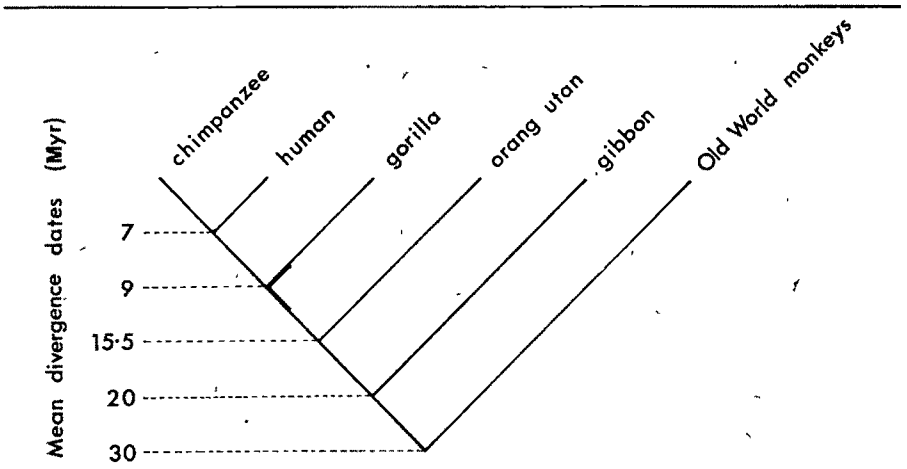
Anthropology

Improved timing of hominoid evolution with a DNA clock

from Peter Andrews

OF THE many contributions in the past year towards the taxonomic applications of protein, amino-acid and DNA analyses, it is worth singling out the approach of DNA-DNA hybridization, which has been claimed by C.G. Sibley and J.E. Ahlquist (*J. molec. Evol.* **20**, 2; 1984) to provide new insights into the evolution of the hominoid primates. How well does this claim stand up to examination?

Molecular approaches to taxonomic studies were initiated by Morris Goodman, who compared the equivalent protein in different species by immunological techniques. This was followed by Sarich's calculations of protein 'distances' from microcomplement fixation data. Others have calculated allelic differences measured by electrophoresis. What these methods have in common is that they produce overall distance measures from the study of proteins, and if they are compared with morphological analyses they are seen to be akin to the numerical taxonomy and multivariate analyses that were performed in the 1950s and 1960s.



Two claims are made for these protein analyses. One is that genetic similarity between taxa can be identified by minimizing the genetic distance between them, and from this the relationships and evolutionary branching patterns of the taxa can be inferred. The other is that the rates of change of the proteins are sufficiently regular for the genetic distances to be applied as a clock. As to the first claim, while it seems likely that the inferred branching patterns are usually correct, it is not possible to test for correctness. This is because there is no way of knowing what properties of the proteins are contributing to the distances measured — the same problem encountered with morphological distances in numerical taxonomy and multivariate analyses for very much the same reasons. The necessary data to overcome this fundamental objection only becomes available when proteins are sequenced (for instance, Goodman *et al. Nature* **303**, 546; 1983).

There are also problems with the use of genetic distances as a clock. The clock hypothesis assumes correctness of branching patterns, and goes on to estimate relative times between branching points based on distances observed. The relative times are translated into absolute times by calibration, usually from the fossil record. Taking the example of the Hominoidea, the zoological group to which man and the apes belong, the branching pattern of the various species of hominoid is established according to the protein data, relative times of divergence between man, chimpanzee, gorilla, orang utan and gibbon are calculated on the basis of the distances between the species and absolute times of divergence are calculated by calibrating one of the relative times with a 'known' divergence date from the fossil record (usually the separation of hominoids from the Old World monkeys).

Two problems affect the accuracy of the protein clock. First, the fossil calibration date may be wrong because it is based on the earliest appearance in the fossil record of a species belonging to a particular lineage. It gives only a minimum date for the origin of the lineage, and the 'earliest appearance' is something that is always subject to change from new evidence. Second, the rates of change of the proteins being analysed may change along or between lineages; Goodman and others have shown that, particularly for the Hominoidea, the rate of change in a number of proteins is not constant. The protein clock must therefore be said both to be uncertainly calibrated and to keep irregular time.

Much of what has been said so far applies equally to DNA-DNA hybridization. In this technique, fragments of disassociated single-stranded radioactively tagged DNA from one species are reassociated with single strands from other species; the greater the base-pair similarity between the strands of DNA, the greater the degree of reassociation between them and the greater the force needed subsequently to disassociate them again. Measurement of this force serves as a new measure of overall genetic similarity between the species tested. This similarity is reasonably assumed to be homologous (although inevitably some will be due to homoplasy) but no distinction is made between homologies that are shared uniquely and those that are present in some distant common ancestor. But almost all of the similarities in DNA between hominoid species are likely to be the result of shared mammalian or primate inheritance, and only a few will be unique to the hominoids. Therefore, although DNA-DNA hybridization is based on the whole genome, only a very small part of the genome is relevant to hominoid relationships. How to distinguish this part from the rest of the DNA molecule is not stated by Sibley and Ahlquist, but if it is not distinguished how is it possible to test the claims made for it?

This question is not so intractable as it might seem. First of all, it is justly claimed that when the whole genome is tested the numbers of changes and homologies are so great that discrepancies are minimized for more distantly related taxa. But this might not apply to fine resolution. For example, DNA hybridization is claimed to link man more closely with the chimpanzee than the gorilla — a relationship that is not resolved by any of the protein distance methods. In fact, the distances given (with standard deviations) are 1.8–1.9 ± 0.2 for man/chimpanzee, 2.4 ± 0.2 for man/gorilla and 2.1–2.3 ± 0.2 for chimpanzee/gorilla. This degree of resolution is not impressive, given the size of the standard deviations and that only a small proportion of the genome contains relevant homologies, and I would not consider the question of man's closest living relative to be solved by these data.

The major limitation of the hybridization data is overcome by comparing DNA sequences instead, because both the number and kind of differences between species is unambiguous when sequences are compared. Thus, although the hybridization results seem merely to be confirmed by sequences of a short section of the mitochondrial DNA of the hominoids (Brown, W.M. et al. *J. molec. Evol.* **18**, 225; 1984 and Hasegawa, M. *et al. Proc. Japan Acad. Sci.* **60**, 95; 1984), the sequence data impart a level of confidence that the branching order, shown in the figure, is correct.

Having accepted the branching order, we can return to the DNA hydridization results and consider the value of the DNA clock that was derived from them. Sibley and Ahlquist find a much greater regularity of DNA change than has been demonstrated for protein change, for which there is

evidence of slowing down or speeding up in some cases. To calibrate the clock from the fossil record, Sibley and Ahlquist used two possible dates — 13 and 16 million years — for the divergence of the orang utan. The correct date is probably somewhere in between so that, by taking a range, the other branching points shown on the figure can be estimated.

The conclusion seems to be that DNA hybridization provides a useful insight into evolutionary events, at least for the hominoids. The resolution of branching patterns is perhaps not quite as great at has been claimed and, since it is inherently untestable, needs to be tested by sequencing data. More sequencing data will be needed to confirm the identification of man's nearest living relative. The DNA clock seems to keep very good time, in contrast to the protein clock, and gives a divergence time between man and the African apes of between 7 and 9 million years ago. In this connection, the recent description of a new hominoid from the Samburu Hills of Kenya (Ishida H. *et al. Af. Study Monog.* 2, 73; 1984) is of particular interest. It is placed at about 9 million years ago (the heavy black line on the figure) and is said to be either an immediate ancester of the African apes and man or an African ape with some similarity to the gorilla. □

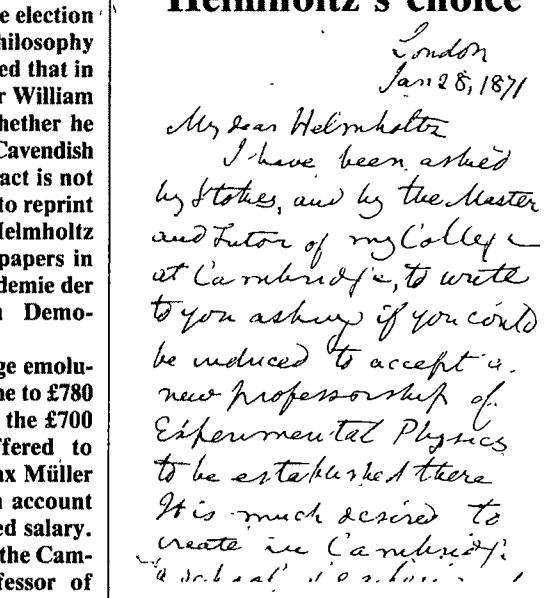
Helmholtz's choice



In my note "Opportunity Lost in 1865?" (*Nature* 306, 313; 1984) about the election of the Chair of Experimental Philosophy at Oxford in the 1860s, I remarked that in 1871 Helmholtz was asked by Sir William Thomson (later Lord Kelvin) whether he would accept the newly founded Cavendish Chair in Cambridge. Since this fact is not widely known, it seems justified to reprint in full Thompson's letter to Helmholtz which is among the Helmholtz papers in The Central Archives of the Akademie der Wissenschaften der Deutschen Demokratischen Republik in Berlin.

The combined university/college emoluments suggested to Helmholtz came to £780 to £800, only slightly more than the £700 which Oxford would have offered to Helmholtz six years earlier if Max Müller had not vetoed the invitation on account of the inadequacy of the proposed salary.

Helmholtz, who at the time of the Cambridge approach was still Professor of Physiology in Heidelberg, declined the offer since in June 1870 he accepted the Chair of Physics at the University of Berlin and was due to take up his appointment in the spring of 1871. There seems to be no record of Helmholtz's answer to Thomson. There is nothing in the Kelvin collection at the Cambridge University Library, but there is a letter from Helmholtz's wife to her mother dated 9 February 1871 (quoted in *Anna von Helmholtz, Ein Lebensbild in Briefen* Verag für Kulturpolitik, Berlin, 1929) in which she wrote that "Hermann has just received an enquiry from Sir William Thomson whether he would be inclined to accept a Professorship in Experimental Physics in Cambridge, under very attractive conditions — however it is to be Berlin" ("*Allein num ist doch Berlin die Losung*"). Then, in a letter dated 13 February 1871 the chairman of the Appointments Committee wrote to Maxwell asking him to stand as a candidate and expressing the hope that his election would be secured. It seems that these matters were dealt with most expeditiously a hundred years ago and that the postal services were gratifyingly swift.

I thank Dr Christa Kirsten, Director of The Central Archives of the Akademie der Wissenschafften der DDR, for the permission to reproduce this letter and Mr J. Deakin, Secretary of the Cavendish Laboratory, Cambridge for the information about the invitation to Maxwell.

N.Kurti, University of Oxford

My dear Helmholtz

I have been asked by Stokes, and by the Master and Tutor of my College at Cambridge, to write to you asking if you could be induced to accept a new professorship of Experimental Physics to be established there. It is much desired to create in Cambridge a school of experimental science, not merely by a system of lectures with experimental illustrations but by a physical laboratory in which students under direction of the professor and his assistant or assistants, would perform experiments, and the professor would have all facilities attainable, for making experimental investigations.

The Duke of Devonshire has already given £6000 for building the laboratory and making a commencement of providing it with instruments. I think it may be confidently expected that funds will not be wanting for carrying out this part of the place well. The University proposes to give £500 per annum to the professor, whose income will also be increased somewhat by fees from students. But if you were accepting the professorship it is I may say quite certain that you would also be appointed at least to a fellowship in St Peter's College which would bring an additional income of £250 or £300.

Thus I believe the income to be relied on would be not less than £800. But I think it probable that a praelector-fellowship of Trinity College would be offered to you, although on this point I speak merely from my own judgement. The duties of the praelector-fellowship, a new institution in Trinity College (of which one in physiology has been given to Dr Michael Foster and it was intended there should be also one in experimental physics) would be fulfilled by giving facilities to members of Trinity College for attending the professorial lectures: that is to say if the *university professor* is appointed to the praelectorship. Otherwise the praelector would lecture on physics in Trinity College simply. The income of the praelectorship would be about £600 so that the professor if appointed to the praelectorship would have £1100 per annum.

I know that the question of amounts of income is very far from the first in respect to the inducements which might possibly cause you to think of accepting such a proposal: and I am quite prepared to learn that you are "absolute for" Berlin. Still it is a question that must be weighed before you could decide to accept, and therefore I have told you what I can regarding it.

If you could at all entertain the idea of coming to this country, I think that the situation at Cambridge would present many advantages. It would certainly be a most interesting field, in respect to our profession, as the desire for physical science is growing stronger and stronger in the University, and the force of public opinion is steadily advancing in support of it, and to stimulate it where stimulus is needed.

The duties of *lecturing* would occupy only 20 weeks out of the year, and all the remainder of the time would be available for experimental or mathematical investigation, and scientific writing. Will you give me a line at the earliest, to say if you think you could be induced to accept or if on the contrary you decide at once against it. I need not say that it would be a great gratification and advantage to English scientific men to have you among us instead of merely having very rare opportunities of seeing you, and that I myself would consider the difference of distances from Glasgow to Cambridge and Berlin a great gain.

I write necessarily in haste, and can only add that, irrespectively of this question, I wished to write to you asking for news of yourself and of your family, and particularly regarding how you have been affected by this terrible war. I hope very much that you have not now cause for anxiety in respect to your son or other relations.

I am in London on account of a Committee invited to advise the Admiralty on Designs for Ships of War, especially in respect to stability, in consequence of the loss of the "Captain" which was upset with 500 men in the Bay of Biscay last September. When you write, address The College, Glasgow, as I am in London only for a few days each fortnight.

Believe me

Yours always truly

William Thomson

Yellow rain and the bee

SIR — Criticism of the bee faeces theory by Rosen *et al.*[1] is misleading and inaccurate. Their assignment of the burden of proof to US government sceptics is misplaced.

The authors assert that "heavy" invasion of substrate is a prerequisite for high toxin levels and that they never observed any "fluffy" mycelium in their samples. In fact, the relationship between mycelial mass and toxin production by *Fusarium* spp. is extremely variable, ranging well over three orders of magnitude. Further, the authors neglect to mention that they did not microscopically examine their samples. While at the University of Wisconsin, I examined bee faeces samples from Thailand. No mycelial growth was obvious but *Fusarium* spp. were present at counts as high as 1,000 colony forming units per milligram. At least one of these strains is capable of producing greater than 1,000 p.p.m. zearalenone under laboratory conditions. It is curious that the authors choose to subject their samples to highly sophisticated GC-MS analysis without also determining the mycoflora present by dilution plating and/or microscopy.

Rosen *et al.* claim that Type A and Type B trichothecenes are "never (except in one case)" found together. This "lone exception" is purported to be a corn sample collected in France. As at least one of the authors should know, this is incorrect[2].

In their final paragraph, Rosen *et al.* state "We are amazed that the proponents of this theory have not yet presented one iota of evidence that trichothecenes can be produced naturally . . .". When one considers the resources available to the US government's laboratories and their intense efforts to identify additional positive samples, it is truly "amazing" that none have been found. More importantly, it is astonishing that the authors imply that the burden of proof should lay with the sceptics. Meselson and others have merely advanced an alternative explanation that is consistent with all physical evidence. In contrast, the US State Department has termed its evidence as "unequivocal" and the so-called "smoking gun".

This "conclusive" evidence has been the basis of serious allegations of Soviet treaty violations and has directly affected such issues as the binary weapons programme and disarmament negotiations. Under those circumstances, who has the burden of proof?

Fivefold symmetry in boron and borides

SIR — A recent News and Views article presented an interesting discussion of fivefold crystal symmetries[1], in particular relating to the recent experiments on Mn-Al alloys[2]. I would like to draw attention to the fact that the fivefold symmetry is also a characteristic feature of the crystalline boron (beta-rhombohedral modification) as well as some borides (such as AlB_{12}). The crystal lattice of β-boron is formed by the repetitive pattern of icosahedrons with the unit cell having 105 non-equivalent atoms. This is by itself rather peculiar for an elemental material. This fact, strikingly little known outside the boron specialists, leads to a number of non-trivial consequences. One example is the possibility of hopping conductivity in an intrinsic (and not doped) semiconductor[3]. Therefore, the naturally occurring fivefold symmetry has another area of manifestation, besides the Mn-Al alloys mentioned.

King Midas and the Red Queen

SIR — Benton's commentary[1] on recent tests of the Red Queen hypothesis draws attention to the difficulty of distinguishing changes in the biotic environment from those in the abiotic one, over geological time. The hypothesis demands that evolution is driven by an *antagonistic* biota. However, *mutualistic* interactions among species cause the biotic environment to improve rather than to deteriorate[2], and the need for continual change just 'to keep in the same place' is lost. Thus, an alternative way of testing the hypothesis is to compare the rates of evolution of taxa in antagonistic environments with those found in mutualistic ones, specifically in associations where one species lives inside the cells of another. We suggest that the homeostatic intracellular environment experienced by mutualistic endosymbionts is buffered from antagonists while, at the same time, subject to much the same major abiotic changes (such as climatic perturbations) as the environment of their hosts.

Nature has been kind enough to provide many such evolutionary experiments, including mutualistic symbioses as diverse as algae within coelenterates (for example, corals), and bacteria within plants (for example leguminous and non-leguminous nodules, see Table 1 of ref. 2). A striking feature of these and other mutualistic associations is that the symbionts which live intracellularly for a prolonged period are represented by a much smaller number of taxa than their external partners[2]. We argue that this supports the view that biotic interactions do play an important part in evolutionary processes[2,3].

For those inclined to regal metaphors, we would contrast the Red Queen of deteriorating, antagonistic environments, with King Midas's golden touch of species in improving, mutualistic environments, although the outcome is evidently more stable for mutualistic species than it was for the king himself[3].

Biological role of IgG hinge region

SIR — We feel compelled to point out that an article correlating IgG antibody flexibility and complement fixation by the classical pathway[1], while an important piece of work, is a regrettable example of authors failing to acknowledge the intellectual and experimental contributions of earlier workers. Surely the findings of Oi *et al.* must be considered a quantitative refinement of principles laid out originally by us in a series of papers over the past decade (for example refs 2–6). The following[5], for example, is unambiguous:

> (These) studies ... highlight the crucial role played by the hinge region and its constituent disulfides in allowing IgG to perform its biological effector functions. An essential feature of this role is to limit segmental flexibility; yet this flexibility seems to be important for optimal antigen binding. Thus, the hinge serves to balance the antigen-dependent and antigen-independent flexibility requirements of the molecule.

It is surprising that the editorial review practices of *Nature* can be so accommodating to what we believe an imbalanced presentation.

The World Ocean Circulation Experiment

J. D. Woods

Institut für Meereskunde an der Univerität Kiel, Düsternbrooker Weg 20, D 2300 Kiel 1, FRG

The international oceanographic community is preparing for an ambitious five-year experiment. Starting in 1990, it will provide the first comprehensive global survey of physical properties of the oceans. The resulting data set will be used to test computer models of the ocean circulation needed for predicting decadal climate change. The results will also benefit research in marine chemistry, biology and geology. This review looks at the climatalogical problems that motivated the project and discusses new observing techniques, from space and in situ, *which make it timely to embark on this major step in physical exploration of the ocean.*

THE World Ocean Circulation Experiment (WOCE) is being planned to survey the global distributions of ocean variables with a view to greatly improving estimates of the circulation of heat, water and chemicals around the world ocean, and their exchange with the atmosphere. Such experiments become necessary when the existing database is inadequate for a particular purpose; a new data set stimulates new thinking and reveals deficiencies in old ideas and models. A recent example was the Global Weather Experiment (GWE) in 1979, which has had a major impact on improving models used in weather forecasting[1]. The aim of WOCE is to collect a data set that will do the same for oceanic circulation. It will provide the first comprehensive global perspective of the ocean as an element in the planetary climate system. The experiment will open a new chapter in the history of ocean exploration, as the *Meteor* Atlantic expedition did in 1925-27, the *Discovery* Southern Ocean expeditions in the 1930s, the International Geophysical Year (IGY) Atlantic expedition in 1957 and the International Indian Ocean expedition in 1966 (ref. 2).

This article opens with a brief survey of the climatological problems that motivate the WOCE, then considers the present state of ocean circulation modelling, and surveys the data available to test them. The urgent need for a new global data set becomes evident. Finally, the aims, options, strategy and design of the experiment intended to meet that need are discussed.

Decadal climate change

There are many potential applications of a detailed understanding of the global circulation of the oceans, but the driving force for attempting a WOCE is the recognition that predicting decadal climate change will depend on accurate calculation of changes in the large-scale flow of heat, freshwater and chemicals in the oceans. The global pattern of climate on the continents is strongly influenced by those fluxes[3]. Estimates based on the difference between the radiation budget at the top of the atmosphere and the fluxes carried by the atmosphere[4] have revealed that the meridional heat fluxes in the ocean and the atmosphere both lie in the range 0.1–1 PW (10^{15} W), with the ocean contributing more in the tropics and the atmosphere more at higher latitudes (Fig. 1). Attempts are being made to extend the calculations with a view to discovering how much the flow in each ocean basin contributes to this zonally averaged heat flux[5–7]. This indirect approach has been stimulated by concern that calculations based on maps of surface energy fluxes may be unreliable because of errors in the bulk formulae used to calculate the fluxes from ship meteorological observations and uneven distribution of and errors in the observations. Global maps of heat and freshwater circulation based on the best available estimates are characterized by large flows between the basins (Fig. 2)[8]; the mean energy and water supply to the atmosphere in the Atlantic depend in part on solar heating and rainfall in the Pacific. Attempts have been made to calculate the fluxes more directly from hydrographic data at a few sites[9] (Fig. 3); the method gives values in the same range (0.1–1 PW) but differing significantly in detail. The great width of the Pacific Ocean presents special problems, and there is disagreement about the direction of the fluxes in some regions.

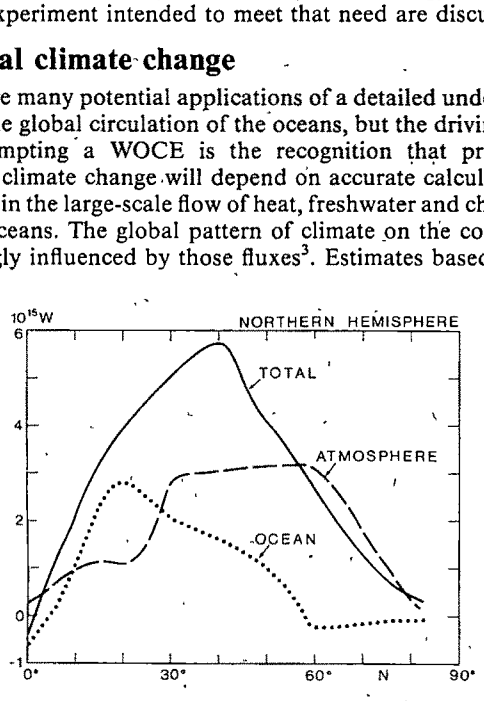

Fig. 1 The meridional heat transport carried by the ocean and the atmosphere[4]

The bulk formula method is suspect because it gives unrealistic budgets for the Mediterranean and Red Sea[10]; the direct method can be used reliably only at locations where the flux calculation is insensitive to the unknown barotropic component of the geostrophic current; the residual method is suspect because calculations of the atmospheric flux divergences give unrealistic values over the continents. The discrepancies between the three methods are quite modest by comparison with those in other aspects of planetary physics, and might be thought of as presenting no urgent challenge. But we are not concerned here with the energy balance of some distant planet. We are discussing the energy and water budgets which govern the climate of Earth[11]. The impact of climate change on mankind provides the motivation for predicting future changes in climate. Climate prediction provides challenging specifications for the accuracies to which we must measure ocean fluxes.

Consider the North Atlantic. The incoming heat flux (1.2 PW) is lost to the atmosphere at a basin-average rate of 50 W m^{-2}. The flow is unevenly distributed, but errors in the bulk method prevent us from mapping the distribution more accurately than ±50 W m^{-2}. The global patterns of surface heat and water fluxes are not constant; they exhibit a broad spectrum of variability. There has long been speculation[12] that such oceanic changes cause some of the observed variations in climate over the continents, but because of the deplorable inaccuracy of the methods used to measure the surface fluxes, there is usually no hope of deducing the changes from past records. Exceptions are sites such as the Eastern Equatorial Pacific, where interannual variation exceeds 50 W m^{-2} (ref. 13).

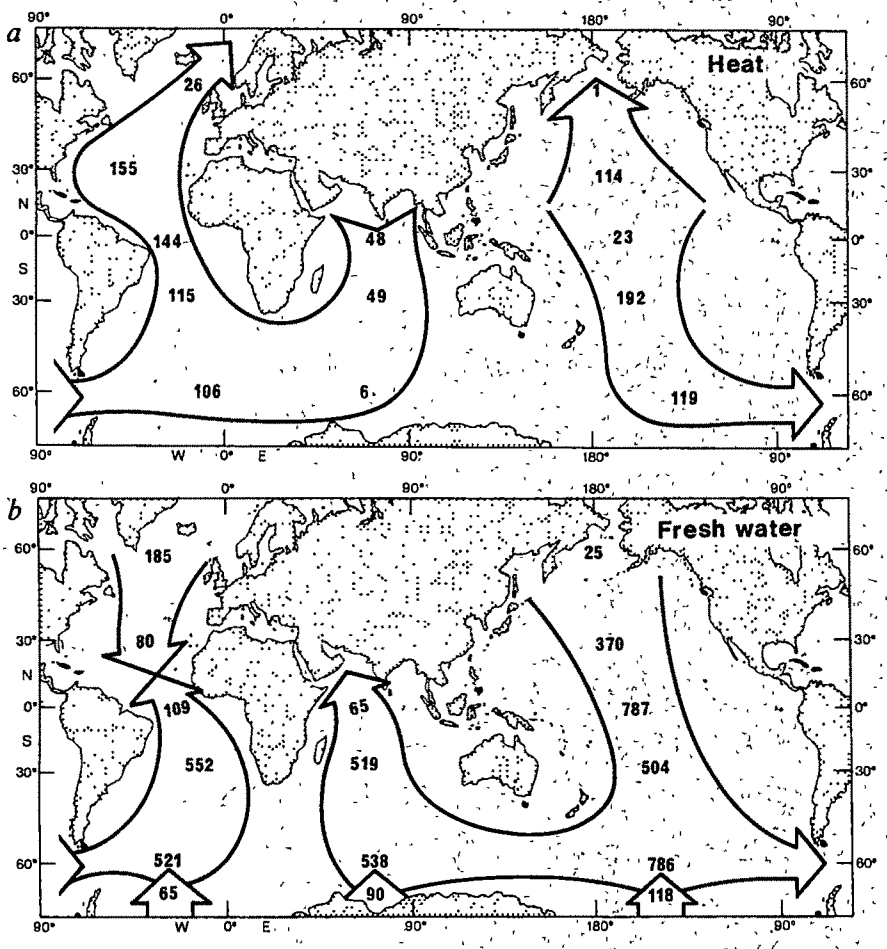

Fig. 2 Global circulations of heat (*a*, 0.01 PW) and fresh water (*b*, 10^3 tonnes s^{-1}) based on surface fluxes estimated from ship weather observations[8].

Even quite small changes in the surface fluxes averaged over large areas can have a large impact on climate if they persist for decades. They can be provoked by changes in the solar constant or in the atmospheric concentrations of dust or gases. The palaeoclimatological record derived from polar ice cores contains evidence of such changes[14]. The forcing might involve quite a small deviation in the surface radiation flux; for example, the natural doubling of atmospheric P_{CO_2} during the past 15,000 years changed the surface infrared flux by about 10 W m^{-2} (ref. 15). Sensitivity tests with atmospheric climate models have shown that important consequences can result from such forcing[16].

When we consider the possibility of forecasting decadal climate change, we become concerned with the processes inside the ocean (circulation and mixing) that provide the link between changes in surface forcing and the resulting changes in energy, water and gas fluxes to the atmosphere. Here we concentrate on the energy flux, although for some purposes the change in gas flux (especially CO_2) is also important. The scientific problem is to calculate the thermal response of the ocean to an externally induced change in surface radiation balance. The forcing changes the heat content of the ocean, leading to a change in the surface temperature and consequently in the rate of oceanic cooling to the atmosphere. Given a step change in the radiation input, the oceanic temperature will relax to a new equilibrium value, for which the globally averaged surface energy flux budget is again balanced. The new balance will involve a different partition between the components that make up the total cooling to the atmosphere; long-wave radiation, conduction (sensible heat flux) and evaporation (latent heat flux). The climate is sensitive to that partition. An increase of solar constant or of P_{CO_2} will lead to increased evaporation balanced by greater precipitation, some of which will fall on the continents.

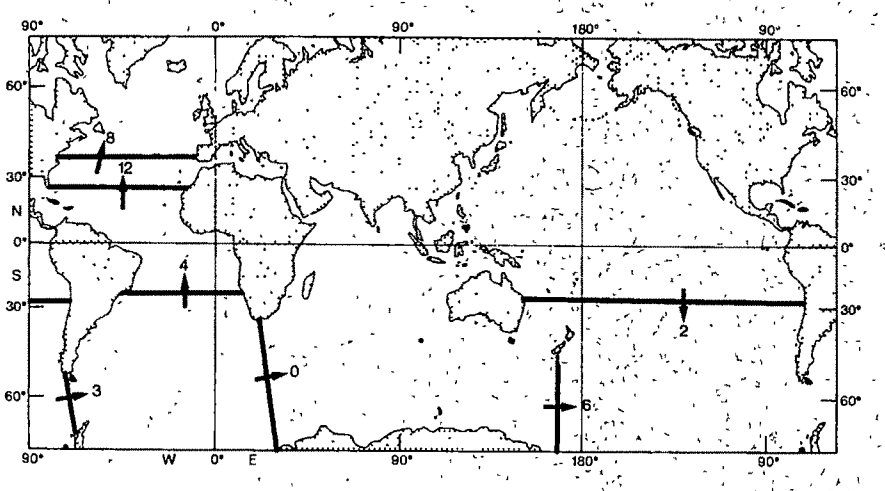

Fig. 3 Direct measurements of heat flow (0.1 PW) in the ocean based on hydrographic sections and other oceanographic measurements[9].

Decadal changes of ocean heat content are not confined to the surface mixed layer (mean depth 70 m), but are ventilated by deep winter convection and by Ekman pumping to depths of the order of 1 km (ref. 17). The involvement of a greater mass of water prolongs the relaxation time, giving ocean currents scope to redistribute the change of heat content over great distances. As a result, the equilibrium change in surface cooling and evaporation may be distributed quite differently from their mean patterns and from the distribution of surface forcing. Furthermore, the transient change may have different characteristics in different parts of the world, and the annual mean response may involve different seasonal changes at different locations.

To summarize, the global patterns of seasonal and annual climate—in particular rainfall—will change over decades in response to radiative forcing of the ocean by natural variations of solar constant and atmospheric dust and gas concentrations. These lead to changes in ocean heat content. There is no prospect of predicting decadal climate changes until it is possible accurately to model the action of oceanic circulation and mixing in redistributing the decadal heat content anomalies, as an essential prerequisite to calculating the changes in surface fluxes of energy, water and gases to the atmosphere[18].

A computer model designed to predict decadal climate change must, therefore, include the ocean circulation and mixing, as well as the atmospheric circulation and physics of clouds, radiation and precipitation. No such comprehensive model exists at present, although several groups are working towards that end[19]. The atmospheric component of such a model is well advanced, but the oceanic component lags behind. Ultimately the two components must be integrated because of feedback between the atmospheric climate and the oceanic circulation. It will not be satisfactory to treat the ocean currents as a stationary feature of a changing climate, but that refinement is of secondary importance compared with the urgent task of creating a model that can at least simulate the circulation of the ocean forced by a steady atmospheric climate. The availability of such a model would revolutionize our ability to diagnose the role of the ocean in our present climate, and would act as a springboard for developing the coupled atmosphere-ocean models needed to predict decadal changes of climate.

The strategy for oceanographers contributing to the problem of predicting decadal climate change is to develop a model that accurately describes the circulation of heat, fresh water and selected dissolved chemicals (notably those involved in the carbon cycle), using a description of the present seasonal cycle of atmospheric forcing; to test this model against a description of the circulations derived from observations; and progressively to improve the model until it predicts the fluxes of energy, water and gases (notably CO_2) into the atmosphere with errors significantly smaller than the observed decadal fluctuations.

Modelling the ocean circulation

The aim of WOCE is to collect a data set that will test and stimulate the development of models of ocean circulation needed for predicting decadal climate change. The class of model to be considered here is sometimes called 'prognostic', but it is not yet used in a forecasting mode, as that would require coupling to an atmospheric model. It is used in a diagnostic mode, being designed to calculate the seasonally varying distributions of currents, temperature, salinity and chemical concentrations around the world ocean, given the surface fluxes of momentum and vorticity, radiation, heat, water and gases as functions of season and geographical distribution. One of the triumphs of oceanography in the past decade has been the successful development of such a model at Princeton[20]. Starting with a uniform motionless ocean, the model has been integrated for the equivalent of 1,000 years with prescribed surface boundary conditions to give realistic patterns of surface geostrophic flow (Fig. 4).

The output of such a model integration can be used as a synthetic data base for the world ocean, with the desirable

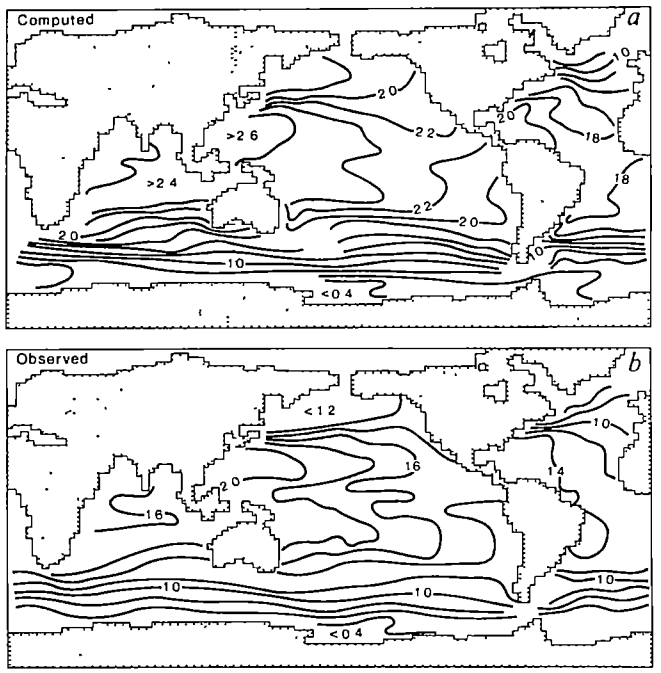

Fig. 4 The distribution of surface elevation of the ocean relative to the geoid (*a*) from the Princeton model (*b*) deduced from the observed density distribution using an assumption that the velocity is zero at 2,000 m (ref. 20). The surface geostrophic flow goes along the isolines, with a speed given by the horizontal gradient of surface elevation (that is, hydrostatic pressure)

attribute that there are none of the data-sparse regions that plague analysis of real data. For example, it is possible to calculate the fluxes of heat and water through trans-ocean sections[21]. The results agree remarkably with those derived from analysis of observations (notably across the Atlantic at 23 °N), giving us confidence in the model. Although encouraging, are the predictions sufficiently accurate to meet the needs of climate forecasting? And if not, can we identify and correct the sources of error in the way that meteorologists have systematically improved models used in weather forecasting? We do not have an adequate data base to answer such questions fully; that is why oceanographers need a WOCE, just as meteorologists need the GWE. We can, of course, spot obvious differences between the distributions of temperature and salinity predicted by the model and those printed in oceanographic atlases[22], but we cannot say whether differences are significant for prediction of decadal climate. However, most oceanographers are concerned about the difference in structure of the permanent thermocline (Fig. 5), since that is likely to be symptomatic of an error in the rate of ventilation of heat from the surface into the interior of the ocean, a process of central importance for decadal climate change[23,24].

One reason that the world ocean model gives a false thermocline structure may be that, to run it on the Princeton computer (one of the most powerful in the world), the spectrum of motion has had to be truncated at 250 km. The energetic eddies which constitute the oceanic equivalent of weather systems were not resolved; their effects on the velocity, temperature, salinity and chemical distributions had to be parameterized in the model equations by Boussinesq eddy transport coefficients (Fig. 6). Furthermore, the large truncation scale meant that rather large values had to be used for those coefficients; it was not possible to simulate the observed regional variation of eddy kinetic energy by prescribing regional variation of the coefficients, although sensitivity tests showed that the model results were affected by arbitrary (homogeneous) variations in their magnitude[20]. As meteorologists had learned with the much broader atmospheric weather systems, the problem could be largely eliminated by using a computer powerful enough to resolve the eddies. The arrival of a new generation of supercomputers in

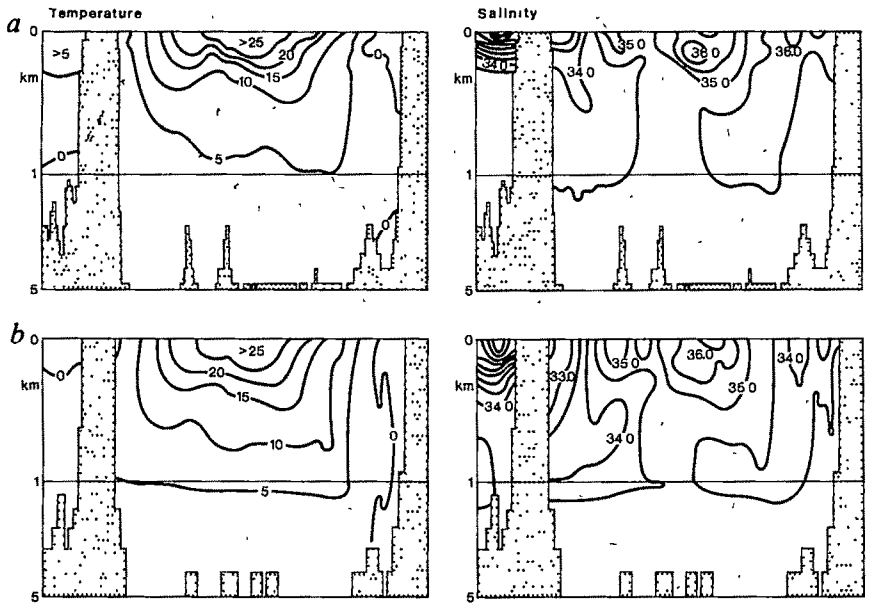

Fig. 5 The distribution of temperature and salinity in a vertical meridional section through the Pacific Ocean: *a*, from the Princeton model; and *b*, from hydrographic data[20]. The similarities in *a* and *b* are encouraging, but the difference in the depth of the 10 °C isotherm indicates that the model does not describe upper ocean ventilation adequately for decadal climate prediction.

the mid-1970s made it possible to test that hypothesis for a small ocean basin. Holland[25] demonstrated that the eddies influence the mean circulation and showed that the mean circulation is affected by bottom topography and the density distribution through the action of the eddies. Several modellers are exploring more sophisticated parameterizations designed to permit progress without resolving the eddies (J. S. A. Green, personal communication), but it is generally believed that they will have to be resolved in future climate models. The present generations of computers makes that impossible except in limited regions, or idealized ocean basins. But in designing WOCE we are looking forward to models that will be in operation at the end of the century. By then there will be two more generations of computers, with at least a factor of 100 in power, making global eddy-resolving models a practical proposition.

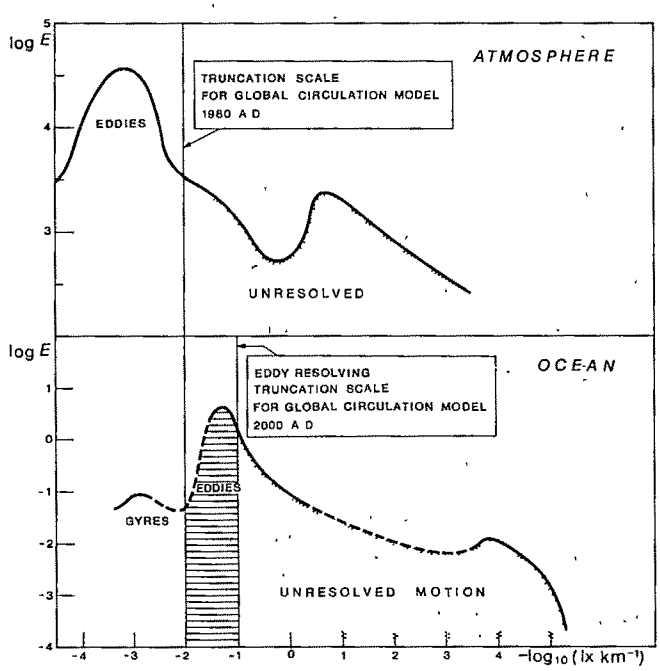

Fig. 6 Typical spectra of motion in the ocean and atmosphere showing the energy peaks associated with eddies. The eddy energy must be resolved in models of the global circulation. Existing computers permit a truncation scale of 100 km, which resolves eddies in the atmosphere, but not in the ocean. The continuing increase in computer power will permit progressively smaller truncation scales until, by the end of the century, it should become possible to resolve the ocean eddies.

Another source of error is the parameterization of vertical mixing in the statically stable interior of the ocean. In the world ocean model, this is based on a vertical eddy diffusivity for scalars and a vertical eddy viscosity for momentum. Research into small-scale transport processes has cast doubt on the efficacy of such parameterization. While many details remain to be settled, there are several processes with different transport characteristics: scalar mixing is effected by billow turbulence[26], double diffusive convection[27] and cabelling[28]; momentum transport is effected by internal waves[29] and quasi-geostrophic eddies[30]. Analysis of scalar distributions measured during large-scale geochemical surveys have emphasized the need to distinguish between vertical and diapycnic mixing[31]. Numerical techniques have been proposed to avoid this source of error by coordinate transformation[32] or, more drastically, by reformulating the circulation models in terms of isopycnic rather than isobaric surfaces[33]. Such techniques will not only improve the prediction of scalar diffusion by unresolved motions, but they also simplify the treatment of potential vorticity conservation, which is the theoretical linchpin of eddy and gyre scale dynamics[34].

Climate models are particularly sensitive to the parameterization of boundary layer processes, which control the deep ventilation of anomalies entering the ocean at the surface, and, conversely, the mixed layer temperature and therefore the fluxes of energy, water and gases into the atmosphere[36]. The standard practice in ocean circulation models is to treat the boundary layer physics one-dimensionally[37]. That is useful for simulating the response of sea-surface temperature and salinity to the seasonal variation of surface energy and water fluxes, but it does not take account of advection of heat and water by ocean currents, the essence of global climate[17]. Nor is it possible with such boundary layer parameterization to predict the depth of the mixed layer in winter, when surface water mixes deepest (Fig. 7). As a result, it is not possible to calculate the regional and temporal variation of annual water mass transformation in the boundary layer, a crucial mechanism for decadal climate change. Recent work by the Princeton group has revealed the sensitivity of deep-water ventilation to the depth of winter mixings[23,24]. It was shown that simulation of the observed distribution of tritium (from nuclear bomb tests) in the North Atlantic was greatly improved by artificially making the mixed layer in winter have the regional distribution deduced from observations. The need for accurate parameterization of boundary layer processes will become increasingly important when climate models are based on freely coupled ocean–atmosphere circulations, for which the present expedient of prescribing the seasonal variation of mixed layer temperature, salinity and depth will no longer be appropriate.

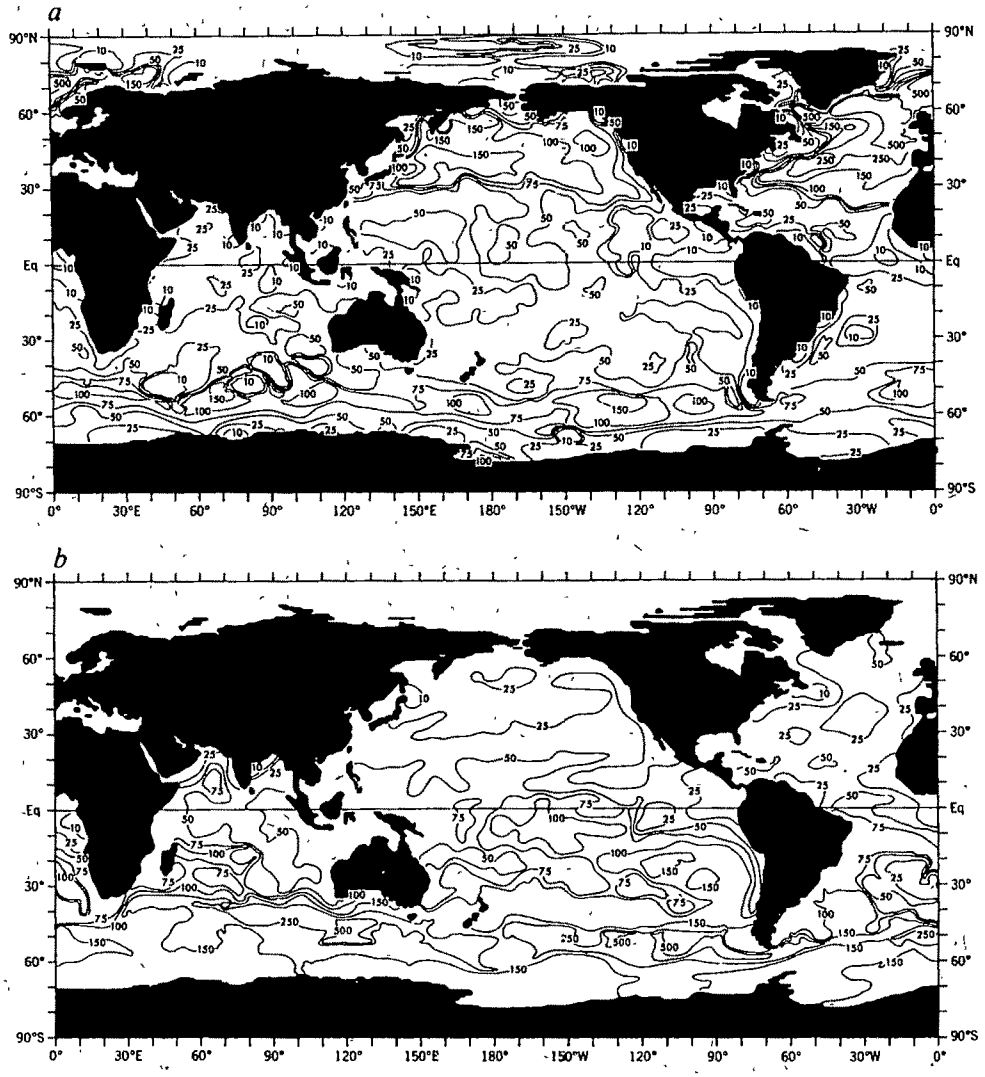

Fig. 7 The climatological mean distribution of the depth of the oceanic mixed layer at the end of winter, as deduced from density profiles[44], has been used as a parameter in models designed to simulate the penetration of anomalies from the atmosphere into the interior of the ocean[23,24]. *a*, March; *b*, September.

Future models

Increasing computer power will improve the resolution of ocean circulation models and include more elaborate parameterizations of unresolved processes. Faced with such opportunities, the modeller has to ask how much emphasis to give to processes competing for each increment in computer power. His decisions are influenced by three factors: (1) theoretical ideas illustrated by process models; (2) the availability of data to run the model with new features; and (3) the availability of data to test the resulting model predictions. It is also important that the modeller has a specific goal in mind.

The ultimate goal for modelling in WOCE is decadal climate prediction, which emphasizes those aspects of ocean circulation that influence oceanic feedback to the atmosphere over timescales of 10 or 100 years, and stresses the coupling of the global circulations of the ocean and atmosphere. The theoretical ideas that will most strongly influence WOCE model development will be those concerned with the oceanic boundary layer, the ventilation and circulation of the thermocline (the warm water sphere), and the fluxes between basins which give the ocean its global integrity. The problem facing the modeller is to assimilate the many advances made in recent decades in our understanding of processes that influence these aspects of the large-scale circulation, and to decide how much weight to give to each as the model evolves. A powerful theoretical tool for making such decisions is provided by Ertel's concept of potential vorticity conservation[34]. The full implications of the concept are still being investigated, but it has already been shown that most aspects of the dynamical state of the ocean can be determined if one knows the distribution of potential vorticity along isopycnic surfaces and the density distribution along the boundary[35]. By focusing on the distribution of potential vorticity along isopycnic surfaces, it becomes possible to assess the relative importance (for large-scale circulation) of a multiplicity of transient motions, including the quasi-geostrophic eddies and fronts, convection in the boundary layer (due to surface cooling) and in the interior (due to double diffusion), turbulence in the mixed layer and the interior, and so on. It seems likely that potential vorticity will be the dynamical touchstone of WOCE, just as geostrophy was for the great oceanographic expeditions of previous generations.

The data needed to run ocean circulation models include: (1) the topography of the sea floor as lower boundary condition; (2) the distributions of velocity, temperature, salinity and selected chemicals as initial conditions; and (3) the global patterns of seasonally varying fluxes of momentum, energy, moisture and gases at the ocean surface interface as upper boundary conditions. The bathymetry is already known to the required resolution of 30 km in some regions[38,39], but remains undersampled in most of the ocean. It is significant that 70 unknown seamounts were discovered by analysis of the Seasat altimeter data[40,41]; geophysicists predict many more. The accurate mapping of passes through which deep water passes between ocean basins presents a continuing problem.

In a recent census of the world ocean waters, Worthington[42] assessed the accumulated hydrographic data base available in the World Data Centres. There are large gaps in the Southern Hemisphere that have to be spanned by interpolation. The uncertainty in the mean heat content and total mass of salt is important even when the model is integrated from a

'homogeneous, motionless' initial state. The alternative of initializing the model, as meteorologists do in weather forecasting, with the best available description of the present day distributions is more challenging[43]. That requires a knowledge of the global distributions. The first systematic world analysis of temperature, salinity and oxygen distributions (with a resolution of $1°\times1°\times33$ layers) has recently been published[44]. The potential of surface pressure maps from altimetry for initialization of ocean circulation models is being investigated[45]. Looking further ahead, acoustic tomography[46] may provide the synoptic data required for model initialization.

The upper boundary condition for ocean circulation models used in decadal climate prediction will come from the atmospheric general circulation models (GCMs) coupled to them. At present, there are design faults in atmospheric GCMs which lead to large errors in the surface fluxes they predict[11]. Attention is now being given to identifying and eliminating the causes of those errors. Meanwhile, the ocean modeller must proceed in the uncoupled mode, using observed surface fluxes as the upper boundary condition. At present, they are calculated from ship meterological observations using formulae which have been calibrated against measurements made during air-sea interaction experiments such as JASIN 1979 (ref. 47). The unacceptably large uncertainties in the surface fluxes so determined have been widely discussed[3]. They represent a major source of error in predictions of ocean circulation models. There is a very real risk of rubbish in: rubbish out. Nevertheless, the global analysis of seasonally varying surface fluxes derived from ship observations represents the state of the art. Precipitation is notoriously difficult to estimate at sea and published distributions have to be treated with caution[48,49]. Some modellers, faced with the uncertainty in maps of surface fluxes of energy and water, have used the better observed distributions of surface temperature and salinity. That has permitted useful progress with many aspects of circulation modelling, but it is one stage further removed from the goal of coupled atmosphere–ocean climate models. The early attempts at developing coupled models have been based on a simpler parameterization of the surface fluxes based on the newtonian cooling law[19].

Summarizing, the existing descriptions of bathymetry, hydrographic distributions and surface fluxes needed to run ocean circulation models already pose difficulties and it is becoming increasingly urgent to improve them so as to avoid the risk that ocean circulation models with greatly improved resolution and physics fail to realize their potential because of inadequacies in the data used to run them. Improvements are needed in accuracy, spatial and temporal resolution and in global coverage.

Testing the models

There are two strategies for using observations to test models. The first focuses on products closely related to what the customer wants, in our case decadel climate forecasts. The second focuses on internal properties of the system being modelled; does the circulation look right? The weather forecaster can follow the first approach. The absence of adequate time series from the past, and the need to make predictions before another century has passed, forces the oceanographer to concentrate on the latter. In designing WOCE, we must choose to observe those aspects of the ocean circulation that offer the best prospect of testing the plausibility of models that will be working at the end of this century.

The requirement is for global models that treat the circulation around the world ocean in its totality. But the present state of oceanographic knowledge is uneven, and even the major advance expected as the result of WOCE cannot realistically be expected to raise our level of knowledge of all regions to the highest level. Special emphasis will be placed during WOCE on filling the most glaring gaps in our data base, but the resources available are limited and will be deployed in a way that offers the best prospect of testing future models, not simply on a regular grid. The pragmatic criterion for deciding what constitutes useful testing of a new model depends on pushing back the frontiers of our state of knoweldge. The detailed specification varies considerably from region to region. In some places, such as the North Atlantic, our knowledge of the circulation is relatively advanced and we can proceed to specify errors in measurements of, for example, the heat flux. Elsewhere, we are still relatively ignorant of the general character of the circulation; for example, we have neither documentation nor theory concerning the variability of the Antarctic circumpolar current, and we simply do not know how it connects with the circulations in the Pacific, Atlantic and Indian Oceans to the north. In such cases, WOCE must be designed to reveal the unknown; comparison with model predictions will have to be more qualitative than quantitative. The major discoveries of WOCE are expected to come from the Southern Hemisphere, which has been poorly sampled in the past, for obvious logistic reasons.

Broadly, the procedure will be to extract products from the WOCE data set that can be compared with equivalent products generated by the prognostic models. At the simplest level, it is useful to compare the distributions of temperature, salinity and dissolved chemicals (see Fig. 5). The same goes for the patterns of mean and variance of the surface pressure distribution measured by satellite altimetry. The velocity field presents greater difficulties because it must be calculated from a diagnostic model supplied with scalar distributions. Classical attempts at diagnostic modelling (reviewed in ref. 50) involved arbitrary assumptions. Recently, there have been significant advances in the application of inverse theory to the design of diagnostic models that extract products from oceanographic data, with explicit statements about the errors in the data and the tolerance to which dynamical constraints apply[51]. Once the velocity field has been diagnosed, it is possible, in principle, to compute the fluxes of heat, water and chemicals, and to establish the relative contributions of the different classes of motion to those fluxes (that is, the Ekman transport in the mixed layer, the wind-driven gyre circulations, the meridional circulation driven by deep convection at high latitude, and the eddies). By comparing the observed distributions of dissolved chemicals with those computed using a model that incorporates the WOCE empirical velocity field, it will be possible to assess the stationarity of the circulation on the ventilation timescales of the different regions, and so resolve the present uncertainty as to the origin of water in the deep Pacific; is it a fossil of an earlier climate or in equilibrium with our present climate? Inverse theory warns us that it will not be easy to determine velocities and fluxes accurately. In general, even with the great increase in data we expect from WOCE, the system will be under-determined, and model testing will be more effective if we concentrate on collecting data that will permit us to calculate a few products accurately. Compared with the richness of detail meterologists have following their global experiment, the number of such products expected from WOCE may seem discouragingly small, but they will provide powerful constraints on the models at the global level.

On a smaller scale, it is necessary to test the parameterizations of motions that cannot be resolved even in the models running on twenty-first century computers. Here the comparison will be between observed large-scale indicators of those motions, for example, the annual maximum depth of the mixed layer, which is crucial in parameterization of the ventilation of properties acquired in the boundary layer into the interior of the ocean[17]. Comparison of isopycnic potential vorticity distributions will provide one of the crucial tests of the model parameterizations of the effects of internal mixing on large-scale circulation. It is emphasized, however, that WOCE will not incorporate any detailed process studies related to particular classes of mixing: the experiment will deploy all available resources on the largest scales of motion.

Summarizing, the existing database tests models by revealing errors in scalar distributions, but provides very little information about the velocity field and the large-scale fluxes. New data are needed to extend the existing tests globally and to make it possible to test the velocity field, fluxes and internal dynamics of the models.

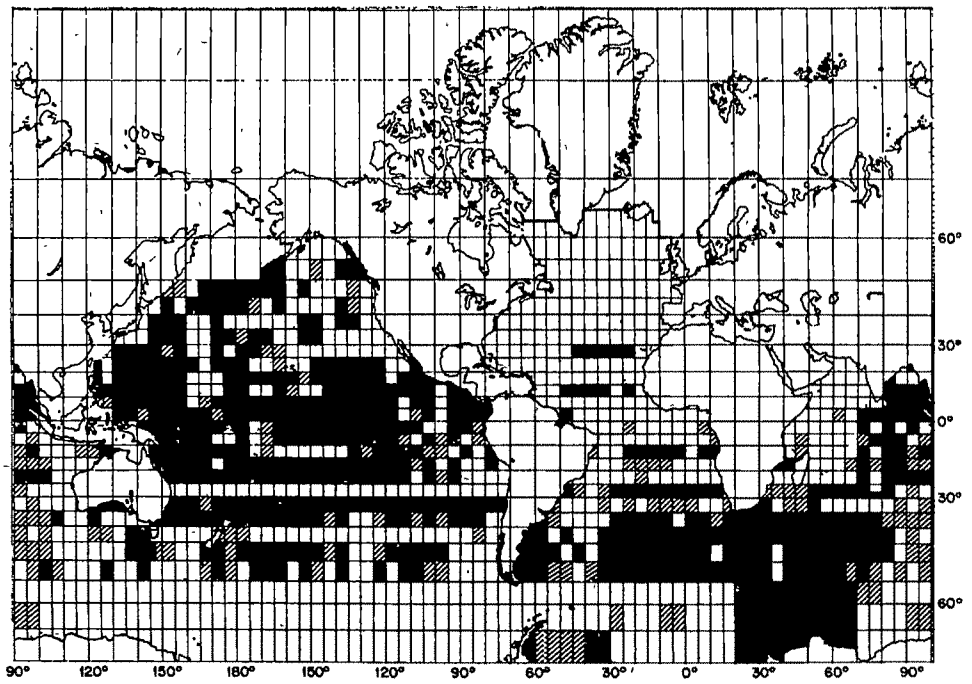

Fig. 8 The global distribution of data available for running ocean circulation models is biased towards the Northern Hemisphere, shipping lanes, fisheries zones, and against the winter months when extra-tropical air-sea interaction is strongest. The distribution of high-quality hydrographic data[42] is shown as an example. Black areas contain no suitable data; hatched areas contain data only in shallow locations.

Aims of WOCE

The discussion of model testing has revealed serious deficiencies in the existing database, which can be grouped into three categories.

First, inadequate coverage of the world ocean. The Southern Hemisphere data coverage is sparse at all seasons; everywhere there is poor coverage in winter compared with summer (Fig. 8). Merchant ship observations, which are crucial for calculating surface fluxes needed to run the models, are concentrated on the shipping lanes and biased against rough weather, when much of the air-sea interaction may be occurring. There is an urgent need for a homogeneous global data base covering all seasons.

Second, although the large oceanographic data archives available at the World Data Centres still contain untapped information, the individual measurements were often collected with other objectives in mind (such as to solve regional circulation problems) and are not well suited to testing global circulation models designed for climate prediction. There are many hydrocast profiles, but few eddy-revolving, top-bottom, trans-ocean sections.

Third, the accuracy of many measurements does not meet the specification generated by analysis of climate prediction requirements, because measurements were made originally for other purposes, for example the surface fluxes derived from ship meteorological observations. More frustrating, because it arises from sloppy practice, is the poor salinity accuracy in deep profiles from some laboratories.

The aim of the WOCE is to remedy those deficiencies by new measurements, designed specifically to meet the needs of global circulation models for climate prediction. It will take advantage of the remarkable advances that have been made in theoretical understanding of ocean circulation, in instrumentation and in design concepts since the last great international expeditions[52]. Above all, the aim will be to collect a data set that will permit a global perspective in studies of ocean circulation.

Timing of WOCE

Those are very ambitious aims and the question is, is it timely to embark on such a major project only five years hence? The answer is that four significant advances in the past decade have made it possible to take this logical next step in the physical exploration of the oceans: (1) exploration of the transient, quasi-geostrophic eddies, (2) the first computer model of the world ocean circulation, (3) new techniques for exploring the ocean from space and *in situ*, (4) recognition that improved knowledge of ocean circulation was needed before the climate impact of CO_2 pollution could be predicted. These four developments will now be discussed briefly in the context of the WOCE.

Eddies. The importance of the transient quasi-geostrophic eddies for ocean circulation had not been recognized when the last international expeditions were being planned, even though, with hindsight, there is evidence of the eddies in earlier data. Following the POLYGON, MODE and POLYMODE experiments in the past decade and associated theoretical studies, it is possible to assess the role of the transient eddies in the larger-scale permanent gyres[53]. It is also possible to design an observing strategy and data analysis techniques that take account of the eddies, whether as a dynamically important signal in their own right or as a noise on the gyres. The form of the spectrum of oceanic motion is known to a wavelength of 10 km, which is probably sufficient for designing WOCE. The recognition that general circulation models will have to resolve the eddies is a major factor in planning the experiment.

Models. The successful completion of the first computer model of the world ocean circulation, with the three-dimensional distribution of temperature and salinity, was an important milestone in oceanography. It provides the springboard for successive improvements that will eventually lead to climate prediction models. Future improvements, including resolution of the eddies, diapycnic rather than vertical mixing, and coupling of circulation and boundary layer physics, were discussed earlier. The implementation of those improvements in global models will depend on the availability of adequate computer power. The spatial resolution problem poses the greatest difficulty; a 100-fold increase in computer power is needed to achieve resolution equivalent to that currently used in weather forecasting models. Happily, there is every prospect of that being achieved by the end of this century. The most powerful machines in the world today, the Cray-XMP and Cyber 205, can perform several hundred million instructions per second; laboratories leading research into eddy-resolving ocean circulation models are already planning to order computers that can perform more than a thousand million instructions per second. Even if some of the more bullish predictions of the rate of increase in computer power prove optimistic, there is no doubt that early in the next century, ocean circulation modellers will need a data set to test global eddy-resolving models. The WOCE cannot be completed before 1995 at the earliest and, judging by the time it has taken to complete the GWE data set, the WOCE data set will barely be ready for use by the end of the century—none too soon for testing models using fifth-generation computers.

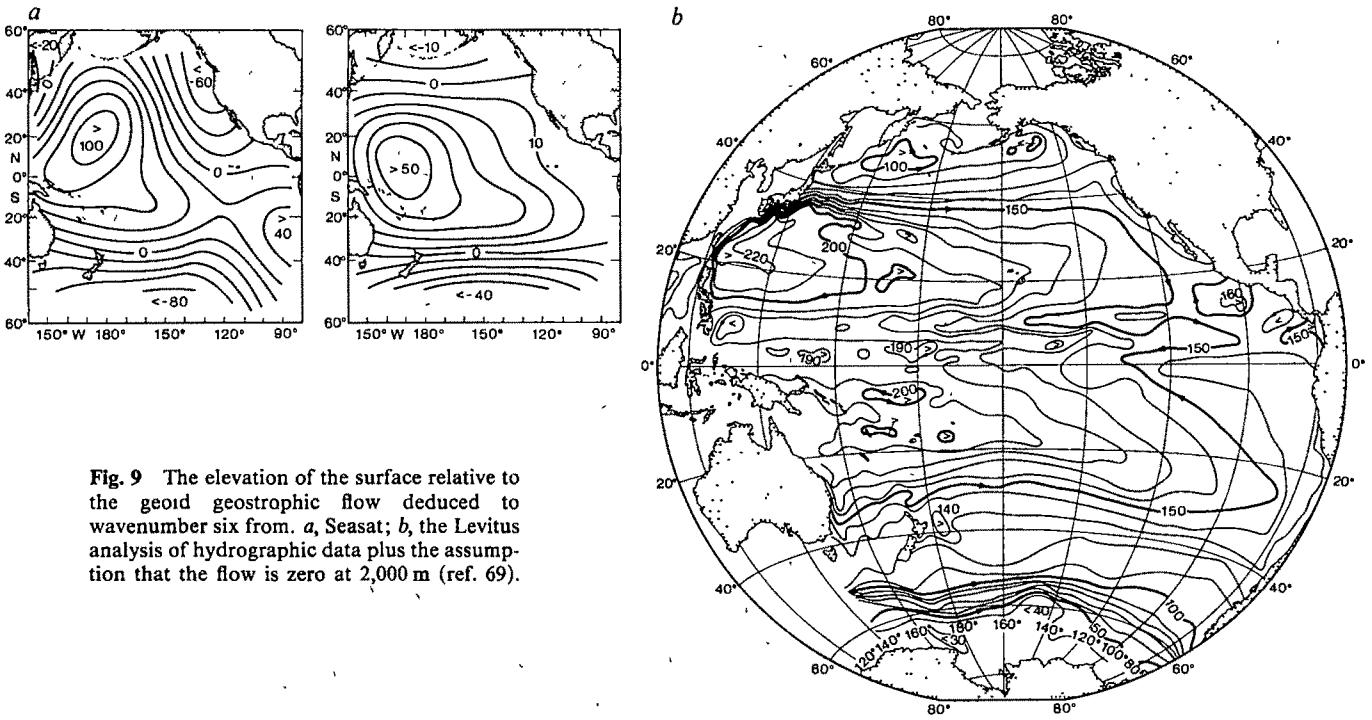

Fig. 9 The elevation of the surface relative to the geoid geostrophic flow deduced to wavenumber six from. *a*, Seasat; *b*, the Levitus analysis of hydrographic data plus the assumption that the flow is zero at 2,000 m (ref. 69).

New tools. The Atlantic expedition during the IGY was based almost entirely on instruments lowered from research ships. The most revolutionary tool was the bathythermograph, which could give a shallow temperature profile without stopping the ship. The IGY data set is the mainstay of contemporary calculations of Atlantic circulation. Research ships will continue to have the central role in ocean exploration for the foreseeable future, and they will provide the core of the WOCE data set. New techniques will improve the efficiency of ship use. The increasing use of expendable instruments (bathythermograph, current profiler) has made it possible to supplement the limited research fleet with ships of opportunity. Systematic surveying of temperature anomalies has been undertaken in this way during North Pacific Experiment[54], and is now being used in the Tropical Ocean and Global Atmosphere[55] project.

During the 1970s there was also a rapid development of moorings and drifters for circulation studies. Moorings can now be deployed for up to a year, making it possible to explore variability with periods much longer than the eddy lifetimes[56]. Surface drifters tracked by satellite[57] and deep drifters tracked acoustically[58] can be followed for many months. Pressure gauges deployed on the ocean floor for several months have been used to map the tides[59]. The accumulated number of buoy-months has already made it possible to map velocity mean and variance in the North Atlantic[60]. Theoretical studies have helped to clarify the interpretation of the quasi-langrangian tracks of these drifters[61].

Methods of chemical analysis of water samples collected by research ships have advanced rapidly in the past decade. It is possible to measure the concentrations of chemicals present at very low concentrations with far smaller samples than hitherto. And many of the chemicals can now be analysed at sea. Mass spectroscopy has revolutionized the measurement of tritium and other elements previously detected by counting radioactive decay[62,63]. Those advances have made it possible to undertake extensive surveys of chemical distributions in the world ocean: first GEOSECS (Geochemical Ocean Sections Study)[64] and more recently TTO (transient tracers in the ocean)[65]. These chemicals supplement the variables (temperature, salinity, oxygen and nutrients) used traditionally to infer the circulation[52,66].

The most spectacular advance in ocean observation has come from the demonstration by Seasat during a 100-day mission in 1979 that satellite radar and passive microwave techniques now offer the accuracy needed for ocean circulation research[67,68]. The success of the radar altimeter in measuring the shape of the ocean to a precision better than 10 cm opens the door to global mapping of the surface geostrophic velocity (Fig. 9), thereby allowing oceanographers to dispense with the classical and unwarranted assumption that the flow goes to zero at some arbitrary deep level[69]. The advent of satellite altimetry and plans for future altimetric missions provided the initial impetus for WOCE. The technique offered the prospect of a truly global perspective of the ocean circulation for the first time. The timing of the experiment has from the start been based on the launch date of the next altimetric mission. At present, it seems likely that the European Earth Resources Satellite ERS-1 and the American-French Topex-Poseidon will be launched in 1990 and operated for 3–5 years. The success of other satellite techniques has also influenced the early planning of WOCE. In particular, the radar scatterometer, which promises to provide systematic global measurements of the wind stress on the ocean for the first time[70]. The measurement of sea-surface temperature by infrared radiometer has had a chequered past, but at last seems to be yielding measurements accurate to 0.6 K, with the prospect of improvement to about 0.3 K in the future[71]; that begins to be useful for WOCE.

Other techniques showing promise for WOCE include acoustic tomography, which has mapped eddy patterns in an early sea trial[46], and acoustic Doppler current profiling, which might be deployed widely on merchant ships to map currents in the top few hundred metres of the ocean[72]. Increasing attention is being paid to collecting data from research ships moving at speed (in contrast to the classical technique of profiling on station): undulating profilers derived from the Batfish have been used to collect upper ocean sections several megametres long[73]. Baker[74] has reviewed these and other new techniques that lead us to believe that some of the old problems preventing oceanographers from observing the ocean globally are being solved.

CO_2 pollution. Early calculations of the climate response to CO_2 pollution of the atmosphere suggested that equilibrium with twice the present concentration would be achieved when the atmosphere was on average about 2 K warmer than now, with a smaller rise in the tropics but up to 8 K at high latitudes, and an associated change in the pattern of precipitation[75]. There was speculation that the temperature rise might cause the West Antarctic ice sheet to melt, raising sea level by several metres[76], and that the change in rainfall pattern might have a major impact

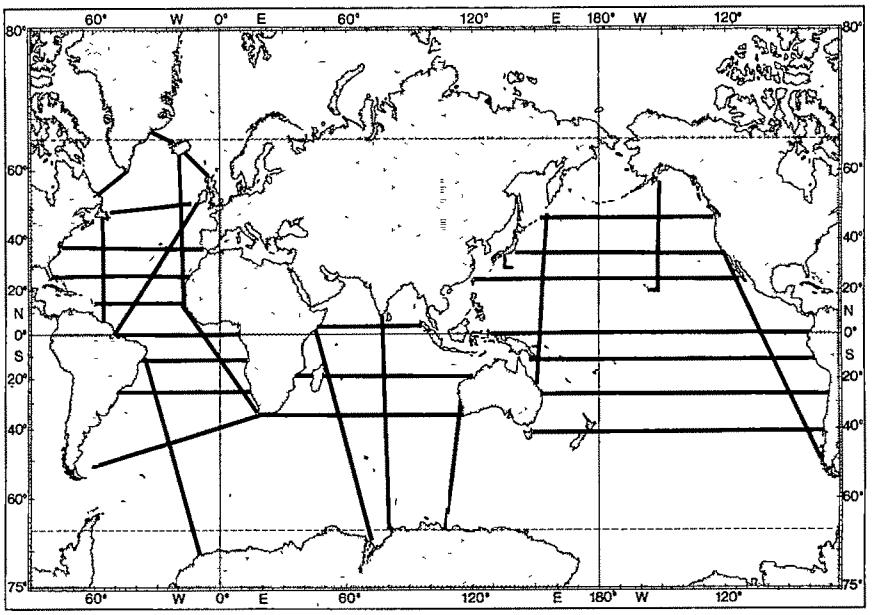

Fig. 10 One possible distribution of trans-ocean hydrographic sections for WOCE based on a realistic estimate of ship time likely to be forthcoming from existing resources available to the world oceanographic community (ref. 78). Additional ship resources will be needed to undertake the WOCE hydrographic and tracer programme in the Southern Hemisphere, which is not adequately covered by the sections identified in this map.

on agriculture in some countries[77]. These predictions were sufficiently alarming to create a demand for research into predicting decadal changes of climate (CO_2 concentration being predicted to double within 50 years). Further modelling made it clear that the rate and global pattern of atmospheric temperature rise will be largely determined by sea-surface temperature response to the changing infrared flux from the atmosphere. It was realized that early models based on heating limited to the mixed layer, which gave a response time of a few years, were wrong. It is necessary to take account of the subduction of water from the mixed layer into the interior by Ekman pumping and deep convection in winter[17]. That spreads the heat input over a much greater water depth, delaying the attainment of an equilibrium sea-surface temperature rise for decades, and allowing the ocean circulation to distribute the thermal anomaly widely, perhaps even between ocean basins. Unfortunately, the present state of ocean circulation modelling, and especially the treatment of the subduction process, is inadequate to the task of predicting accurately the transient thermal response of the ocean to the changing surface infrared flux due to CO_2 pollution. The early timing of WOCE is, in part, a response to the sense of urgency generated by those concerned with predicting climate response to CO_2 pollution.

Experimental strategy

The primary goal of the experiment is to develop ocean models useful for predicting decadal climate change and to collect the data necessary for testing them. The specific objectives are to determine and understand on a global basis the following aspects of the world ocean circulation and their relation to climate: (1) The large-scale fluxes of heat and fresh water and their divergences within 5 years, and in addition their annual and interannual varaiblity. (2) The inputs and fluxes of potential vorticity. (3) Components of oceanic variability on months to years, megametres to global scale, and the statistics on smaller scales. (4) The rates and nature of formation, ventilation and circulation of water masses that influence the climate system on time scales ranging from 10 to 100 years.

The experimental design strategy being followed for WOCE offers three perspectives on the circulation: the global scale; the links between the separate ocean basins; and inside the basins. Inevitably, there will be overlap between those three perspectives, but the detailed experimental design, and the precise specification for similar measurements, will be different.

The field programme will be intensive, with a limited duration related to the planned mission lives of the next generation of ocean observing satellites, which provide the first opportunity to collect global observations. The expected launch year of those satellites is 1990, and their planned lifetimes are 3–5 years. The intensive oceanographic programme of WOCE will, therefore, concentrate on the period 1990–95, with the possiblity of adjustment according to changes in satellite launch dates. Those measurements in the ocean that need to be made simultaneously with the satellite measurements must be concentrated into that period. Other measurements (for example, some aspects of the deep tracer surveys) can safely start earlier and continue after the 1990–95 period.

The fact that the intensive field programme will extend over several years does not mean that the resulting data set will constitute an average or synoptic description of the world ocean during that period. The satellite data will come closest to the ideal of a time series of synoptic observations. Most of the *in situ* observations will be made once, sequentially as part of a rolling programme extending over 5 or more years. A few measurements will be repeated to check for significant changes, and there will be a small number of time series. There is no single name that describes such a non-synoptic sample, which will inevitably alias most of the changes occurring within the intensive field phase. The word 'snapshot' captures something of the spirit in which the WOCE data set will have to be analysed, provided one bears in mind the photographic problems of camera shake, focal plane distortion, and so on. Despite these problems of interpretation, the WOCE snapshot will be far more coherent and closer to being synoptic than the existing data archive accumulated over several decades. It will, therefore, represent a significant advance in sampling technique, as well as in global coverage. A conscious effort will be made in designing the experiment to minimize the remaining problems of aliasing. Selected measurements will also be continued for a longer period to discover how representative was the WOCE snapshot of the ocean, given its broad spectrum of natural variability.

WOCE design

The development of an experimental design soon becomes a juggling act between the desirable and the possible. This section outlines the principal ingredients of the experiments, as proposed by Wunsch[78]:

(1) The fields of surface forcing as determined by (i) satellite scatterometers (anticipated spacecraft are the European Space Agency's ERS-1 and the US National Remote Ocean Sensing Satellite NROSS) for wind stress; (ii) conventional meteorological analyses for wind stress and heat and moisture fluxes based on improved atmospheric modelling efforts and an upgraded surface observational system using drifters in otherwise uncovered regions.

(2) The field of oceanic surface topography (the oceanic surface pressure boundary condition) determined by (i) satellite altimeters (anticipated spacecraft are ERS-1 and the US NASA Topex Mission); (ii) tide gauge network on coasts and oceanic islands.

(3) Global hydrography from ships using both highest quality conductivity–temperature–pressure profilers plus developing free-fall instruments from 'research ships of opportunity' to provide both a climatological temperature–salinity data base plus continent-to-continent, top-to-bottom sections for use with dynamic method and ancillary observations and models (Fig. 10).

(4) Global measurements from ships (probably combined with hydrographic measurements) of chemical tracers, including tritium, fluorocarbons, oxygen and nutrients. These observations, along with the hydrography, provide the primary observable parameters representing the integrated (that is, time-average) behaviour of the ocean circulation.

(5) Global, but sparse, sampling of selected chemical tracers such as ^{14}C as part of the determination of time-integrated oceanic behaviour.

(6) Global, but sparse, determination of the dominant source-sink terms of the biogeochemical tracers involving transfers to and from the sea floor and continental margins by sediment traps and so on, for purposes of using the tracers.

(7) Direct observations of the flow fields over large areas for long time periods by 'clouds' of neutrally buoyant floats and surface drifters, both communicating directly with satellites.

(8) Measurements of large areal averages for long times, of heat content, velocity and vorticity and potential vorticity through moored acoustic tomography arrays.

(9) Ship of opportunity programmes involving near-surface velocity measurements through acoustic backscatter and direct near-surface density field measurements through expendable bathythermographs.

(10) A few special, regional foci involving ships, conventional moored current meters, floats, temperature recorders, tide gauges and other *in situ* instrumentation.

It is expected that it will take about 5 years to complete this measurement programme. A related programme will monitor critical aspects of the ocean over a longer period to relate that 'snapshot' of the circulation to the broad band spectrum of ocean variability.

Potential for new techniques

The WOCE design outlined above depends heavily on new techniques. How safe is it to base an experiment on new technology, and what is the criterion for rejecting promising but as yet unproven techniques? Experience gained during the GWE is relevant. The core measurements for GWE were the World Weather Watch routine synoptic observations; the equivalent for the WOCE are the research ship hydrographic and chemical surveys. Satellites were crucial for GWE, as they will be for WOCE; if present plans for altimeter and scatterometer satellites were cancelled, the WOCE would have to be postponed. Special observing systems planned for the GWE included neutrally buoyant balloons and buoys drifting on the ocean; the former failed, but the latter were successful and transformed the ability of meteorologists to analyse weather systems in the Southern Hemisphere. Special observing planned for WOCE include acoustic tomography and neutrally drifting buoys that pop up to be interrogated by satellite; both lie at the leading edge of oceanographic technology. Planners of the GWE counted on being able to improve the quality and data returns of well-established routine measurements on land; WOCE needs to do this for the meteorological measurements made by voluntary observing ships.

Looking back on the GWE, it is clear that all the observing systems that were eventually deployed in 1979 had been identified 10 yr earlier. Gaining from that experience, WOCE planning has, therefore, proceeded on the basis that no completely new techniques announced during the 1980s would be ready in time for WOCE. Most of the techniques that have been listed as needed for WOCE are the subject of intense development efforts. Perhaps the greatest uncertainty concerns the development of a new temperature–salinity profiler that can be used from research vessels not equipped with deep winches. If successful, this new instrument will make it possible to share the enormous task of the WOCE hydrographic programme among a much larger number of research institutes.

Novel techniques will be tested during the WOCE snapshot to discover their potential for cost-effective long-term monitoring of the ocean in the next century.

Conclusion

The World Ocean Circulation Experiment is an undertaking planned to support research in decadal climate variation. It will also provide a unique global perspective of ocean circulation with applications in many other aspects of marine science.

The WOCE is a major component of the World Climate Research Programme (WCRP) sponsored jointly by intergovernmental and non-international governmental organizations. The WCRP is concerned with discovering whether it is possible to predict climate on timescales of several weeks to several decades, and to determine the effect of man's influence on climate. The programme is divided into three streams, concerned respectively with climate prediction in periods of (1) months, (2) years and (3) decades. The critical scientific problem limiting our ability to predict decadal climate change is the inadequate description of and ability to model the circulation of the world ocean. The organizers of the WCRP have therefore proposed the WOCE as the principal activity within stream (3) of the WCRP. They have established the WOCE Scientific Steering Group (SSG) to plan and organize the experiment. The tasks of the SSG are to identify the primary goals and objectives of WOCE, to design a core research programme including modelling and fieldwork, to identify the resources needed to undertake the programme, and to work with international and national bodies, with research institutes and universities and with individual scientists to achieve that core research programme and to encourage the development of associated projects that support the goals of WOCE. J.D.W. is co-chairman of the SSG.

Cosmic γ rays and the mass of gas in the Galaxy

Chaman L. Bhat*, Mohamed R. Issa†, Brian P. Houston, Chris J. Mayer & Arnold W. Wolfendale

Physics Department, University of Durham, Durham DH1 3LE, UK

We make the case that the cosmic-ray particles that produce cosmic γ-rays in the 100-MeV region can penetrate most of the dense clouds of gas that seem to contain much of the mass of gas in the Galaxy. We determine a probable form for cosmic-ray intensity as a function of Galactic position and use the measured γ-ray intensities to derive the surface density of gas as a function of position. Our estimate of $\sim 6 \times 10^8$ $M_\odot$ for the total mass of molecular hydrogen compared with 1×10^9 $M_\odot$ for atomic hydrogen in the inner Galaxy is a significant change in the contemporary perspective.

THE state of the interstellar medium (ISM) has been investigated in all wavelength regions. We describe here the distribution of gas on the galactic scale from γ-ray studies and put forward other recent supporting evidence.

Information about the magnitude of gas density and its division between the major components, atomic H I and molecular hydrogen, is relevant to several problems in astronomy, one being the manner in which the cosmic-ray intensity varies with position in the Galaxy. The gas distribution must be known to interpret the diffuse γ-ray flux. γ Rays, produced by the interaction of cosmic rays with gas in the ISM, are an ideal tracer because they are not absorbed by the gas.

The distribution of H I is known reasonably well from observations of the 21-cm line. The situation with the other major gas component, H_2, is less clear, however, because the observations are indirect, obtained by detection of ^{12}CO and ^{13}CO. It is thought that the CO is excited by impacts with H_2 molecules and various arguments can be used to relate the CO densities to those of H_2 (see, for example, the comprehensive analysis of Sanders *et al.*[1]; to be referred to as SSS).

A detailed study of the H_2 problem has been made by SSS under the usual assumption of radial symmetry (Fig. 1). This can be regarded as the 'conventional' estimate of the surface density of H_2, $\sigma_{H_2}(R)$; here, we estimate this quantity by quite different means (see Fig. 1 legend).

The γ-ray view

In the absence of a significant contribution of γ rays from discrete sources[2-4], the relation between the cosmic-ray intensity (I_{CR}), the surface density of gas and the observed γ-ray intensity is straightforward.

First, we examine very local molecular clouds where I_{CR} is presumably the same as that at the Earth and determine the best value of α, the conversion factor relating the measured quantity from CO measurements, $\int T\,dV$, (where T is antenna temperature and V velocity) to the column density of gas, $N(H_2)$. $\alpha = N(H_2)/\int T\,dV$ in units of 10^{20} atoms $cm^{-2}\,K^{-1}\,km^{-1}\,s$ (note that some authors use 'X' $= \alpha/2$ in units of molecules $cm^{-2}\,K^{-1}\,km^{-1}\,s$). The value can then be used in the inner Galaxy, suitably modified according to our view of interstellar chemistry. Second, we use the dependence of I_{CR} on radial distance (R) in the outer Galaxy to imply its probable dependence on R in the inner Galaxy, and thereby determine the total gas surface density independently.

We start by studying the local clouds, particularly those in Orion. As well as determining a value for α, we must show conclusively that the cosmic rays are able to penetrate most of the gas in the clouds.

Local molecular clouds

Several γ-ray studies of the Orion clouds have been made already, but here we follow the analysis of Houston and Wolfendale[5] and concentrate on the two clouds A and B. The question of a possible exclusion of cosmic rays from the dense parts of

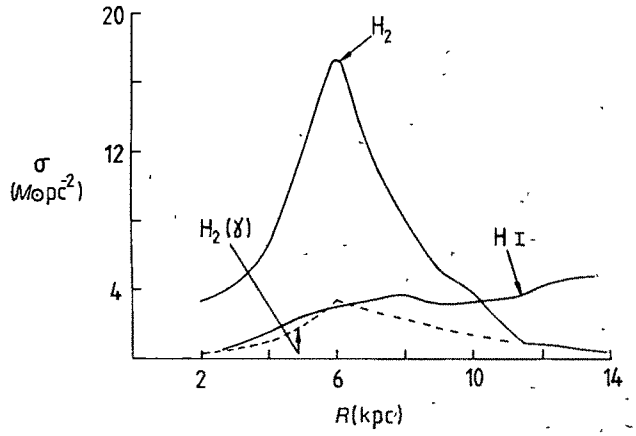

Fig. 1 Dependence of the surface density of H_2 and H I on Galactocentric radius, R. H_2 is estimated in ref. 1; in other analyses different conversion factors have been applied, resulting in maximum densities varying from about 13 $M_\odot\,pc^{-2}$ (ref. 8) to 32 $M_\odot\,pc^{-2}$ (ref. 35). The conversion factor for $^{12}CO \rightarrow H_2$ used in ref. 1 in deriving H_2 is $\alpha = 7.2\times10^{20}$ atoms $cm^{-2}\,K^{-1}\,km^{-1}\,s$. The curve for H I is the mean of derivations in refs 8 and 9; both use the basic Berkeley data[36]. $H_2(\gamma)$ is our own estimate of $\sigma_{H_2}(R)$.

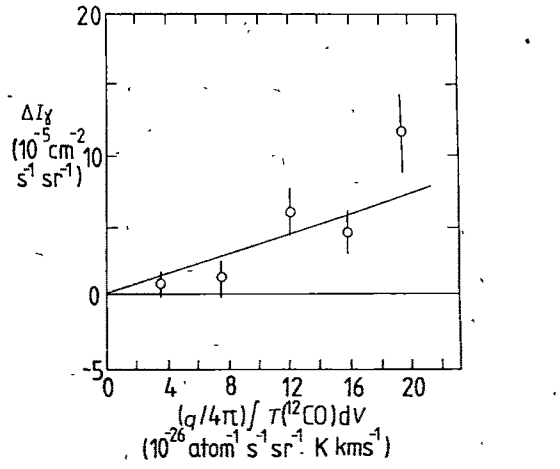

Fig. 2 Correlation of γ-ray intensity ($E_\gamma > 100$ MeV) with $\int T(^{12}CO)\,dV$ for the Orion clouds A and B (after ref. 5). ΔI_γ is the γ-ray intensity less the predicted contribution from CR interacting with H I along the line of sight. The CO data are from Kutner *et al.*[37] and the areas adopted were within the 1 K km s^{-1} contours. The γ-ray intensities are from the COS B experiment[4]; $q/4\pi$, the emissivity per H atom, has been taken as 2.0×10^{-26} atom^{-1} s^{-1} sr^{-1}, this value being the mean of various 'high latitude' estimates. The mean slope gives $\alpha = 3.7\times10^{20}$ atoms $cm^{-2}\,K^{-1}\,km^{-1}\,s$; the errors shown are statistical.

the clouds has been examined[5]. Although the cosmic-ray energies are probably sufficiently high for exclusion not to be dramatic, as suggested theoretically by Skilling and Strong[6], nevertheless an experimental demonstration is essential.

The result can be seen in Fig. 2 and its legend. Note that there is near linearity of ΔI_γ with $\int T\,dV$; if linearity is assumed, α follows as the gradient of the line and is found to be 3.7 ± 1.0 atoms $cm^{-2}\,K^{-1}\,km^{-1}\,s$. This value of α is much less than that in Fig. 1 (3.7 compared with 7.2); it is in fact a little smaller than the value we used previously (for example, 4.6 in ref. 7, following Gordon and Burton[8]), although Li *et al.*[9] made the case for $\alpha = 2.3$, locally, from various other arguments. A more detailed discussion of these α values is given later.

Figure 2 shows that there is no evidence for cosmic-ray (CR) exclusion from the densest parts of the clouds (on the angular scale of the COS B observations). If anything, there might be an excess of CR in the densest parts. If the γ-ray excess were attributed to an excess of cosmic-ray particles (or unresolved γ-ray sources), then the true value of α for the $CO \rightarrow H_2$ conversion would be significantly smaller than in Fig. 2, but the evidence is not yet strong enough for this assumption.

Other local clouds

The 'local' CR intensity adopted for Orion can probably be used out to ~1 kpc (despite evidence for local gradients[10]); the analysis of Issa and Wolfendale[11,12] examined the local clouds. The objects in this range comprise Taurus, Corona Austrina, Ophiuchi and Gum and Monoceros OBI as well as Orion. Masses have been estimated both with and without the local thermodynamic equilibrium (LTE) condition and using $\alpha = 4.6$, and suitable allowance has been made for H I and ionized gas where appropriate. The lower limits to the mass (that is, adopting LTE) now seem more appropriate and the results of Issa and Wolfendale[11,12] show that the average value of the CR enhancement factor (F is the ratio of I_{CR} in the cloud to I_{CR} locally) needed to satisfy the γ-ray data is $F \simeq 0.5$. Thus, a re-analysis of this work gives $\alpha = 2.3$, somewhat smaller than that derived in the previous section.

Here, we have presented evidence for two local values of α, 3.7 and 2.3. Of these, the first is statistically firmer, but there is almost certainly a correction to be applied because the 'metallicity' M (defined here as the ratio of O to H, normalized to the local value) is lower in Orion than in its surroundings by a factor of ~1.7 (refs 13, 14).

Later, we argue that the conversion from CO to H_2 depends on the metallicity (in particular, we take α as proportional to M^{-1}); to be consistent we must adopt the same procedure with Orion to derive from its α-value the corresponding average local value α_L. Because metallicities have not been determined for other galactic molecular clouds (as distinct from H II regions in the inner Galaxy which are used to give the so-called metallicity gradient), we adopt a local average value of α higher than α/M but lower than α. Accordingly, $\alpha_L = 2.7$ is used here as a compromise.

Other estimates of α locally

The Virial Theorem can be used to give estimates of cloud masses (strictly for clouds in equilibrium). Application to the local clouds surveyed by Stark and Blitz[15], after adopting intracloud velocities for the optically thin ^{13}CO line ($\simeq 1.5$ km s^{-1} half-width half maximum), yields $\alpha_L \simeq 2$. Direct determination of the column density of ^{12}CO from an optically thin transition in Orion[16] gives an upper limit to $N(H_2)$, implying $\alpha < 3.5$, if $^{12}CO/^{13}CO$ is $\simeq 40$, as often assumed. Another important result of this observation is that the velocity dispersion is $\lesssim 1.5$ km s^{-1}, a small value leading again to a small virial mass and a small α. Taken together, the evidence indicates that $2 < \alpha_L < 4$, hence we adopt $\alpha_L = 2.7$.

Cosmic-ray gradient

We have demonstrated that the new value of α (2.7) is 0.37 times that used in deriving the surface density of H_2 (Fig. 1). We next examine cosmic-ray evidence for an even smaller α value in the inner Galaxy. Starting with the γ-ray method, we examine the evidence for cosmic-ray gradients, that is, systematic changes of I_{CR} with R. There is agreement amongst those who have examined the SAS II (ref. 17) and COS B (ref. 18) γ-ray results[10,19] that there is a fall-off of CR electron intensity in the outer Galaxy (Fig. 3).

There is an approximate agreement of I_{CR} with the surface density of supernova remnants (Fig. 3) at the lower energies. There are admittedly problems with the determination of I_{CR} in the inner Galaxy (because of uncertainty in the effect of allowing for the ubiquitous H_2 component), but the situation in the outer Galaxy is well established. Here, there is fall-off in I_{CR} (ref. 10) and it is probable on general grounds that there will be a corresponding increase in I_{CR} in the inner Galaxy. It would be surprising if this increase in I_{CR} did not occur to at

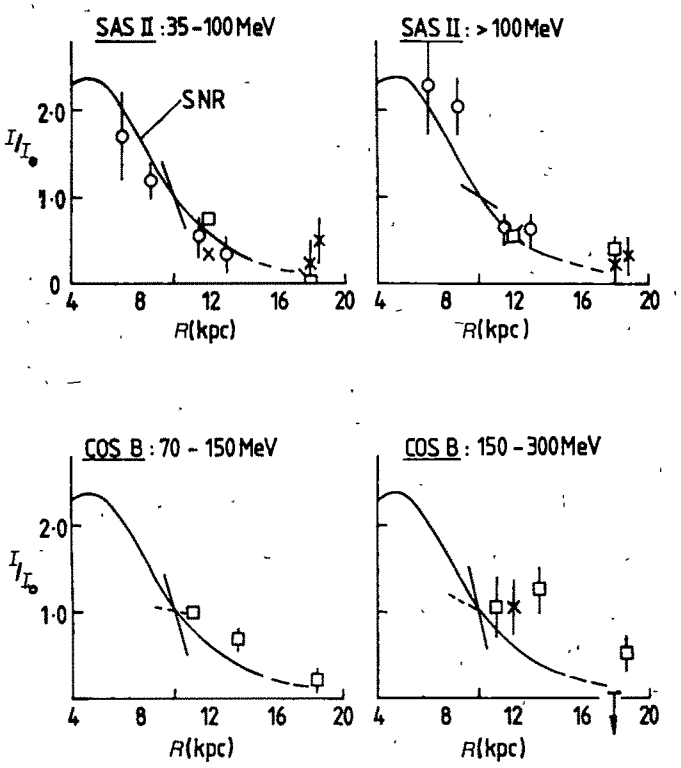

Fig. 3 Gradient of cosmic-ray intensity derived by various workers from the data of the SAS II experiment[17] and COS B[18]. The ordinate is the ratio of the cosmic-ray intensity to that locally, I/I_0. The SNR distribution[38] is shown as a probable distribution of the low energy cosmic rays responsible for the γ-rays. O, Data from Issa *et al.*[39]; □, data from Bloemen *et al.*[19]; ×, data from Bhat *et al.*[10,40]. The inclined lines through $R = 10$ kpc (the local position) refer to an analysis of γ-rays in the range $|b| = 11$–$19°$ (ref. 40); dotted inclined lines refer to an extreme Inverse Compton contribution; errors are statistical.

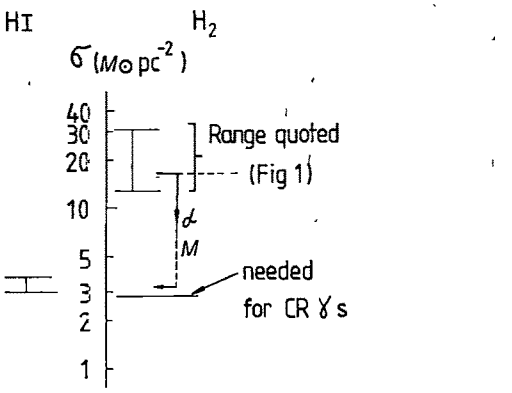

Fig. 4 Surface densities of H I and H_2 at $R = 6$ kpc. The range of quoted values from CO observations (using various α values) is indicated, as is the value from Fig. 1. The effect of reducing the surface density of H_2 by 0.37 times (to allow for the change in α) and by 0.5 (to allow for metallicity) is shown. Also indicated is the value needed to satisfy the cosmic γ-ray results.

least $R = 6$ kpc (all other indicators of galactic activity, such as H II regions, pulsars and H_2 surface density show similar increases). The effect of such an increase on the required surface density of all galactic gas is considered below.

Surface density of gas

The estimation of the surface density of gas at $R = 6$ kpc as required by the γ-ray data is straightfoward. Figure 4 gives the result. Taking the SSS value of $\sigma_{H_2}(R = 6\text{ kpc})$ as datum and 'correcting' to our new value of α (that is, $2.7/7.2 = 0.37$ times) yields a value of σ_{H_2} still too high for conformity with the γ-ray results; a further reduction is required. Therefore, we investigate the metallicity in the ISM and introduce a 'metallicity correction'[20,21]. Briefly, the O/H ratio in the ISM increases towards the Galactic Centre (GC) and we consider this to cause an increase in the $^{12}CO/H_2$ conversion, the factor of increase amounting to two at $R = 6$ kpc and ~3–5 at the GC. Applying the factor two, there is now a reduction in $\sigma_{H_2}(R = 6\text{ kpc})$ by a factor $0.37 \times 0.5 = 0.18$ of the SSS value, in agreement with the γ-ray expectation.

The use of the metallicity correction is controversial; it is argued against in ref. 1. The arguments for the correction are described in ref. 21 and further evidence is obtained from more detailed studies of interstellar chemistry described below. Higher temperatures and probable greater shock density in the inner Galaxy may augment or simulate a metallicity dependence.

Interstellar chemistry

We investigate the relationship between $N(^{12}CO)$ (the apparent column density of ^{12}CO), the actual value of N_{H_2} and the metallicity, characterized by the O/H ratio. We have assumed here that α is proportional to M^{-1} and we seek support for this relationship from arguments of interstellar chemistry. Comprehensive calculations have been made recently (D. A. Williams and T. Millar, personal communication and ref. 22).

Starting with the important optically-thin ^{13}CO component and limiting the argument to spherical inert clouds of mass $M_C(\sim 10^4\ M_\odot)$, the column density along a diameter divided by N_{H_2} varies approximately as $M^{1/2}$ (specifically for $T = 10$ K, gas density $n = 600$ nuclei cm^{-3}), that is, α is proportional to $M^{-1/2}$. The result is very similar for all densities in the range $200 < n < 1{,}800$ cm^{-3} and does not depend on cloud mass for $3 \times 10^3 < M_C < 10^5\ M_\odot$. The dependence on the ultraviolet intensity and the cosmic-ray heating rate is slight.

The results with ^{12}CO are very similar, although because ^{12}CO is optically thick, the detected signal in practice would not depend necessarily on M in the same way. It is here, however, that we return to the fact that over most of the Galaxy there is proportionality between the strengths of the ^{12}CO and ^{13}CO signals; we interpret this in terms of turbulence in the clouds and associated density variations such that velocity smearing allows ^{12}CO to be detected over wide regions of clouds. The result is that, although the premise of large uniform clouds (on which the chemistry calculations were made) breaks down, it seems to be in the sense of increasing the metallicity rather than reducing it. More sophisticated cloud modelling is necessary, but the best estimate so far is that α is approximately proportional to M^{-1}.

Inner Galaxy α estimates

There are other ways of estimating α at $R \simeq 6$ kpc, notably involving the virial mass, X-ray and infrared absorption, which are summarized here and discussed elsewhere in detail.

The virial masses are low when velocity dispersions for optically thin lines are used and we again have $\alpha \simeq 2$. The X-ray technique, which measures essentially the column density of atoms such as O, was first used with success by Blitz and Shu[20]. We have updated the treatment using new observations, with the result that $\alpha \simeq 1$ for $R \simeq 6$ kpc. Infrared observations give a complementary view; using the extinction data of Eaton *et al.*[23] we again find $\alpha \simeq 1$. The dust/gas ratio is probably lower by a factor of two in the region $R \simeq 6$ kpc (ref. 24) and applying this factor increases α to two.

The range of the α-values is 2 (virial), 1 or 2 (infrared) or 1 (X-ray), consistent with the γ-ray result, where $\alpha \simeq 1.4$.

Galactic Centre

Indirect evidence about the $CO \rightarrow H_2$ calibration comes from the claim by millimetre wave astronomers for considerable masses of H_2 within ~0.4 kpc of the GC on the basis of high

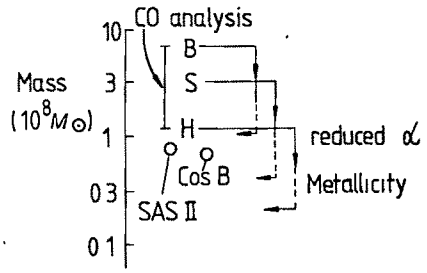

Fig. 5 Mass of gas within 400 pc of the Galactic Centre. The range of values corresponds to different CO analyses: B, data from Bania[41]; S, from Sanders *et al.*[1]; H, data from Heiligman[42]. Using our own α and the metallicity correction ($M = 3$) gives the reduced values shown by the arrows. Circles represent masses derived from the SAS II and COS B data assuming that the CR intensity at the Galactic Centre is the same as that locally (that is, $F = 1$). Adopting the mean of the reduced mass estimates would indicate $F \simeq 2$, a reasonable result.

$\int T(^{12}\mathrm{CO})\,\mathrm{d}V$ values in that direction. Several estimates have been made (Fig. 5).

For the γ-ray fluxes from the GC region, we follow the recent analysis of Houston and Wolfendale[25], who derived a GC 'source' flux of 2.3×10^{-6} cm^{-2} s^{-1} for $E > 100$ MeV for SAS II. For COS B, we identify the source 2CG359−00 from the catalogue of Hermsen[26] with the GC; this has a flux above the same energy of 1.8×10^{-6} cm^{-2} s^{-1}.

The problem now is the expected magnitude of I_{CR} in the GC region. A detailed study by Wolfendale and Worrall[27] shows that a self consistent model can be made in which the production rate of CR per unit mass of gas is approximately the same at the GC and locally (and is thus $\simeq 100\times$ greater than locally per unit volume at the GC). In the model, there is agreement with radio synchrotron data in showing that the ambient I_{CR} at the GC is $\sim 10\times$ that near the Sun. If this factor were used, we would expect a GC mass of $\simeq 0.07 \times 10^8\ M_\odot$, a very low value. As a lower limit to I_{CR} at the GC the local value can be used (that is $F = 1$), resulting in a mass of $\simeq 0.7 \times 10^8\ M_\odot$. The masses shown in Fig. 5 use $F = 1$.

The effect of applying the new α and the metallicity correction (a reduction of at least $M = 3$ at the GC) can now be examined. Figure 5 shows the new CO-implied masses which are now 'reasonable' in that they corespond to a modest CR enhancement of intensity ($F \simeq 2$). With the higher metallicity factor $M = 5$, implied by extrapolating the O/H gradient of -0.07 kpc^{-1} back to the GC, the mass would be correspondingly lower and $F \simeq 4$, a still reasonable enhancement.

Blitz *et al.*[28] have recently made a similar analysis and concluded that a very small α at the GC is probable. The main value of the present analysis of the GC is that it lends support to the presence of a metallicity effect (or perhaps shocks and temperature effects simulating it) and thereby to the correctness of our α-values in the inner Galaxy. (Blitz *et al.*[28] also make important comments about 'time variability' of the CO results; that is, the presence of systematic errors between different instruments and sets of measurements.)

Discussion

We have derived an independent estimate of the magnitude of the surface density of gas in the Galaxy as a function of galactocentric radius using γ-ray astronomy and supported by other techniques. Figure 1 shows that our estimate, $H_2(\gamma)$, is considerably lower than the 'conventional' estimate, from ref. 1, an estimate made using the usual procedure of relating $\int T\,\mathrm{d}V$ for the 2.6-mm CO line to the column density of H_2. Although we argue that the new estimate is reliable, it also contains assumptions; therefore, we have examined the 'conventional' method and, using the basic data on CO, made our own estimate of the surface density of the molecular gas.

The basic results[1] for $\int T\,\mathrm{d}V$ versus longitude have been taken, together with our own unfolding, to give the radial distribution of CO. Adopting radial symmetry, the result is CO surface densities ~60–80% of those given by SSS. This discrepancy presumably relates to differing assumptions in allowing for the clumpy nature of the gas distribution.

The important question of the CO → H_2 conversion has been examined in detail. Dickman's[29] results of $\int T(^{13}\mathrm{CO})\,\mathrm{d}V$ against visual extinction A_V for local clouds, and similar data for Taurus[30], have been examined and, as found by SSS, there is evidence for a saturation of $\int T\,\mathrm{d}V$ versus A_V. ($\int T\,\mathrm{d}V$ is proportional to $A_V^{0.5}$, approximately fitting a power law to the whole range in ref. 1, but we can have $\int T\,\mathrm{d}V$ proportional to A_V up to values of 6 for A_V for Taurus at least, with a flattening above.) It is conventional to follow Bohlin *et al.*[31] and adopt a linear relation of N_{H_2} versus A_V ($N_{H_2} = 0.95 \times 10^{21}\ A_V$ molecules cm^{-2}, although this relation has only been verified observationally for $A_V < 2$, clearly another region of uncertainty). The crucial questions concern the effective mean value of $\int T\,\mathrm{d}V$ for the GMC, where on the $A_V^{0.5}$ plot are we situated and the corresponding α value. These questions are examined in detail below.

For the Orion molecular clouds the 'median mass' $\int T(^{12}\mathrm{CO})\mathrm{d}V$ value (half the cloud mass is within and half without) is ~11 K km s^{-1} and 2 K km s^{-1} for ^{13}CO. Such a value is well on the linear part of the $\int T(^{13}\mathrm{CO})\,\mathrm{d}V$ against A_V relation.

Inspection of the data on Dickman's[29] clouds, five of which are completely mapped, indicates that the mean value of A_V is ~2.5 and the median $\int T(^{13}\mathrm{CO})\,\mathrm{d}V \sim 4$ K km s^{-1}. It is immediately apparent that with such a low value of $\int T(^{13}\mathrm{CO})\,\mathrm{d}V$, the derived α value will be low; specifically 3.0 for the five fully mapped clouds, very close to our earlier γ-ray value of 2.7 for the local region.

There is evidence that the 'clouds' detected on the galactic plane in the inner Galaxy have high values of $\int T(^{13}\mathrm{CO})\,\mathrm{d}V$ (for example, ref. 32, 7.2 K km s^{-1}, used in ref. 1), although other data[33] give values of only ~3 K km s^{-1}. We consider that many of the so-called clouds are almost certainly conglomerates of smaller clouds, each of the latter probably resembling those seen locally (Orion, Taurus). If this is so, we are not on the saturated part of $\int T\,\mathrm{d}V$ versus A_V, which corresponds for local clouds to those rare passages through very dense regions, but, usually to low values of $\int T\,\mathrm{d}V$, on the linear part. For example, with passage through three clouds, the operative value of $\int T\,\mathrm{d}V$ is $7.2/3 = 2.4$ K km s^{-1}. This contention is supported by data on identified clouds of large radius[34], indicating that the mean density (molecules cm^{-3}) of the clouds falls as their linear dimension increases; this is what we would expect if loose conglomeration were occurring. The point now is that the separate parts of the conglomerate have different velocities and the constituent $\int T\,\mathrm{d}V$ values are additive.

Using the analysis presented here, we can derive the 'new' mass of H_2 in the inner Galaxy (corresponding to $H_2(\gamma)$ in Fig. 1). Neglecting the region $R < 1$ kpc, the value is 6×10^8 M, compared with 8×10^8 M for H I.

We thank Drs M. G. Edmunds, L. Blitz and T. Millar and Professors B. E. J. Pagel, M. Peimbert and D. A. Williams for helpful comments and discussions.

Acceleration of cosmic rays in the Loop I 'supernova remnant'?

C. L. Bhat*, M. R. Issa†, C. J. Mayer & A. W. Wolfendale

Physics Department, University of Durham, Durham DH1 3LE, UK

Attempts are being made to establish the origin of cosmic rays using the γ-ray method, that is, by dividing γ-ray intensity by gas-column density to chart the cosmic-ray intensity. Here we present evidence from satellite data on γ rays and from new results on the distribution of gas in the interstellar medium (ISM) for an enhancement of electron and proton intensity in the Loop I supernova remnant (SNR). There follows from this a straightforward explanation for the origin of the bulk of the low-energy cosmic radiation.

Here, we describe a study of the secondary γ rays in the 100-MeV region, generated by the interactions of cosmic rays (protons of 1-10 GeV and electrons of several hundred MeV) with the ISM. It is generally considered[1,2] that most of the γ rays detected in the satellite experiments are, in fact, generated by these interactions rather than by unresolved discrete sources, particularly at the galactic latitudes, $|b| > 10°$, considered here.

Early work by Dodds *et al.*[3] using SAS II data[4] gave evidence (subsequently confirmed[5,6]) for a gradient of cosmic-ray intensity in the outer galaxy, indicative of a galactic origin for the mixed beam of relevant electrons and protons. To distinguish between the relative contributions of protons and electrons, however, is not a trivial problem and, although it is now generally agreed that there is a gradient for electrons[5,6], the situation for protons is debatable[6,7]. (In fact, acceptance of the arguments presented here would resolve the debate; we shall argue that the strong local gradient[7] will have an important contribution from the Loop.)

That there is a strong correlation of the γ-ray flux with the intensity of synchrotron radiation, both in and out of the plane is well known[8,9]. Prominent features of the synchrotron map out of the plane are a number of Loops of which the most prominent is Loop I. This has been identified by Berkhuijsen *et al.*[10] with a SNR centred on a point ~130 pc away, with diameter ~230 pc and having central coordinates $l = 329°$, $b = +17.5°$. The corresponding position for the supernova was 40 pc above the plane and the bulk of the shock front is still in the gas disk; the Loop is prominent between latitudes −30°-+80° and longitudes 260°-60°.

It is natural to search for a specific correlation of the γ-ray flux with this Loop to support a popular hypothesis[11-15] that the supernova is the seat of cosmic-ray acceleration. We mention particularly the work of Blandford and Cowie[15], who have not only considered the cosmic-ray energetics of radio loops but have made specific predictions of γ-ray emissivities.

Concerning γ rays, there are data from the SAS II experiment[16] and, for each of a number of latitude bands (Fig. 1), we have determined the dependence of γ-ray intensity on longitude. The expected γ-ray intensity for the same conditions has been derived assuming a constant cosmic-ray intensity and adopting a new estimate of the column density of gas.

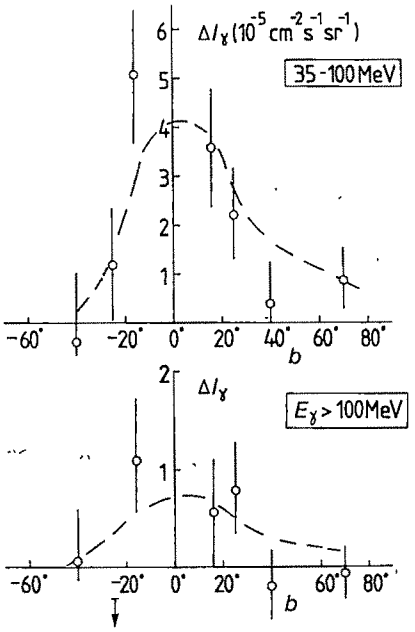

Fig. 1 The excess γ-ray intensity associated with Loop I as a function of galactic latitude. The basic γ-ray data are from the SAS II experiment[16] ΔI_γ is the difference between observed and expected γ-ray intensity for the Loop region minus the same quantity outside the Loop. The smooth curve is the corresponding T_{408}, averaged in the same way, normalized in height to observation. The particles generating the γ rays are almost entirely electrons in the lower energy band. At higher energies protons generate about 60% of the γ rays

The column density of gas (N) comprises two components—HI, N_{HI} and H_2, N_{H_2}. The former is well known[17-19], but the latter is uncertain and it is on the choice for N_{H_2} that the present work rests; thus, if we have seriously underestimated N_{H_2}, our conclusions will be invalid. Our method consists of using galaxy counts[20] to give N_{H_2} for those regions where CO observations are not available and calibrating the galaxy-count column density against N_{H_2} in the region where CO data are available (l: 5°-35°; b. 10°-20°; ref. 21). For the longitude range above $l = 210°$, where galaxy counts cease, we adopt interstellar reddening data[8,9]. As an indication of the importance of H_2 in the lowest latitude range considered (12.8°-19.5°), the adopted average N_{H_2} is ~25% that for N_{HI}. Other spot measurements using different techniques in the l,b range considered also give very small N_{H_2} values[22,23]. For latitudes outside $|b| = 20°$, we follow previous work[24,25], neglecting N_{H_2} altogether. The emissivity values used to derive the predicted γ-ray intensities are $q/4\pi = 3.7 \times 10^{-26}$ and 2.6×10^{-26} atom^{-1} s^{-1} sr^{-1} for 35-100

Permanent addresses * Bhabha Atomic Research Centre, Srinagar, India; † University of Doha, Qatar

and >100 MeV respectively. (In fact the absolute values are not very important because of the subtraction technique used.)

The procedure is now to determine the excess of the observed γ-ray intensity relative to that expected as a function of longitude, $I_e(l)$, both inside the loop region, $I_{e,L}$, and outside it, $I_{e,o}$, and to determine $\Delta I_\gamma = I_{e,L} - I_{e,o}$, representing the excess contributed by the Loop (the longitude range embraced by the Loop is $l = 260° \rightarrow 60°$ over the relevant latitudes). Figure 1 shows the Loop contribution as a function of latitude. A similar analysis has been made for the COS B data[20] in the latitude range $|b| = 11° \rightarrow 19°$, but, unfortunately, no COS B data are yet available for $|b| > 19°$. Figure 2 gives a comparison of the Loop contributions for the positive (N) and negative (S) latitude ranges ($11° \rightarrow 19°$) (correcting the SAS II values to the same b-range).

There is no question of the γ-ray excess being constant over the SNR; in fact, it peaks just inside the well known radio-continuum North Polar Spur, but, insofar as we wish to determine the energetics of the remnant, the analysis is made in terms of averages over the object. Figure 1 contains a plot of ΔT_{408} (T_{408} is the antenna temperature of the radio emission at 408 MHz) against latitude from which the general correlation can be seen. It is obvious that there is clear evidence for a Loop contribution, particularly for the 35–100 MeV data.

Discounting the possibility that a dense gas cloud in the direction of the Loop has been missed, the most probable alternative explanation to cosmic-ray acceleration in a SNR is that we are dealing with inverse Compton (IC) interactions of electrons with an enhanced radiation field in the vicinity of the Loop. Using the analysis of Riley and Wolfendale[8], it seems unlikely that >50% of the Loop contribution can be attributed to IC, at any energy; Bloemen's work would give an even smaller IC contribution (J. B. G. M. Bloeman, personal communication). It is reassuring that the COS B excess is present at all energies and; given that cosmic-ray protons predominate as primaries of the γ rays in the highest energy region, this is the best evidence for an excess of protons in the Loop.

We turn now to questions of enhanced cosmic-ray intensities and energetics, starting with the electron component. That the Loop is actually seen in synchrotron radiation shows that there is an enhanced cosmic-ray electron intensity and/or an increased magnetic field intensity (the electron energy being ~3 GeV for typical ISM fields). Surprisingly perhaps the magnetic field seems not to be enhanced[26] and thus the electron intensity must be increased considerably. Heiles *et al.*[26] estimate an increase by a factor $F_e \sim 20$ in the radio-continuum North Polar Spur. Averaging over the whole SNR gives an electron enhancement factor $F_{e,r} \sim 5$–10.

Figure 1 ($E_\gamma = 35$–100 MeV) can be used to estimate F_e for the initiating electrons for the γ rays ($\langle E_e \rangle \sim 200$ MeV). Using the model of Blandford and Cowie[15] with a mean density of 0.4 cm^{-3} (0.2 cm^{-3} in the hot ISM and 0.2 cm^{-3} for the average contribution of cold sub-clouds) the average enhancement factor is $F_{e,\gamma} \sim 6$, in good agreement with $F_{e,r}$.

We now consider the ambient energy density of the cosmic-ray electron component needed to calculate the electron energy residing in the remnant. The magnitude seems to depend critically on the lower limit to the energy, unlike the proton case, because of the need for a steep electron spectrum below 1 GeV to explain the ambient γ-ray and radio spectra. Adopting the interstellar electron spectrum of Strong and Wolfendale[27], the energy densities in electrons are 2.3×10^{-2} eV cm^{-3} above 100 MeV and 3×10^{-3} eV cm^{-3} above 1 GeV, to be compared with ~0.5 eV cm^{-3} above 100 MeV and ~0.4 eV cm^{-3} above 1 GeV for protons.

Adopting the 100-MeV limit and $F_{e,\gamma} = 6$, the total energy in electrons in the remnant is $\sim 2 \times 10^{49}$ erg. Turning now to protons, the mean value for SAS II and COS B is $F_{p,\gamma} \sim 4$ and the corresponding energy is 2×10^{50} erg. Considering the problem of the IC contribution, it is best to reduce these values by a factor of two, to $E_e \sim 10^{49}$ erg and $E_p \sim 10^{50}$ erg and attach an uncertainty of a factor of three to each.

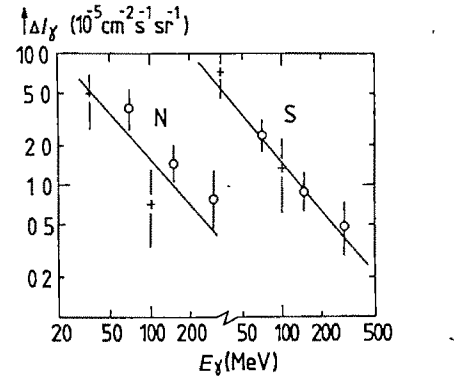

Fig. 2 The excess γ-ray intensity defined in Fig. 1 as a function of threshold energy. The latitude ranges are: N 11°→19°, S −11°→−19°. The circles refer to COS B data and the crosses to SAS II. The spectral shape is not dissimilar to the average spectrum of galactic γ rays. There appears to be a significant excess for the highest energy γ rays, these quanta being generated very largely by cosmic-ray protons

We can now make a comparison with the predictions of Blandford and Cowie[15]; their average γ-ray surface brightness, above 100 MeV, of 7×10^{-6} cm^{-2} s^{-1} sr^{-1} is very similar to that in Fig. 2. Concerning the energy content of the Loop, our estimate is $\sim 10^{50}$ erg for protons and $\sim 10^{49}$ erg for electrons, again close to estimates based on the Blandford and Cowie model for a supernova of initial energy 10^{51} erg.

We can now return to the important question of the acceleration of protons; unlike electrons, for which there is the synchrotron enhancement, the γ-ray results alone provide supporting evidence. The argument in favour of accelerated protons is demonstrated by the higher energy band in Fig. 1 (protons probably give ~60% of the γ rays) and the two highest energy bands in Fig. 2, particularly that for $E_\gamma > 300$ MeV, where we expect at least 80% to have been produced by protons. An important feature here is that the correlation between I_γ (> 300 MeV) and T_{408} is singularly strong, thus confirming that the protons are being accelerated along with the electrons. That we find approximate agreement between $F_{e,r}$ and $F_{e,\gamma}$ suggests that our estimates of gas column density are not seriously in error.

The implications of the results for the origin of cosmic rays are obvious, the most important feature being that the efficiency for conversion of supernova energy into cosmic-ray protons is very high. For Loop I we have presently about 10% of the initial energy in protons, which presumably will soon be released into the ISM. The energy requirement for cosmic radiation in the Galaxy can be calculated as follows. With a galactic volume for cosmic rays of 8×10^{67} cm^3, a lifetime for the particles of 2×10^7 yr and an ambient energy density of 0.5 eV cm^{-3}, the cosmic-ray energy input is $\sim 10^{41}$ erg s^{-1}. Adopting a supernova rate of 1 per 30 yr and total energy per supernova of 10^{51} erg, the efficiency required for generation of cosmic radiation at the moment of release into the ISM is simply 10%, that is, the value we estimate for Loop I. Such agreement is surely fortuitous in view of the many uncertainties involved, but it does demonstrate the cogency of the entire argument. We are currently looking for the expected cosmic-ray enhancements in other SNR to attempt to confirm our conclusions.

We thank the SERC for its support and Dr J. L. Osborne, Dr L. Blitz and Mr M. Rogers for helpful discussions.

Terrestrial impactors at geological boundary events: comets or asteroids?

Paul R. Weissman

Earth and Space Sciences Division, Jet Propulsion Laboratory, 4800 Oak Grove Drive, Pasadena, California 91109, USA

Evidence has been presented[1,2] for a 26–28-Myr periodicity in both the terrestrial extinction record and the age of large well-dated impact craters on the Earth. A cometary source controlled by perturbations associated with either the Solar System's galactic z-motion, which has a 33-Myr half-period, or an unseen solar companion star in a 26–28-Myr orbit has been suggested[3–5] for the impacts. Identifications of meteoritic material in the impact melts of the craters[6] used to demonstrate the periodicity, however, are indicative of highly differentiated impactors, which are more representative of asteroids than of comets. Clustering of crater ages at some dates may be indicative of random comet showers, some associated with extinctions and some not. The source of asteroidal impactors with a ~28-Myr period remains unknown and casts doubt on the entire periodicity argument.

The cause of biological extinction events at geological boundaries has been much studied recently, especially since the detection of extraterrestrial material at the Cretaceous–Tertiary (K–T) boundary[7]. Among the extinction triggering mechanisms suggested are passage of the Solar System through interstellar dust clouds, asteroid and comet impacts, geomagnetic field reversals, nearby supernova explosions and exposure of the Earth to intense galactic cosmic rays. The impact arguments have gained wide acceptance, at least for the well-studied K–T event where shocked quartz grains (presumably impact ejecta) have been found[8], in addition to the large global siderophile anomalies.

The 28-Myr periodicity in the crater record is based on 16 craters with diameters >5 km and ages whose probable error is <20 Myr[2,9]. These craters are listed in Table 1 along with their diameters and ages. For eight of the sixteen craters, identifications of the impacting body composition have been made (Table 1) based on meteorite siderophile signatures in the impact melt[6]; in some cases the identification of impactor types is not completely certain.

Of the eight identified impactor compositions, six are differentiated or highly differentiated meteorite types. Formation of iron, stony and achondrite meteorites all require melting and differentiation in fairly large parent bodies. Ordinary chondrites may or may not be partially melted, but are depleted in volatiles as compared with the more-primitive carbonaceous chondrites. Only the impactors at Wanapitei, Canada at 37±2 Myr and Lappajarvi, Finland at 77±4 Myr are primitive undifferentiated meteorite types. Interestingly, Lappajarvi is the only crater in the list (except for the youngest one, of age 7 Myr) which is not identified with a periodic impact[2]; it falls almost exactly between the impact cycles at ~65 and 95 Myr.

Table 1 Periodic terrestrial craters

* Data from refs 2 and 6
† Data from refs 6 and 9

It is difficult to reconcile impact craters formed by highly differentiated meteorite types with a cometary source. Comets are believed to have formed[10] as primitive undifferentiated icy planetesimals in the region of the outer planets and beyond. The typical cometary nucleus is believed to be a heterogeneous mixture of icy volatiles (mostly water ice) and micron-sized dust particles, a few kilometres in diameter[11]. Because of their small size neither gravitational accretion energy nor internal radiogenic heating is sufficient to differentiate the nuclei[12], whose large formation distance from the sun and long-term storage in the Oort cloud precludes any subsequent possibility of extreme heating.

Interplanetary dust particles recovered by high-flying aircraft, which are presumed to have a cometary origin, seem to be agglomerations of interstellar dust grains and show no evidence of melting or differentiation[13]. Although comets may be a source for the very primitive carbonaceous chondrites, even those meteorites may be too processed to come from such a primitive source.

On the other hand, the differentiated meteorite types are believed to come from large parent bodies where gravitational and radiogenic heating is sufficient to have caused either partial or complete melting, or more modest-sized bodies where the heating has only been sufficient to drive off the more volatile elements and compounds and to cause partial melting of individual chondrite grains. Reflectance spectroscopy studies of meteorites and asteroids have shown many common analogues between the two, both in the main belt and among the known Earth-crossing asteroids (L. A. McFadden, M. J. Gaffey and T. B. McCord, personal communication). Thus, the data on impactor compositions at six of the seven periodic craters in the sample are more consistent with an asteroidal source for the impactors than with a cometary one.

Additionally, although no specific impact crater has been identified with the K–T extinction, Palme has found that the siderophile signature in the boundary clay "does not match the siderophile element pattern of unfractionated meteorites (chondrites)"[9]. An iron asteroid impactor has been suggested but is not a certainty.

It is difficult to imagine a dynamic mechanism that would supply asteroidal impactors to the Earth with a 26–28-Myr period. The typical dynamic half-life for bodies placed in Earth-crossing orbits is ~30 Myr. Impacts from any periodic injection of asteroids into Earth-crossing orbits would be scattered randomly in time over that period. What would be needed is a mechanism that both injected bodies into Earth-crossing orbits periodically and then destroyed them relatively quickly (in 1–5 Myr) if they were not swept up by the Earth.

If there is no dynamic mechanism for supplying asteroidal impactors with the suggested (or any) period, then one may

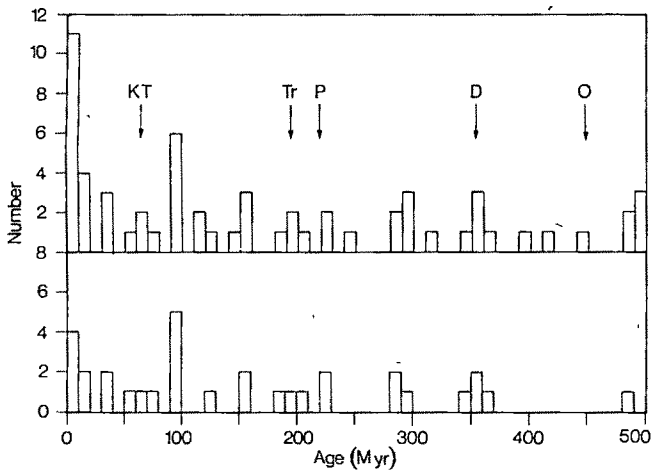

Fig. 1 Distribution of ages for dated craters on the Earth. Upper histogram is for all dated craters; lower histogram is for those with diameter ≥10 km. Arrows indicate the approximate times of the five major biological extinction events in the past 500 Myr.

suspect that the periodicity in the cratering and extinction records is not real but is a statistical fluke. Additionally, one may speculate that the extinction mechanism is not always impact related but also results from some other terrestrial or extraterrestrial event or process, such as the passage of the Solar System through a giant molecular cloud or close to a supernova explosion or an unusual period of terrestrial vulcanism.

Another question is, if there are no periodic comet showers from the inner Oort cloud, is there still evidence of random showers as suggested by Hills[14]? The distribution of ages of known impact craters on the Earth over the past 500 Myr is shown in Fig. 1. The upper histogram includes 61 craters listed by Grieve[6], without regard to the formal error on the age; the lower histogram includes only those 32 craters with diameters ≥10 km. Also shown are the approximate times of the five major extinctions in the past 500 Myr, as given by Sepkoski[15].

There seem to be non-random clusterings of craters at certain times in the Earth's past, and in some cases these may be correlated with recognized extinction events. In particular, the five craters at ~360 Myr BP (four of them ≥10 km in diameter) are close in age to the late Devonian (D) extinction event; an iridium anomaly was recently identified at this boundary[16]. Another grouping of five smaller craters at ~490 Myr BP may be associated with one of the lesser extinction events identified by Sepkoski, the Cambrian biomere events. On the other hand, a cluster of five craters at ~290 Myr BP (three, ≥10 km) is not associated with any recognized extinction and the late Ordovician (O) extinction at ~440 Myr BP has no substantial clustering of impacts simultaneous with it. The record is less clear for the Permian (P), Triassic (Tr) and K–T events where there is a more continuous distribution of large and small craters in time.

The crater clusterings associated with the late Devonian and Cambrian biomere events may be evidence of random cometary showers in the past, caused by random stars passing through the inner Oort cloud. A random star might be expected to pass within 10^4 AU of the sun, the approximate transition distance between the inner and outer Oort cloud, every 80 Myr[17]. Of the 10 craters possibly associated with these two events, only the 5-km crater at Saaksjarvi, Sweden has an identified impactor type, a stony-iron. The lack of identified impactors is largely attributable to a failure to search for them. Higher velocity impacts, however, tend to leave a smaller fraction of the meteoritic material in the impact melts[9], making the impactor type harder to identify. Cometary impacts are expected to be at average velocities of 29 km s^{-1} for short-period comets and 57 km s^{-1} for long-period comets, considerably greater than the 15–20 km s^{-1} expected for asteroids[18]. On the other hand, the crater clusterings may only be the result of random small-number statistics; more detailed analysis is clearly required.

It seems that there is not a simple one-to-one relationship between major asteroid and/or comet impacts, siderophile anomalies and biological extinction events on the Earth. Although impacts may be occasionally, or even often, the major triggering event, it is still possible that there are other types of events that may also trigger extinctions. Similarly, the secondary mechanism that actually causes the extinction, for example, long-term darkness, planetary cooling or atmospheric pollution, may vary from one extinction to another depending on the exact state of the planet and its biota at the time of the event. These questions remain open, awaiting new and better data for their resolution.

I thank Bonnie Buratti, George Wetherill, Richard Grieve, Frank Kyte and Mark Bailey for useful discussions and comments. This work was supported by the NASA Planetary Geosciences Program and was performed at the Jet Propulsion Laboratory under contract with NASA.

Timescale of natural annealing in radioactive minerals affects retardation of radiation-damage-induced leaching

Yehuda Eyal*† & Robert L. Fleischer*

* General Electric Research and Development Center, Schenectady, New York 12301, USA
† Department of Nuclear Engineering, Technion-Israel Institute of Technology, Haifa 32000, Israel

There is concern that if solidified nuclear waste is exposed to ground water, accelerated dissolution of radioactive waste nuclides will ensue because of the accumulation of radiation damage created by α decay. We report here the results of radioisotope measurements on ancient uranium- and thorium-rich minerals and find that 'self-annealing' strikingly reduces the rate of dissolution. That short-lived ^{228}Th is leached, whereas long-lived ^{230}Th and ^{234}U are not, sets a limit on the timescale of self-annealing; given a simple assumption, we estimate an annealing time of 15 kyr. Two further conclusions emerge. First, even though the overall structure of the minerals remains crystalline (inferred from X-ray diffraction), there must be localized submicroscopic loss of order because preferential leaching takes place. Second, the inference that damage fades and slows the leaching rate indicates that minerals in which such annealing occurs are better waste-storage media for minimizing loss of radionuclides by dissolution.

Safe storage of solid nuclear waste requires a matrix that will not be easily dissolved by ground water if a buried container is breached. Although waste-storage materials that have minute

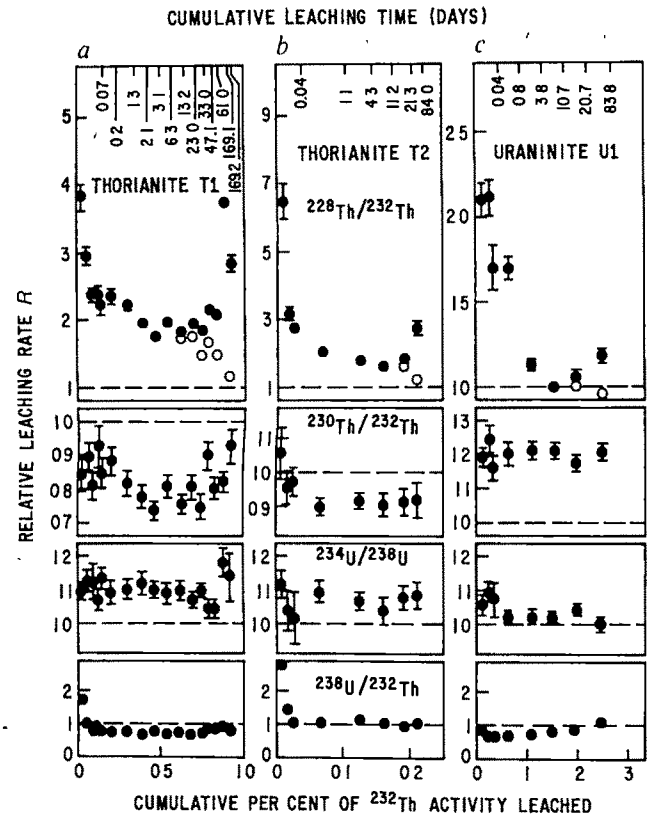

Fig. 1 Relative leaching rates R (solid circles) of uranium and thorium isotopes leached at 25 °C by a bicarbonate/carbonate solution from two thorianite specimens (*a*, *b*) and a uraninite (*c*). The value of R is the ratio of fractions of radioactivities leached. Values of $R(^{228}Th/^{232}Th) \gg 1$ show that the ^{228}Th lies in leachable radiation-damage sites, whereas values of $R(^{230}Th/^{232}Th)$ and $R(^{234}U/^{238}U)$ elevated by no more than 20% imply that the damage fades over considerably less time than the mean life of ^{234}U (3.5×10^5 yr). For the $^{228}Th/^{232}Th$ fractionation, the open circles give the lower limit of $R(^{228}Th/^{232}Th)$, assuming the ancestor nuclide of ^{228}Th, ^{228}Ra, is completely retained in the solid phase.

leaching rates are available, it is possible[1] that the radioactivity that is to be isolated will itself cause radiation damage and thus bring about greatly accelerated chemical attack by ground water. The major source of damage is expected to result from α decay of heavy elements, which produces heavy residual nuclei that recoil a distance of ~200 Å, displacing ~1,500 atoms[2].

The evidence for accelerated dissolution by such damage comes both from laboratory experiments and field observations. Individual α-recoiling nuclei can be implanted in a crystal or glass and then released by exposure to water[3,4], implying that the damaged region is dissolved to where the implanted atoms come to rest and that doses of implanted low-energy ions sufficiently intense that the clumps of diplaced atoms overlap, produce bulk dissolution to the depth of the implantation[5]. Ground water commonly leaches ^{234}U, in preference to ^{238}U, out of rocks that it permeates[6], which is widely (but not universally) regarded as a result of the ^{234}U being located within α-recoil tracks[7] produced by decay of ^{238}U. The ^{238}U atoms are at the start of the decay chain and are therefore not located in radiation-damaged material.

The preferential leaching in nature of ^{234}U (mean life 3.5×10^5 yr or half-life 2.4×10^5 yr) provides a test of the stability of α-recoil-produced radiation damage over times that are vastly greater than those attainable in the laboratory and in conditions that are relevant to underground storage of nuclear wastes. For minerals where the radiation damage is stable at ambient temperatures, the long-term accelerated ^{234}U leaching will be troublesome for disposal. However, in minerals where chemical attack is not accelerated, we have suitable candidates for waste storage media[8] which could well be useful in other high-radiation environments such as those at fission or fusion reactors.

In contrast to long-lived ^{234}U from primary ^{238}U, the thorium decay product of primary ^{232}Th, ^{228}Th, has a mean life of 2.7 yr. The latter nuclide is formed by decay of the α-recoil atom ^{228}Ra (mean life, 8.3 yr). Therefore, the leaching of ^{228}Th will display the effects of radiation damage that is always relatively fresh. A second radiogenic thorium isotope is available for comparison, namely, the long-lived ^{230}Th (mean life, 1.1×10^5 yr) from the uranium decay chain. We have observed profound differences between the behaviour of the $^{228}Th/^{232}Th$ pair and the pairs $^{230}Th/^{232}Th$ and $^{234}U/^{238}U$.

The stability of a material against radiation damage is closely correlated with its propensity to become amorphous (metamict) during irradiation[9]. Understanding what controls the ease of disordering is a basic question in solid-state physics[10]. For example, Ewing *et al.*[11] have shown how the leachability of zircon increases with the natural internal irradiation dose and Clinard *et al.*[12] have examined ^{238}Pu-doped zirconolite in which damage accumulates rapidly enough for laboratory experiments.

We report here leaching tests on two types of ancient radioactive minerals, thorianite and uraninite, composed primarily of highly-crystalline thorium-rich and uranium-rich ThO_2/UO_2 solid solutions, respectively. Structurally, these are the natural analogues of fluorite-type actinide dioxides, which are important nuclear-waste materials. Included are two thorianite specimens from Sri Lanka (samples T1 and T2) and a uraninite (sample U1) from Wilberforce, Ontario, Canada. Analysis by electron microprobe (EMP) showed that uranium, thorium and lead were uniform within the major phase of each mineral studied (< 10% variation) and that only small-volume fractions of accessory phases were present. The latter was confirmed by the absence of unexplained X-ray diffraction spots. The ThO_2 and UO_2 contents were determined by radiochemical analyses (procedures described in refs 13, 14). Lead isotope analyses with an ion microprobe, together with elemental analyses by the EMP, gave radiometric ages according to the U/Th/Pb methods. These data are given in Table 1, which also lists the number of times the average atom has been displaced by α-recoil and α-particle processes. The ages agree with those previously measured for other samples from the same locale[15]. Note that, if the displaced atoms remained displaced over all of time, the material would be thoroughly and uniformly damaged and therefore would be uniformly leached. But we find that this is not the case.

We subjected the finely pulverized (mean particle diameter of the order of 1 μm, maximum particle size of ~100 μm) mineral samples to a series of successive leaching treatments in a bicarbonate/carbonate solution (0.1 M $NaHCO_3$/0.1 M Na_2CO_3) and then determined the relative leaching rates of ^{238}U, ^{234}U, ^{232}Th, ^{230}Th and ^{228}Th (see refs 13, 14). The enhanced dissolution, shown in Fig. 1, of ^{228}Th relative to its parent ^{232}Th, clearly indicates the presence of localized damage by α-recoil atoms. However, the much smaller isotope fractionation, on dissolution, between ^{234}U and its parent ^{238}U and between ^{230}Th and ^{232}Th suggests that almost complete annealing of the damage occurs in $< 10^5$ yr. Note that the initial reduction in the value of $R(^{228}Th/^{232}Th)$ as dissolution proceeds may be attributed to the rapid depletion of ^{228}Th in the layer of the mineral that is in contact with the solution. However, further exposure of the mineral to the solution causes an increase in the value of $R(^{228}Th/^{232}Th)$. As recently observed for the mineral monazite[13,14], the effect has been caused by retention of ^{228}Ra in the solid phase.

The presence of residual atomic-displacement damage in the minerals is further suggested by two consequences of annealing the samples at 810 °C for ~7 h; the leaching rates are lower and the lattice parameter decreases by 0.2–0.5% (full details are given elsewhere[16]).

The leaching results allow a damage storage-time to be derived. The emerging physical picture is of minerals in which each atom over the age of the mineral has been displaced from its lattice site many times; yet the mineral remains crystalline.

Table 1 Compositions, U/Th/Pb ages and radiation damage in thorianite and uraninite specimens

Mineral	ThO_2 (wt %)*	UO_2 (wt %)*	Age (Myr)†	Dpa‡
Thorianite				
T1	47.6	31.6	550	155
T2	51.9	26.9	550	141
Uraninite				
U1	14.8	61 3	1,000	450

* Uncertainties ~2%.

† Uncertainties ~7% For specimens T1 and T2 a composite age is given.

‡ Estimated displacements per atom, assuming 1,500 atomic displacements per α decay in the uranium, actinium and thorium series.

The inescapable conclusion is that the damage has been healing itself. We now consider the consequences of a steady-state process of damage and recovery, in which severe localized damage from α-recoil events survives for some time before vanishing into a background of more dispersed damage. This mode generates vital annealing-time information. For all three mineral samples, T1, T2 and U1, the value of $R(^{228}Th/^{232}Th)$ was found to be initially much greater than unity (3.8, 6.4 and 2.1, respectively, from Fig. 1), whereas the values of $R(^{234}U/^{238}U)$ were 1.11, 1.12 and 1.08, respectively. As the ^{228}Th is short lived and ^{234}U is long lived, the simplest interpretation of these results is that self-annealing heals the radiation damage in a time between ~11 yr (the combined mean lives of ^{228}Ra and ^{228}Th) and $\sim 3.5 \times 10^5$ yr. Assuming that in the absence of annealing the $^{234}U/^{238}U$ fractionation would have been as high as the observed $^{228}Th/^{232}Th$ fractionation, then the annealing time is τ_{234}, $[R(^{234}U/^{238}U) - 1]/[R(^{228}Th/^{232}Th) - 1]$, where τ_{234} is the mean life of ^{234}U (3.5×10^5 yr) and R is the initial relative isotope leaching rate. (The derivation is given in more detail elsewhere[16].) We find average annealing times[16] of ~15 kyr (14, 7.8 and 25 kyr for the three samples). A time of 18 kyr is implied by the monazite data of Eyal[13,14], who, however, quoted only an upper limit of 10^5 yr.

Two conclusions emerge. First, even highly non-metamict minerals, as usually inferred from X-ray diffraction, may be subjected to radiation damage by α-recoil atoms. The localized submicroscopic variation in atomic order in these minerals may cause preferential leaching and, consequently, radioactive disequilibrium, as is often observed in nature. Second, the method of isotope analysis used here should allow the damage storage time of other minerals to be measured and improved waste-storage materials to be identified.

An understanding of the mechanical response of the continental lithosphere to vertical surface loading is crucial when considering geodynamic processes such as intraplate basin formation, post-glacial rebound or mountain building. Previous models of the mechanical behaviour of the lithosphere, which are more successful in oceanic than in continental regions, have used specific isotherms to delineate an effectively elastic zone of the lithosphere and result in mathematically convenient descriptions of mechanical behaviour. Heat flow and lithosphere flexure data for continents, however, suggest that this relationship is more complex, which can be demonstrated by numerical modelling of the loading of a heterogeneous visco-elastic lithosphere with temperature-dependent viscosity. Viscous stress relaxation in the lower and hotter section of the lithosphere results in a region of stress concentration dependent on the thermal state of the lithosphere, its structure and the time since loading. Here we present initial numerical models, based on a relatively simple steady-state thermal model constrained by present-day heat flow, which explain observations of continental flexure except in regions which have experienced a long or complex thermal history since loading.

As a first approximation, both oceanic and continental lithosphere loading have been modelled as a flexed elastic plate overlying an inviscid fluid substratum[1-3]. But laboratory studies of the deformation of rocks[4-6] and detailed modelling of the above phenomena[7-10] suggest the actual rheology of the lithosphere must be considerably more complex. Based on studies of the deformation of olivine, Goetze and Evans[7] proposed a rheology in which the uppermost lithosphere is weakened by brittle failure and stresses in the lower lithosphere are relaxed by a temperature-dependent non-linear dislocation flow mechanism, leaving most recoverable strain in the region between. They further suggested that the temperature-dependent flow could be approximated by a plastic failure criterion. This allows a time-independent calculation of stress distribution and, more specifically, predicts an observable property of apparent elastic lithosphere thickness. This yield-stress envelope model was applied with particular success to oceanic lithosphere flexure[9,11,12] and assisted in explaining the apparent correlation between elastic thickness and depth to the 450 °C isotherm as calculated from the cooling plate model associated with sea-floor spreading[2,13].

Recently, Karner *et al.*[14] applied this thermo-elastic model to continental lithosphere flexure. Their analysis of flexural rigidity of continental lithosphere in terms of thermal age of the lithosphere at the time of loading led them to conclude the following: (1) flexural rigidities for continental lithosphere are compatible with oceanic results and are explained universally by a simple thermo-elastic model; (2) the long-term thermal behaviour of continental lithosphere is governed by a simple cooling plate model with a 200–250-km plate thickness; (3) the effective elastic thickness of continental lithosphere coincides with the depth to the 450° isotherm at the time of loading and does not change with time. Although we find support in heat-flow data for the basic contention of Karner *et al.*[14] that lithosphere mechanical behaviour is controlled largely by its thermal state, the precise relationship between thermal state and mechanical behaviour may be more complex than their conclusions suggest and we offer here an alternative explanation for continental flexure observations.

Table 1 is a compilation of continental flexure observations and estimates of present surface heat flow at each site. The latter values are generally averages of many heat-flow determinations with effects such as anomalous radiogenic heat production of surface rocks, or possible hydrological effects weighted so that the average heat flow is a reliable indicator of lithospheric thermal state. We make two observations from these data. First, the present thermal state of continental lithosphere at flexure sites is not a simple function of its age (compare column 6 with columns 3 and 4 in Table 1). This observation is consistent with results obtained from much larger heat-flow data sets not restricted to flexure sites[15-17] and should be considered in judging the general applicability of a thermal evolution model. Second, apparent elastic thicknesses for continental flexure sites do not correspond to the 450 °C-isotherm position. In fact, by using present-day heat flow to compute the present thermal state, we see that elastic thicknesses correspond to depths for a variety of isotherms from 300 °C to >900 °C (Fig. 1). The thermal regime has not necessarily been constant since loading. But as a plastic yield-stress model responds to the warmest thermal state following loading, the data (Fig. 1) represent lower limits along the surface heat-flow axis. The observation of very high temperatures or of a wide range of temperatures controlling elastic thickness is inconsistent with the oceanic thermo-mechanical model.

Is there a rational explanation for the apparent success of the plastic yield-stress approximation in explaining oceanic lithosphere flexure but its lack of success for the continents? Courtney and Beaumont[18] have demonstrated that the rapid cooling of oceanic plates effectively locks in the stress field and prohibits significant stress relaxation. In continental lithosphere subjected to a longer and more complex thermal history, we believe this total damping of the long-term relaxation may not be taking place. However, this seeming contradiction can be examined by obtaining complete time-dependent solutions to the more general visco-elastic problem.

To obtain a time-dependent solution of lithosphere flexure with a non-linear thermally activated rheology, we must resort to numerical methods. The model we have developed consists of a heterogeneous Maxwell visco-elastic lithosphere overlying an inviscid asthenosphere. The viscous strain rates $\dot{\varepsilon}$ in the lithosphere are determined by a power law ($n=3$ in stress σ) which is exponentially dependent on absolute temperature T through an activation energy E^*, that is, $\dot{\varepsilon} = A\sigma^n \exp(-E^*/RT)$, where A, n and E^* are properties of the material and R is the gas constant. For the mantle we have used the experimentally determined flow parameter for olivine given by Goetze[5] ($A=7\times10^4$ MPa^{-3} s^{-1}, $E^*=0.53$ MJ mol^{-1}). Parameters for crustal rocks are difficult to determine because of the scarcity of data, but seem to have consistently lower activation energies. We used values of $A=7\times10^{-6}$ MPa^{-3} s^{-1} and $E^*=0.23$ MJ mol^{-1}. The thickness of the lithosphere is determined by its thermal state; its base is taken to be approximately the position where the geotherm intersects the 1,300 °C adiabat. A vertical uniformly-distributed surface load of width equal to the lithosphere thickness and infinite length is applied to the upper surface. This load is supported by buoyancy forces resulting from flow in the mechanical asthenosphere. The mechanical strength of the lithosphere determines the redistribution of these opposing forces. We have used a finite element method to solve for the time-dependent displacements and stresses within the visco-elastic body incorporating an algorithm and code from Owen and Hinton[19]. (Details of this modelling are given in Willett *et al.*[20].)

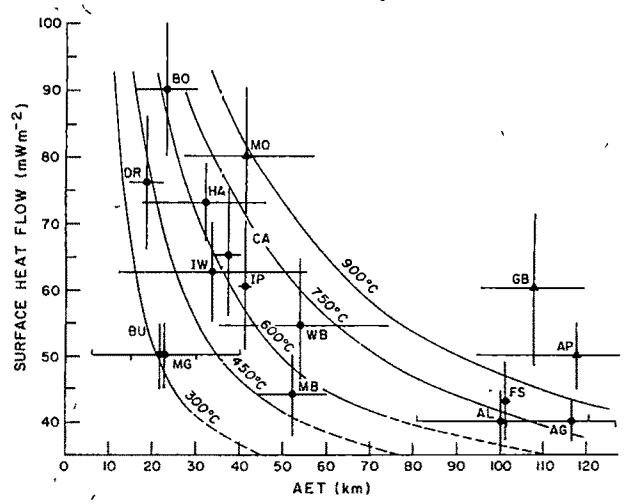

Fig. 1 Surface heat flow at selected flexure sites versus AET. Data and symbols from Table 1. Solid lines indicate depths to isotherms at a given heat flow for a steady-state thermal model.

Salient features of the flexure of a continental lithosphere with this rheology are shown in Fig. 2*a*, *b*. These two examples are chosen to represent end-member thermal states for continental lithosphere. Fig. 2*a*, labelled 'cold lithosphere', represents deformation of a lithosphere with a vertical temperature distribution corresponding to a steady-state geotherm with surface heat flow of 40 mW m^{-2}; Fig. 2*b*, labelled 'hot lithosphere', has a 90 mW m^{-2} or active-rift geotherm[21]. The displacements in both cold and hot lithosphere show characteristics of visco-

Table 1 Continental lithosphere age, flexure and thermal characteristics*

Site	Symbol	Basement age at time of loading (Myr BP)	Age of load (Myr BP)	AET (km)	Present heat flow (mW m^{-2})	Heat-flow reference

* Modified from ref. 23; † data from ref. 1; ‡ data from ref. 36.

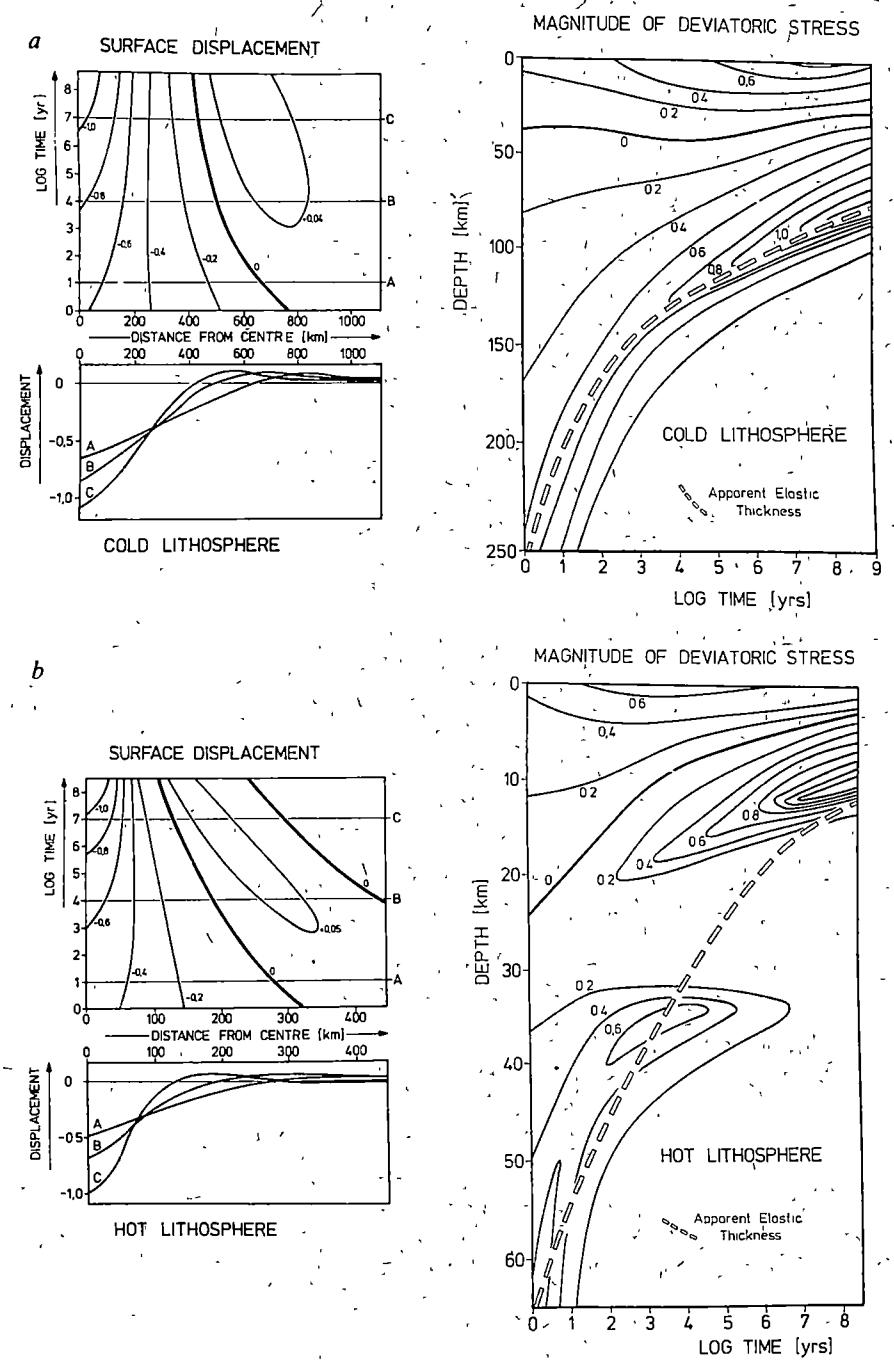

Fig. 2 Flexure properties for two end-member thermal states of visco-elastic continental lithospheres. In *a* and *b*, the upper left figure shows surface vertical displacements mapped as a continuous function of time; lower left figure gives the original surface (that is, basement) profile at three distinct times. Right figures show deviatoric stresses on a plane directly below the centre of the load and the temporal evolution of this stress field following instantaneous loading at time zero. Dashed line gives apparent elastic thickness as calculated from the wavelength of the surface displacements. The 'cold lithosphere' has a vertical temperature distribution corresponding to a geotherm with a surface heat flow of 40 mW m^{-2}; displacements are normalized to 1,200 m; stresses are normalized to 50 MPa. The 'hot lithosphere' has a temperature distribution corresponding to a geotherm with a surface heat flow of 90 mW m^{-2}; displacements are normalized to 1,600 m; stresses are normalized to 100 MPa.
